Lung metastasis (TxNxM1b)	Mostly asymptomatic; rarely, chest pain, dyspnea, cough, hemoptysis	CT with contrast or PET-CT; chest X-ray not preferred but may be used for pulmonary screening in lower risk patients; bronchoscopy or interventional radiology for tissue confirmation
Gastrointestinal or liver metastasis (TxNxM1c)	• GI: abdominal pain, signs of anemia (e.g. fatigue, chest pain), vomiting, constipation, melena	• CBC, CT with contrast or PET-CT; colonoscopy for tissue confirmation
	• Liver: abdominal pain, jaundice	• Liver function tests, LDH; CT with contrast, PET-CT, or MRI; liver biopsy for tissue confirmation
Bone metastasis (TxNxM1c)	Pain, spontaneous fractures	Bone scan or PET-CT; biopsy for tissue confirmation

*Always include a thorough medical history and physical examination as well as complete blood count (CBC) and blood chemistry including lactate dehydrogenase (LDH). A multidisciplinary approach involving cutaneous, surgical, medical, and radiation oncologists is recommended to determine the most appropriate metastatic evaluation.

Table 113.15 Symptoms and diagnostic tests for metastatic melanoma. C/A/P, chest/abdomen/pelvis; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

for evaluation of brain metastases or special clinical situations such as deciding on the operability of soft tissue metastases[178].

MANAGEMENT

The management of cutaneous melanoma has rapidly changed over the past decade with the advent of molecular tests that aid in diagnosis, in addition to the paradigm-changing use of targeted therapy for *BRAF*-mutant melanoma and immune checkpoint blockade.

Management of the Primary Melanoma (Stage I and II)

Following histologic diagnosis, the primary cutaneous melanoma site should be re-excised with an appropriate surgical margin determined by the tumor thickness (Table 113.16). The rationale for excisional margins is based on the capacity of melanoma cells to migrate away from the tumor origin, i.e. melanoma may extend wider or deeper than is visibly apparent. The major goal is to prevent local recurrence, including persistent disease-type and satellite (lymphatic) metastasis.

Beginning in 1980, several prospective RCTs led to an evolution of surgical margins, although these studies, with one exception, excluded MIS and invasive melanoma in acral and head/neck sites. In the prior era, invasive melanoma was often excised with a wide margin of 5 cm, independent of tumor thickness. Then a WHO randomized trial demonstrated that 1 cm surgical margins (compared with 3 cm margins) were safe and effective for melanomas <1 mm in thickness and for melanomas up to 2 mm in depth[179,180]. A subsequent RCT focusing on intermediate-thickness melanoma (1 to 4 mm) found that 2 cm margins

SURGICAL TREATMENT OF PRIMARY CUTANEOUS MELANOMA		
Tumor thickness	**Excision margins (cm)**	**Comments**
In situ	0.5–1.0	• Melanoma *in situ*, lentigo maligna type, may require wider surgical margins (≥1 cm) for histologic clearance • Surgical techniques allowing for comprehensive peripheral and deep margin assessment (Mohs micrographic surgery, staged excision with permanent sections) may enhance local control • Topical treatment with imiquimod and radiation therapy are considered second-line modalities and may be used when surgery is not possible or postoperatively (in the case of imiquimod)
≤1 mm	1.0	• Thin, minimally invasive (T1a) lentigo maligna melanoma: Mohs micrographic surgery may be considered for tumors on the face or other anatomically constrained sites • Other cutaneous melanomas: Mohs micrographic surgery has not yet been prospectively studied in comparison to staged excision with permanent sections or conventional wide excision
>1–2 mm	1.0–2.0	
>2 mm	2.0	

Table 113.16 Surgical treatment of primary cutaneous melanoma. Evidence from available randomized trials is insufficient to address the optimal margins for the excision of primary cutaneous melanoma, but multiple expert international committees have produced fairly consistent guidelines, as summarized here. Of note, further investigative efforts will likely alter the standards of care over time. *Adapted from National Comprehensive Cancer Network. Melanoma: Cutaneous. NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines) Version 2.2023: https://www.nccn.org/professionals/physician_gls/pdf/cutaneous_melanoma.pdf.*

were as effective as 4 cm margins in preventing local metastatic recurrence[181]. Another RCT demonstrated the long-term safety of a 2 cm excision margin for thick melanomas (>2 mm thickness) at a median follow-up of 19.6 years, essentially confirming a maximum of 2 cm surgical margins for T3/T4 melanomas[182]. While current randomized trial evidence is non-existent for MIS (typically excised with 0.5 to 1 cm margins) and insufficient with regard to optimal surgical margins for T1 melanoma, expert international committees have produced fairly consistent guidelines, as summarized in Table 113.16[172,175].

Surgical margins in anatomically constrained sites such as the face, ears, digits, and mucous membranes may be narrower to preserve function and/or cosmesis[183]. For MIS of the face, which is typically LM/CSD type, Mohs micrographic surgery (MMS) or staged excision techniques with permanent sections may be employed to provide complete circumferential peripheral and deep histologic margin assessment (CCPDMA), while providing the narrowest possible margins. At the same time, subclinical extension of MIS, LM type, may require margins of 1 cm or greater for complete histologic clearance[184]. Similarly, lentiginous acral and mucosal melanomas are often poorly defined clinically and multifocal in nature. As a result, local recurrences are more frequent in these melanoma subtypes.

Mohs micrographic surgery (MMS)

In the US, the use of MMS for melanoma has nearly tripled over the past two decades[185]. As noted previously, MMS and staged excision using paraffin-embedded permanent section analysis may be considered for the treatment of MIS, LM type, especially in the head and neck region, as well as MIS in acral sites. Utilization of CCPDMA in these surgically challenging sites with significant photodamage has been associated with lower rates of persistent-disease type local recurrence[184]. The use of frozen section immunohistochemistry for MART-1 or other melanocytic markers has further improved intraoperative assessment of tumor clearance, although melanocyte hyperplasia in the setting of chronic actinic damage may complicate histopathologic interpretation of margins[186]. For MIS in non-anatomically constrained sites (e.g. trunk, extremities) and/or with distinct clinical margins (e.g. superficial spreading type), 5 mm surgical margins are typically performed, and MMS/CCPDMA is not generally needed for histologic clearance[34].

The role of MMS for invasive melanoma remains controversial. Proponents have argued that CCPDMA often results in surgical margins greater than those recommended for conventional excisions, ensuring full tumor resection[187]. Retrospective analyses of the National Cancer Database (NCD) have demonstrated improved overall survival (measured by all-cause mortality) for thin (T1a) invasive melanomas of the head and neck treated with MMS as compared to excision with >1 cm margins[188,189], but importantly, MSS is not assessed in the NCD. Other retrospective studies using SEER and NCD data have found similar MSS rates between MMS and standard excision, suggesting at least non-inferiority of MMS in melanoma treatment[190,191]. Of note, these studies do not provide information about the specific MMS technique employed, the precise surgical margins or other treatment details, local recurrence types (persistent disease vs satellitosis), and MSS rates.

A more recent systematic review and meta-analysis assessed local recurrence following MMS, staged excision, or conventional WLE for nearly 14 000 head and neck melanomas (100 published studies); 51.0% (7138) were treated by WLE, 34.5% (4826) by MMS, and 14.5% (2034) by staged excision[192]. Local recurrence rates were the lowest for MMS (0.61%; 95% CI, 0.1%–1.4%), followed by staged excision (1.8%; 95% CI, 1.0%–2.9%) and WLE (7.8%; 95% CI, 6.4%–9.3%), although definitions of local recurrence and proportions of invasive melanomas varied, with marked heterogeneity among the studies. A subsequent critical review of quality and data reporting in the MMS/staged excision literature noted serious or critical bias in 98% of publications eligible for analysis when modified "risk of bias in non-randomized studies of interventions" (ROBINS-I) criteria were employed[193]. The authors cited the need for longer follow-up periods, clear tumor classifications, and prospective, randomized study designs to improve the quality of future research.

Large, prospective, head-to-head comparisons of MMS and other margin control techniques versus conventional excision are now being proposed. Presently, there is insufficient evidence for national guidelines to recommend the use of MMS to treat invasive melanoma. Current NCCN guidelines do recognize the value of comprehensive histologic margin assessment for MIS, LM/CSD and acral types, along with minimally invasive (T1a) LMM in anatomically constrained sites[25]. It anticipated that greater consensus will emerge from further investigations.

Topical imiquimod

Another area of debate is the treatment of LM with topical imiquimod, a Toll-like receptor (TLR)-7 agonist, rather than with surgical excision. An important distinction is its use in the primary setting (in lieu of surgical resection) versus in the adjuvant setting (after optimal surgery has been performed). *Primary* therapy is most often utilized in elderly patients with limited function or life expectancy and/or comorbidities that prevent surgical excision, in addition to facial lesions where surgical removal would lead to disfigurement. *Adjuvant* use of imiquimod may be initiated when the surgical margin is histologically narrow (≤1 mm) or transected, but clinically no residual tumor is evident. Imiquimod may also be used as a neoadjuvant therapy so as to shrink the tumor preoperatively.

Because most published studies consist of case series, there is significant variation in: (1) frequency and duration of applications; (2) pre-treatment and post-treatment disease assessments; (3) use of combination therapies (e.g. cryotherapy, topical 5-fluorouracil); and (4) duration of surveillance. In two studies that described imiquimod as a neoadjuvant therapy prior to staged excision with a 2 mm margin, an 82%–83% histologic clearance rate and 4% recurrence rate were reported; however, an initial excisional biopsy was performed so the application of imiquimod was actually more adjuvant in nature[194,195].

In recent analyses, when imiquimod was used as a *primary* therapy with similar mean follow-up times, clinical clearance rates of 72%–84% were reported[196–199]. In a single-arm, phase II trial of primary imiquimod for LM diagnosed by partial punch biopsy, histologic clearance rates were somewhat lower at 37% after application 5 days per week for 12 weeks. However, distinguishing residual LM from actinic melanocytic hyperplasia in excisional specimens was a noted challenge in this study, which did not assess long-term response rates[200]. In an open-label, nonrandomized prospective study of 89 patients with MIS, LM type, treated until significant inflammation developed and followed for a median of 4.8 years, 16 (18%) relapsed; a greater number of lesional melanocytes (counted in biopsy specimens) was associated with an increased risk of local recurrence[201]. Two recent systematic reviews suggest the importance of cumulative dose and treatment intensity, with at least 60 applications of imiquimod at >5 times per week associated with the highest likelihood of complete clinical and histologic clearance[202,203].

In the *adjuvant* setting, i.e. following surgery, the clinical clearance rate in one retrospective study was 94% with a mean follow-up of 43 months[204]. Use of imiquimod versus radiation therapy as second-line therapy for LM is currently under investigation in an RCT in Australia, when staged surgical excision with 5 mm margins is not possible, declined by the patient, or fails to clear the tumor histologically (RADICAL Trial, www.clinicaltrials.gov/ct2/show/NCT02394132).

Adjuvant Therapy Considerations for Stage II Melanoma

Based upon results of a phase 3, randomized, double-blind trial, adjuvant pembrolizumab was recently approved for resected stage IIB (T3b/T4aN0) and IIC (T4bN0) melanoma. The trial involved 976 patients ≥12 years of age who underwent pathologic staging with SLNB to confirm node-negative status. They were treated with adjuvant pembrolizumab (200 mg IV every 3 weeks) for one-year (17 cycles) versus placebo. At a median follow-up of 20.9 months, adjuvant pembrolizumab significantly reduced the risk of recurrence or death (hazard ratio 0.61, 95% CI, 0.45–0.82); the 18-month recurrence-free survival rate was 85.8% for pembrolizumab and 77.0% for placebo[205]. Similar quality-of-life measures were observed in the two study arms, along with manageable immunotoxicities – 16% of patients developed grade 3–4 immune-related adverse events (irEAs), similar to adjuvant immunotherapy trials in stage III melanoma. However, careful discussion of risk/benefit ratio and referral to medical oncology is recommended to determine the most appropriate stage II melanoma patients for adjuvant therapy.

Local Recurrences

It is critical to understand the biologic differences between local recurrence from inadequate excision of the primary tumor (termed *persistent disease-type* or "true" local recurrence) from that due to lymphatic metastasis in or around the scar (termed *satellitosis*). Persistent disease-type local recurrence abuts the surgical excision scar, is histologically defined by *in situ* and/or radial growth phase, and should be surgically managed according to Breslow thickness of the recurrence (Fig. 113.28A). Local satellite recurrence is an intralymphatic recurrence within or adjacent (≤2 cm) to the excision scar, although AJCC-8 recognizes this distance as arbitrary, since satellite and in-transit (lymphatic) metastases have similar survival outcomes (Fig. 113.29)[169]. Importantly, local satellite recurrence reclassifies the melanoma as stage III, prompting staging via imaging, referral for WLE and possible SLNB, and discussion of adjuvant therapy.

Melanomas with a higher frequency of subclinical extension, e.g. acral lentiginous, LM, are at higher risk of persistent disease-type local recurrence (Figs. 113.28A-C & 113.30), whereas melanomas that are thicker, ulcerated, have a higher mitotic rate, and/or lymphovascular invasion are at increased risk of metastatic local recurrence (satellites) despite prior adequate surgical margins. Thick desmoplastic melanomas with "pure" desmoplastic histology, extensive perineural invasion/neurotropism, and/or head and neck location may exhibit either type of local recurrence (Fig. 113.28D) and thus are sometimes considered for adjuvant radiation therapy following initial resection.

Satellitosis presents as one or more indurated papulonodules within or immediately surrounding the melanoma scar (generally within 2 cm) and is strongly associated with the development of in-transit, regional, and distant metastases. As noted previously, satellite recurrence reclassifies the melanoma as stage III, with consideration of subsequent systemic therapy. There is no evidence that patient survival is adversely affected if local recurrence results from incomplete excision of the primary melanoma (i.e. persistent disease), provided that the recurrent *in situ* and/or radial growth phase tumor is promptly re-excised and there is no evidence of nodal or distant disease.

Local recurrences of melanoma, particularly the persistent disease-type, can occur several years (rarely decades) after excision of the primary lesion. When a lesion previously diagnosed histologically as a melanocytic nevus recurs locally more than two years after removal, re-evaluation for possible melanoma should be considered.

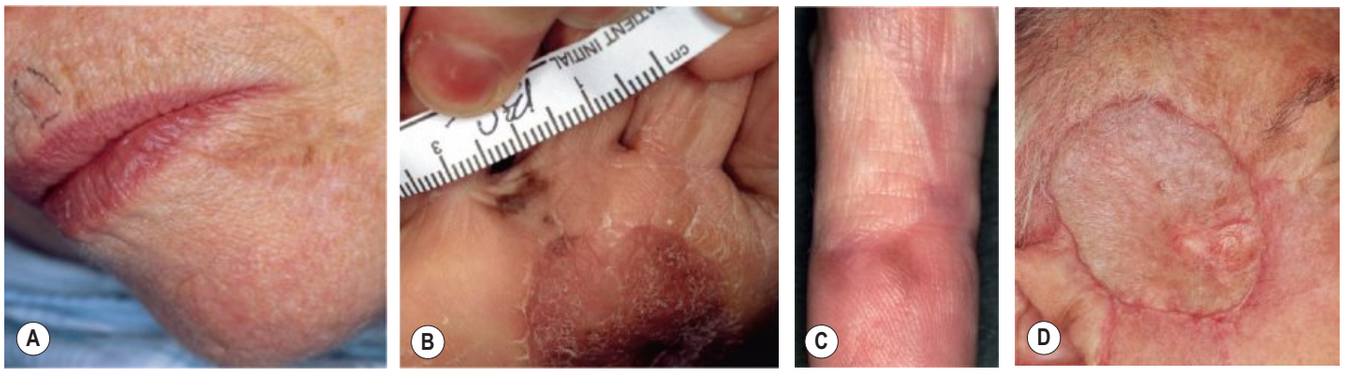

Fig. 113.28 Local recurrences of cutaneous melanoma. A Persistent disease-type local recurrence of lentigo maligna (melanoma *in situ*) along the upper lateral margin of the excision of the chin; inked lesion on the central upper lip is an actinic keratosis. **B** Recurrent *in situ* acral lentiginous melanoma at the 10 o'clock position on the split-thickness skin graft. **C** Recurrent acral lentiginous melanoma on the second finger. The lentiginous types of melanoma have a propensity to recur locally due to persistence of subclinical melanoma (mainly *in situ*) as well as the presence of "field melanocytes" that harbor the same genetic alterations as the primary tumor but are morphologically indistinguishable from normal melanocytes, thus leading to "false negative" histologic margins. Staining with PRAME may highlight positive nevoid melanocytes at the site of the tumor, possibly reducing the risk of recurrence, but data are still very limited. **D** Amelanotic nodule representing local recurrence of a desmoplastic melanoma under the skin graft. *A,B,D, Courtesy Jean L. Bolognia, MD; C, Courtesy Department of Dermatology, Medical University of Graz.*

Management of Regional Metastatic Melanoma (Stage III)

In ~70% of patients, metastatic spread of melanoma is locoregional, i.e. confined to the site of the primary melanoma, its draining lymph nodes, and the lymphatics between the primary tumor and regional lymph nodes. Locoregional metastasis may manifest as clinically occult lymph node micrometastasis, clinically evident (i.e. palpable) lymph node macrometastasis, or as satellite/in-transit metastasis (discussed above). The vast majority of stage III patients are identified with microscopic nodal disease following SLNB.

Sentinel lymph node biopsy (SLNB) and completion lymph node dissection

SLNB was introduced in the 1990s as a method for determining whether the melanoma had microscopically spread to regional nodes and was based upon the presumed migration of melanoma cells from the primary tumor to an initial draining regional lymph node(s). SLNB thereafter replaced elective lymph node dissection (ELND), which was previously considered standard of care for intermediate thickness melanoma until four multicenter, randomized, prospective trials failed to show a survival benefit for patients treated with ELND plus wide excision compared to wide excision alone[206–209].

Approximately 15%–20% of patients with clinically node-negative cutaneous melanoma >1 mm in depth will exhibit microscopic lymph node involvement on SLNB[210]. Increased rates of SLNB-positivity occur with greater tumor thickness and other adverse histologic features in the primary melanoma, e.g. ulceration, high mitotic index, lymphovascular invasion. SLNB is optimally performed in the same operative setting as the surgical excision. Preoperative lymphatic mapping is performed to identify the first draining lymph node(s) within the lymph node basin(s) using technetium sulfur colloid and/or blue dye injected into the skin surrounding the melanoma biopsy site. Lymphoscintigraphy demonstrates the lymphatic drainage pattern from a given melanoma site and can be combined with 3D CT imaging. The tumor typically drains to one lymph node basin and 1–2 nodes within that basin, although there can be multiple draining nodal basins in areas of lymphatic overlap such as the mid trunk or head and neck.

The sentinel lymph nodes are intraoperatively defined as: (1) any pathologically enlarged nodes based on palpation; (2) nodes dyed blue (following injection of dye); (3) the node with the highest emission of radiotracer; and (4) any nodes that emit ≥10% of radiotracer compared to the hottest node. Intraoperatively, a small incision is made overlying the

nodal basin and visual inspection, palpation, and a hand-held gamma counter are used to identify and then remove the sentinel nodes in their entirety, followed by histopathology to identify microscopic deposits of tumor via cytomorphologic and immunohistochemical analyses[121,123].

Pathologic staging of the sentinel lymph nodes is considered standard for staging and prognostication of primary cutaneous melanomas ≥1 mm in thickness. Numerous publications have identified the status of the sentinel lymph node(s) as the strongest prognostic factor for survival and recurrence[211,212]. For melanomas ≥1 mm thickness, pathologic nodal staging is recommended in practice guidelines worldwide and by the AJCC and UICC, taking into account patient factors such as age, functional status, and life expectancy (see Table 113.11 & 113.12)[169]. For example, if a patient has a medical condition such as dementia or comorbid factors that preclude general anesthesia or raise operative risk, it would be reasonable to forgo SLNB.

The role of SLNB for thinner (T1) melanomas is less clear. It may be considered in AJCC-8 T1b melanoma (<0.8 mm with ulceration or 0.8–1.0 mm with or without ulceration), although rates of SLNB-positivity in this group are still relatively low. T1a melanomas (<0.8 mm without ulceration) rarely exhibit a high mitotic index (>2/mm^2) or lymphovascular invasion. However, if these histologic factors are evident, SLNB may also be considered, particularly in younger patients who may be more likely to pursue adjuvant therapy and/or surveillance imaging[25].

Apart from select subgroups of patients with regional nodal disease in the MSLT-1 trial, SLNB has not been demonstrated to improve overall survival and is considered a prognostic, rather than therapeutic, procedure[213,214]. However, identification of occult stage III disease via SLNB now allows for adjuvant therapies that improve relapse-free survival and may ultimately result in increased MSS. Risks of SLNB include those associated with general anesthesia, surgical site seroma, infection, and rarely, lymphedema in an extremity.

Pursuit of completion lymph node dissection (CLND) following a positive SLNB has declined worldwide following two RCTs (DeCOG and MSLT-2) that failed to show an overall survival benefit in SLNB-positive patients who underwent CLND versus those who were observed but followed with regional nodal ultrasound examination[215,216]. Where radiologic expertise is available, surveillance nodal ultrasound (or cross-sectional imaging) is generally recommended in lieu of CLND for SLNB-positive patients per current NCCN guidelines, but imaging does not provide pathologic information regarding non-sentinel lymph node status.

Skin satellite and in-transit metastases

As noted previously, satellite and in-transit metastases occur within the lymphatic vessels located between the primary melanoma and the draining lymph node basin. They represent stage III disease and are associated with increased risk for the development of regional nodal and distant metastasis.

In the past, the treatment of choice for satellite/in-transit metastasis was surgical, but intralesional therapy with immune-activating injectables such as talimogene laherparepvec (TVEC) and the TLR9 agonist tilsotolimod and/or systemic therapies can now be used in a neoadjuvant fashion if numerous or extensive lesions are not initially surgically resectable. TVEC is a genetically engineered herpes virus that replicates in cancer cells, causing them to burst and produce GM-CSF, thus stimulating an immune response against the cancer. For locally unresectable disease in a patient who wishes to avoid the side effects of systemic neoadjuvant therapy, TVEC may be an appropriate choice. TVEC was FDA-approved based upon a phase III study that demonstrated a 32% response rate with a complete remission in 17%[217]; other studies have shown a response rate of up to 88%[218]. TVEC has also been investigated in combination with immune checkpoint inhibitors.

For multiple in-transit metastases on an extremity, isolated limb perfusion with melphalan, with or without tumor necrosis factor (TNF), has palliative value[219]. The procedure may be curative, as indicated by reported 5- and 10-year survival rates of 40% and 30%, respectively. Nowadays, however, intralesional and systemic immunotherapies and targeted agents are more commonly employed.

Clinically detectable regional lymph node metastases

If regional lymph node metastases are diagnosed clinically (i.e. palpable) or via imaging, confirmatory core biopsy or fine needle aspiration is recommended. Therapeutic lymph node dissection (TLND) has been considered standard therapy for bulky regional adenopathy and consists of an anatomically complete dissection of the involved nodal basin[164,167]. The extent of the TLND may be modified according to the anatomic area of lymph node involvement. While TLND has been the standard of care for local basin control of bulky lymphadenopathy, the approach to clinically apparent/macroscopic nodal disease (as well as resectable distant metastases) now includes *neoadjuvant* immunotherapy and targeted therapy prior to surgical excision[25,220,221].

Adjuvant therapy

The goal of adjuvant therapy is the elimination of clinically inapparent micrometastases, primarily in resected high-risk stage II or III melanoma and occasionally resected stage IV melanoma. Prior to the advent of more effective systemic therapies (see below), there was limited success with chemotherapy and immunostimulants such as bacille Calmette–Guérin (BCG) or *Corynebacterium parvum*. The latter were tried because of the finding that melanoma cells express tumor antigens recognizable by the immune system. In 1995, the FDA approved the use of high-dose interferon alpha (IFN-α) for adjuvant treatment of stage IIB and III melanoma (per AJCC staging at the time), and in 1998, high-dose interleukin 2 (IL-2) was approved for unresectable melanoma. Flu-like symptoms, including profound malaise, and depression often led to dose reductions of IFN-α while IL-2 was associated with hypotension and capillary leak syndrome. Prior to the 2010s, adjuvant IFN-α (low- and intermediate-dose in Europe and high-dose in the US) was standard treatment for resected stage III melanoma[222–224].

Based upon the discovery of genetic mutations in melanomas, including *BRAF* V600E, there was a paradigm shift in treatment strategies. While the combination of BRAF and MEK inhibitors was initially approved for unresectable stage III and IV melanoma, in 2018, dabrafenib plus trametinib was approved for adjuvant treatment of resected stage III BRAF V600-mutant disease[225]. The second key discovery was the ability of immune checkpoint blockade to selectively stimulate activated T cells (see below). This eventually led to the approval of anti-CTLA-4 (ipilimumab) and anti-PD-1 antibodies (nivolumab, pembrolizumab) as adjuvant therapies for resected stage III melanoma[226–228]. Based on demonstration of durable relapse-free survival in the seminal prospective randomized trials[229–232], adjuvant therapy is considered a standard treatment option for appropriate patients with high-risk resected stage III and stage IV melanoma, although to date overall survival benefit has not been reported.

Management of Distant Metastases (Stage IV)

Over the past decade, effective targeted and immune therapies have revolutionized the treatment of advanced melanoma, leading to marked improvement in relapse-free and overall survival[226–228]. There is a rapid and high response rate to oral kinase inhibitors (initially targeting BRAF), but development of resistance is an issue. On the other hand, immune checkpoint inhibitors have a slower response rate (apart from dual anti-CTLA-4/PD-1 blockade), but the response is often long-lasting. Prior to the introduction of these therapies, the prognosis of stage IV melanoma was poor, with a 5-year survival rate of <10% and median survival of about 9 months[233]. Within the AJCC substages, differential survival is observed, with soft tissue metastases only (M1a) having a better prognosis than visceral and CNS metastases (M1b, M1c, M1d). For each of these disease sites, i.e. across M categories, an abnormal LDH level is associated with a poorer prognosis, as are a greater number of metastases, multi-organ involvement, and older age at diagnosis (see Table 113.11)[233]. In a small proportion of patients with few metastases involving only one or two organs, surgical or other ablative treatment strategies with curative intent may be considered.

Surgery

Despite melanoma's tendency to disseminate to multiple organs, resection of limited metastases (metastasectomy) may provide palliation and potential long-term survival benefit[234]. Numerous studies have demonstrated clear and durable survival advantages for patients undergoing complete resection of metastatic melanoma, particularly isolated pulmonary, nodal or skin metastases, although modern systemic therapeutic approaches are also an option. Factors that positively influence prognosis are isolated non-visceral metastasis and complete resection with free surgical margins. For certain indications, such as isolated lung metastases, median 5-year survival can approach 30% after surgical treatment, with adjuvant systemic therapy further improving relapse-free survival. For brain metastases, surgical resection alone may extend median survival to about 10 months, with a significant improvement in quality of life[235], but nowadays stereotactic radiosurgery is commonly employed as are systemic therapies (see below). While targeted and immune therapy have become standard of care for resectable and unresectable stage IV melanoma, there are ongoing investigations of combinatorial approaches including neoadjuvant systemic therapy prior to surgery.

Radiation therapy

Although radiation therapy (RT) is rarely indicated for localized cutaneous melanoma, it may be used for primary treatment of unresectable MIS, LM type, and in the adjuvant setting for desmoplastic melanoma at high-risk of recurrence[25]. In the past, adjuvant RT was routinely administered following surgical resection of bulky nodal disease, but then it was found to have no relapse-free or overall survival benefit in a large international RCT[236]. Long-term follow-up did confirm the benefit of RT for improved local control of the lymph node basin, but at the expense of both short- and long-term adverse side effects[236,237]. For stage III disease, the use of RT has been largely replaced by improved adjuvant systemic therapies.

In stage IV melanoma, RT is used primarily for palliation of symptoms related to distant metastases in patients with incurable disease. Specific indications include pain control as well as spinal cord compression, stabilization of bones affected by metastasis, and brain metastases. The latter are typically treated via stereotactic radiosurgery and fractionated stereotactic radiotherapy; these methods are preferred as both primary and adjuvant treatments due to their superior efficacy and improved side effect profile compared to whole brain radiotherapy. Whole brain radiotherapy is reserved for palliation when stereotactic radiosurgery is not possible or when systemic therapy has failed[25].

Systemic therapy

Systemic therapy is the mainstay of treatment in patients with distant metastases, with surgery and RT playing a more limited role (see above). Both small-molecule kinase inhibitors that target BRAF and MEK and immune checkpoint inhibitors (ICIs) have revolutionized treatment strategies (Table 113.17). These therapies are far superior and generally less toxic than chemotherapy and systemic IL-2, and they are considered first-line treatments for unresectable stage III and IV melanoma. Clinical trials have or are currently evaluating regimens in which ICIs and BRAF/MEK inhibitors are administered in combination or sequentially as well as possible advantages of pulse-dosing targeted agents to improve efficacy, combat resistance, and reduce side effects. Of note, severe drug hypersensitivity reactions have been observed when BRAF inhibitors were administered soon after ICIs, with ~20% of patients fulfilling the criteria for DRESS (drug reaction with eosinophilia and systemic symptoms), compared to 5% of patients who received BRAF inhibitors without ICI priming[238].

TARGETED THERAPIES AND IMMUNE CHECKPOINT INHIBITORS		
Targeting the MAPK pathway (see Fig. 113.1)		**FDA approved for advanced melanoma as of August 2023**
BRAF inhibitors (selective*) – combined with a MEK inhibitor	Dab*raf*enib	√

Anti-PD-L1 antibodies	Atezolizumab	√ (in combination with BRAF inhibitor + MEK inhibitor)
	Avelumab	Approved for metastatic Merkel cell carcinoma
	Cemiplimab	Approved for locally advanced or metastatic BCC and cutaneous SCC
	Durvalumab	
Anti-LAG3 antibody	Relatlimab	√ (in combination with nivolumab)

*Target melanomas that have specific amino acid substitutions at position 600 in BRAF, most commonly V600E and less often V600D or V600K.

Table 113.17 Major systemic treatments for metastatic melanoma – targeted therapies and immune checkpoint inhibitors. Pembrolizumab is also approved for metastatic Merkel cell carcinoma. BCC, basal cell carcinoma; MAPK, mitogen-activated protein kinase; SCC, squamous cell carcinoma.

Molecularly targeted therapy

Tumor genotyping indicates that ~45% of cutaneous melanomas harbor activating mutations in *BRAF* and ~15% have activating mutations in *NRAS*, leading to constitutive activation of the RAS–RAF–MEK–ERK (MAPK) signaling pathway that regulates cell proliferation (see Fig. 113.1). A specific point mutation in *BRAF*, which leads to the substitution of glutamic acid (E) for valine (V) at codon 600, hence V600E, accounts for 90% of *BRAF* mutations. Three small molecule inhibitors that selectively target the mutant BRAF kinase have been EMA- and FDA-approved, beginning in 2011. Approval was based upon the results of phase III clinical trials that initially compared dabrafenib and vemurafenib to dacarbazine (DTIC)[239,240].

The three BRAF inhibitors – vemurafenib, dabrafenib, and encorafenib – exhibit similar rapid therapeutic responses and side effect profiles (see Table 21.16), although photosensitivity to UVA and pyrexia are more common with vemurafenib and dabrafenib, respectively. Unfortunately patients treated with BRAF inhibitor monotherapy develop tumor resistance after an average of six months of treatment. Furthermore, due to paradoxical activation of the MAPK pathway in keratinocytes with wild-type BRAF and oftentimes *RAS* mutations, cutaneous SCCs and keratoacanthomas develop in up to 25% of patients treated with BRAF inhibitor monotherapy.

Mechanisms of resistance to selective BRAF inhibitors include increased MEK activity, either via mutational activation or overexpression of COT, as well as expression of truncated forms of BRAF (which dimerize and activate the MAPK pathway) and overexpression of platelet-derived growth factor. MEK inhibitors are therefore combined with BRAF inhibitors in an effort to postpone development of resistance (see Table 113.17). Because this combination of kinase inhibitors prolongs the average time to development of treatment resistance to 10 months[241,242] and improves efficacy, it is considered standard of care for locally advanced or metastatic *BRAF*-mutated melanoma. Importantly, the cutaneous side effects of the selective BRAF inhibitors, including squamous papillomas, plantar keratoses, and cutaneous SCCs, are significantly reduced with the dual regimen. For patients whose melanomas have activating *BRAF* (V600) mutations, initial combination targeted therapy may be used when a rapid clinical response is needed in life-threatening situations, but ICIs are normally preferred as first-line therapy, independent of mutational status[242a].

In patients with *NRAS* mutations, BRAF inhibitors are ineffective, but administration of MEK inhibitor monotherapy can result in objective tumor responses in ~25% of patients. A subgroup of melanoma patients, especially those with acral lentiginous or mucosal melanoma, have amplifications and/or mutations in *KIT* which lead to enhanced activity of the KIT receptor and potential targeted therapy (see above and Fig. 113.1)[129].

Immunotherapy

Immunotherapy is based on the concept that the immune system is able to fight cancer, and melanoma is one of the prototypic and most highly immunogenic malignancies. Therefore, a therapeutic effect might be achieved by infusing effectors of the immune system such as antibodies, cytokines, or killer cells. Not only has the advent of ICIs transformed the treatment of melanoma, it has positively impacted numerous other cancers. Additional anti-melanoma immunotherapies include injection of oncolytic agents (see above), cancer vaccination, and adoptive cell therapy. In the latter, non-myeloablative lymphodepleting chemotherapy is followed by infusion of expanded autologous tumor-infiltrating lymphocytes.

Immune checkpoint blockade

Currently, ICIs are considered first-line therapy in patients with unresectable stage III or IV disease, either with or without an activating *BRAF* mutation[25]. While the anti-CTLA-4 antibody ipilimumab was the first to be FDA- and EMA-approved for advanced melanoma (see Table 113.17), it has largely been supplanted by anti-PD-1 antibodies (nivolumab, pembrolizumab). As single agents, the latter have superior efficacy and less toxicity when compared to ipilimumab alone. Combined anti-CLTA-4/-PD-1 blockade is also considered first-line and is associated with a significantly greater response rate but higher incidence of side effects.

These antibodies *antagonize inhibitory* receptors on T cells, thus leading to stimulation of existing immune responses against melanoma antigens via activation of cytotoxic $CD8^+$ T cells (see Fig. 128.9). This strategy is in contrast to simply enhancing existing immunostimulatory mechanisms as was done for decades in melanoma vaccine trials.

Cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) blockade. Full T cell activation requires stimulation through the T cell receptor as well as a costimulatory signal provided by the binding of B7 on an antigen-presenting cell to CD28 on the T cell. CTLA-4 is a homolog of CD28 and is an inhibitory T cell receptor that is upregulated following T cell activation. The normal function of CTLA-4 is to compete with CD28 to bind B7 in order to downregulate T cell activation, acting as a natural "brake" by removing the costimulatory signal. The CTLA-4–B7 interaction can be blocked with an anti-CTLA-4 monoclonal antibody, which has a higher affinity for CTLA-4 than B7 (see Fig. 128.9). Thus, the *inhibitory signal is prevented* and the "brake" on T cell activation released.

Two fully human anti-CTLA-4 monoclonal antibodies (mAbs) have been investigated, tremelimumab and ipilimumab, with the latter receiving FDA and EMA approval for the treatment of metastatic melanoma[243,244]. As a single agent, objective response rates of 11% were achieved and a significant portion of these responses were durable. At three years, the survival rate for ipilimumab plus dacarbazine was 21% versus 12% for dacarbazine alone. Although responses to anti-CTLA-4 mAbs may persist, they may take as long as 12 weeks or even longer to develop[245].

Side effects from CTLA-4 blockade are autoimmune-related and include colitis, hepatitis, thyroiditis, hypophysitis, myocarditis, and a wide range of skin reactions from dermatitis to leukoderma. Of note, development of vitiligo-like leukoderma is correlated with an improved clinical response[246]. Additional cutaneous and systemic side effects are outlined in Table 21.18. Systemic corticosteroids or steroid-sparing agents are often employed to treat these autoimmune-related phenomena. Although the combination of ipilimumab plus the anti-PD-1 antibody nivolumab can lead to an enhanced objective response (61%) when compared to ipilimumab alone (11%), it results in a significant increase in grade 3 and grade 4 side effects[247]. Newer regimens have employed alternative dosing of combination ipilimumab and nivolumab to try to reduce toxicity while maintaining efficacy[248].

Blockade of programmed cell death 1 (PD-1) and its ligand (PD-L1). PD-1 is an inhibitory immune receptor of the CD28 family that plays an important role in the immune escape of tumors. The interaction of PD-1 (CD279) with its ligand PD-L1 (B7-H1; CD274) inhibits T cell proliferation and effector functions and induces apoptosis of tumor-specific T cells. Blockade of either PD-1 or PD-L1 can restore the immune functions of dysfunctional T cells, including enhancement of cytokine production and cytolysis. Since PD-L1 is widely expressed on tumor cells, this blockage focuses on T cell–cancer cell interactions, i.e. the T cell's effector phase (see Fig. 128.9).

Two anti-PD-1 antibodies, nivolumab and pembrolizumab, have been approved as first-line monotherapy for metastatic melanoma (see Table 113.17), with markedly less toxicity compared to ipilimumab. As with ipilimumab, anti-PD-1 therapy works equally well in *BRAF*-wild type and *BRAF*-mutated melanomas. Compared to an overall one-year survival rate of 42% in dacarbazine-treated patients, the one-year survival rate for patients who received nivolumab was 73%[249], and the objective response rate was 40% (compared to 14% for dacarbazine). As monotherapies, nivolumab and pembrolizumab are more effective than ipilimumab, e.g. nivolumab led to a median progression-free survival (PFS) of 6.9 months versus 2.9 months for ipilimumab[224] while pembrolizumab resulted in an objective response of 33% versus 12% for ipilimumab[250]. A more provocative finding was the enhanced clinical response and reduced incidence of colitis seen in patients receiving anti-PD-1 checkpoint inhibitors who had a diverse microbiome, and the use of oral antibiotics within one month of starting ICIs could impair therapeutic effectiveness[251]. This is presumably because intestinal bacteria play a role in the development of a T cell immune response.

The irAEs seen with anti-PD-1 antibodies overlap with those of anti-CTLA-4 antibodies and include dermatitis, pneumonitis, and nephritis (see Table. 21.18). However, a higher proportion of patients receiving CTLA-4 inhibitors experience grade 3 or higher irAEs compared to those treated with PD-1 inhibitors. As with ipilimumab, patients who had an objective response were more likely to develop vitiligo-like leukoderma. Utilizing antibodies that target PD-L1 rather than PD-1 represents another strategy and these antibodies have been approved for the treatment of other carcinomas that express PD-L1 (see Table 113.17). Of note, in patients with PD-L1-negative tumors, the combination of nivolumab plus ipilimumab prolonged median PFS to a greater extent than did nivolumab alone (11.2 months vs 5.3 months) whereas the two treatment regimens led to a similar PFS in patients with PD-L1-positive tumors[224]. However, further data did not support PD-L1 expression as a biomarker for response to ICIs, and melanoma guidelines do not recommend utilizing PD-L1 expression in clinical decision-making[252]. Lastly, given the durable survival benefit with single agent immunotherapy in pivotal anti-CTLA-4 and -PD-1 antibody trials, ICIs are recommended as frontline therapy over targeted agents in patients with metastatic or unresectable disease[242a,253,254].

Blockade of other immune checkpoints. There are multiple ligand-receptor interactions between T cells and dendritic cells that represent potential therapeutic targets. Recently, the combination of relatlimab, an inhibitor of LAG3 on T cells, plus nivolumab was approved for the treatment of unresectable or metastatic melanoma. Fewer grade 3–4 irAEs were observed compared to dual checkpoint blockade with nivolumab plus ipilimumab. Progression-free survival with the combination was 10.1 months compared to 4.6 months for nivolumab alone[255]. Additional potential treatments include sotigalimab, which interrupts interactions between CD40L on T cells and CD40 on dendritic cells. Given the rapidly evolving immunotherapeutic options in melanoma, attention to guidelines-based care is critical.

Cancer vaccines

Cancer vaccines have long been pursued in the hope of enhancing immune recognition and effector antitumor immune responses via improved antigen presentation and elicitation of effector memory T cell responses that are durable. Increased knowledge of the relevant antigenic epitopes capable of eliciting antitumor immunity has prompted a variety of vaccine approaches. Although vaccines are well tolerated, they rarely have been monitored with methods that are now recognized to be critical for detecting whether or not the vaccine induced an immune response. Not surprisingly, the large phase III trials of older crude autologous tumor cell vaccines did not demonstrate clinical evidence of antitumor activity, either in advanced disease or in the adjuvant setting.

Peptide vaccines have been studied in large, multicenter ECOG trials in the US[256] and led to the induction of immune responses in more than a third of vaccinated patients. However, none showed an improvement in overall survival, with the exception of a combination of gp100 peptide vaccine plus IL-2, which improved progression-free survival compared with IL-2 alone[257]. More recently, mRNA vaccines are being investigated for induction of antitumor immunity in a variety of cancers and hold promise for melanoma[258].

Chemotherapy

Over the past four decades, cytotoxic chemotherapy has demonstrated a low but reproducible level of activity against metastatic melanoma. Drugs most commonly employed include dacarbazine (DTIC)/temozolomide, carboplatin/cisplatin, vindesine/vinblastine, BCNU/fotemustine, and paclitaxel/docetaxel. Unfortunately, despite the identification of multiple chemotherapeutic agents with activity against melanoma both *in vitro* and in phase I/II clinical trials[259,260], to date no significant impact on survival exists for any chemotherapeutic regimen. In those countries where targeted therapy and ICIs are readily available, chemotherapy is now administered as salvage therapy. However, in lower-income countries, chemotherapy may be a first-line treatment due to the high cost of newer agents.

The most widely used single chemotherapeutic agent remains dacarbazine (DTIC). It has shown the greatest effectiveness as a single agent in most trials – an ~10%–15% response rate can be achieved with a median response duration of 5 to 6 months. The oral alkylating agent temozolomide (a prodrug of MTIC, the active metabolite of DTIC) has some efficacy in treating CNS metastases and is equal in efficacy to DTIC[261,262]. Fotemustine is a member of the nitrosourea family and has some activity against melanoma, including brain metastases.

MELANOMA SURVEILLANCE

Protocols for the longitudinal care of melanoma patients vary worldwide and generally depend on the risk of disease recurrence and development of new primary melanomas. Lifelong follow-up of these patients is important because of: (1) the risk of second primary cutaneous melanomas (3.5%–4.5%, depending on nevus phenotype and/or genetic factors); (2) the risk of local and/or metastatic recurrence (greatest in the first 2–5 years after initial diagnosis and stage-dependent); (3) the risk of late recurrence (>10–15 years) which is uncommon but does occur; and (4) the increased risk of other cutaneous malignancies (e.g. cutaneous SCC, BCC).

Most stage I/II cutaneous melanomas will present with locoregional recurrence, while stage III/IV patients most often present with systemic metastases. The latter group is typically followed by an oncologist, although ongoing dermatologic assessment is important for detection of disease recurrence and new primary melanomas, as well as recognition and treatment of cutaneous side effects from targeted and immune therapies. Recommendations for the frequency of dermatologic visits varies internationally and amongst practitioners. As 90% of recurrences occur during the first 5 years following primary diagnosis (with the greatest risk in the first 2 years), most experts recommend dermatologic visits one to four times per year for 2 years after diagnosis (depending on risk of disease recurrence and alternating with oncologic visits in those with higher stage disease), then every 6 to 12 months through year 5 following diagnosis, then at least annually thereafter. Clinical surveillance frequency is also influenced by the number of melanocytic nevi (common and atypical), number of primary cutaneous melanomas, and genetic susceptibility, which increases the risk of additional primary melanomas.

Dermatologic visits should include: (1) updates on the medical history; (2) review of systems (e.g. any new or changing lesions, new "lumps or bumps" in or around the melanoma excision site or in nodal basins, unanticipated weight loss, fatigue, headache or other CNS symptoms, shortness of breath); (3) total body skin examination; (4) examination and palpation of the melanoma scar/excision site and surrounding area for local recurrences or in-transit metastases; (5) examination of regional and distant lymph nodes; and (6) laboratory and radiologic tests as indicated by concerning signs and/or symptoms. Patients should be counseled to adhere to sun-protective measures; perform skin self-examinations at home; and to take an oral vitamin D_3 supplement, particularly if they are practicing regular sun protection. Family members should also be encouraged to undergo routine skin examinations.

While early detection of asymptomatic melanoma metastasis has not been clearly associated with improved survival, most data pertain to the era of minimally effective systemic therapies. The future of melanoma diagnosis and treatment will likely involve molecular techniques that accurately demonstrate residual disease (e.g. ctDNA) or have proven validity for prognosis and staging to determine which patients require SLNB, surveillance imaging, and/or adjuvant therapy following resection of the primary tumor.

The merits of early detection of primary melanoma cannot be understated. Diagnosis of melanoma when thin and most curable will reduce patient morbidity and associated costs of care. Primary prevention aimed at avoiding natural and artificial sources of UVR, and early detection strategies for this visible and largely recognizable cutaneous tumor should be at the forefront of public health measures.

eFig. 113.33 Genetic aberrations in mucocutaneous melanomas – original findings. Of melanomas with somatic mutations in *BRAF*, at least 80% lead to substitution of glutamic acid (E) for valine (V) at codon 600, i.e. V600E. CSD, cumulative sun damage, such as marked solar elastosis; non-CSD, skin without cumulative sun damage. *From Curtin JA, Busam K, Pinkel D, Bastian BC. J Clin Oncol 2006;24:4340–6.*

eFig. 113.34 Comparative genomic hybridization (CGH) as a tool to determine copy number changes in melanocytic tumors. Total genomic DNA is isolated from the tumor and from healthy reference samples, and labeled with fluorescent dyes. The mixture of test and reference DNA is hybridized onto a genome-wide microarray of oligonucleotides. Tumor and reference DNA bind to the complementary oligonucleotides and the ratio of their fluorescence intensities is approximately proportional to the ratio of the copy numbers of the corresponding DNA sequences in the tumor and reference genomes. The copy number ratio can be mapped to the genomic location of the array element.

INVASIVE CUTANEOUS MELANOMA – COMPONENTS OF THE HISTOPATHOLOGIC REPORT
Essential
Tumor thickness (Breslow depth), to the nearest 0.1 mm*
Ulceration (present or absent)*
Presence of macroscopic (gross specimen) or microscopic satellites*
Peripheral and deep margin status (involved/uninvolved with *in situ* and/or invasive melanoma, broad vs focal transection of invasive melanoma at deep margin)
Additional features that are encouraged
Mitotic rate (“hot spot” method), #/mm^2
Lymphovascular/angiolymphatic invasion
Histopathologic subtype of melanoma (if desmoplastic, “pure” or “mixed”)
Regression, if extensive (>75%)
Neurotropism/perineural invasion
Tumor-infiltrating lymphocytes (none, brisk, non-brisk)
Associated nevus
*These elements determine T- or N-stage and are required. Other elements are useful for prognostication and management.

Benign Vascular Neoplasms and Reactive Hyperplasias *2045*
Borderline and Low-Grade Malignant Vascular Neoplasms *2060*
Malignant Vascular Neoplasms *2067*
Perivascular Neoplasms and Neoplastic-Like Proliferations *2070*

INTRODUCTION

In this chapter we use the term *neoplasm* synonymously with *tumor* in a general, albeit imperfect[1], sense, consistent with its common usage: *an abnormal proliferation ("new growth") of cells that appears to be relatively autonomous (i.e. not reactive)*. Of note, common infantile hemangiomas are discussed separately (see Ch. 103) as are telangiectatic lesions (see Ch. 106) and vascular malformations (see Ch. 104); however, in some patients, vascular malformations may be associated with a number of the cellular vascular proliferations discussed herein. The chapter also includes a review of vascular lesions that were previously designated as vascular tumors (angiomas) but have since been reclassified as distinctive vascular malformations, e.g. glomuvenous malformation (previously "glomangioma"), verrucous venulocapillary malformation (previously verrucous "hemangioma"). In addition, several entities with established or suspected features of reactive processes that mimic neoplasms are discussed as is Kaposi sarcoma, a virus-associated process of as-yet-uncertain position on the hyperplasia–neoplasia spectrum, but with an associated mortality rate. Two benign vascular proliferations of more seemingly straightforward infectious etiology (bacillary angiomatosis and verruga peruana) are covered elsewhere (see Ch. 74). With these caveats in mind, a broad working classification of vascular neoplasms and neoplastic-like conditions is presented in Table 114.1. Selected vascular neoplasms and neoplastic-like proliferations with their associated syndromes and characteristic laboratory findings are outlined in Fig. 114.1.

BENIGN VASCULAR NEOPLASMS AND REACTIVE HYPERPLASIAS

Intravascular Papillary Endothelial Hyperplasia (PEH)

Synonyms: ■ Masson's pseudoangiosarcoma ■ Masson's tumor

Key features

- Not a specific disease entity, but rather a distinct histopathological pattern that can be confused with angiosarcoma
- The primary or "pure" form is not associated with a pre-existing vascular anomaly and appears as a solitary, slowly growing, often painful nodule located within a dilated dermal, subcutaneous, or submucosal vein
- Secondary forms are associated with venous malformations and other vascular anomalies prone to thrombosis
- Rare forms are extravascular, probably arising within hematomas
- Thought to represent an unusual, exuberant response of endothelial cells to organizing thrombus

Introduction

Masson first described this process in 1923 in hemorrhoidal veins, terming it *hemangio-endotheliome vegetant intravasculaire*, and interpreted it as a neoplastic process mimicking angiosarcoma. In 1932, Henschen re-interpreted the process as reactive, and in 1971 Kauffman and Stout noted its occurrence not only in thrombosed vessels but also in a hematoma, further demonstrating the potential for confusion with soft tissue angiosarcoma. A lymphatic vessel counterpart of Masson's lesion was reported in 1979 in a cystic lymphatic malformation[2].

Epidemiology

Papillary endothelial hyperplasia (PEH) shows a slight female predominance, most pronounced for the rare extravascular examples[3]. Although lesions can occur at any age, most are in adults, with an average age of 35 years. A history of trauma is elicited in a small minority of patients[3].

Pathogenesis

Areas of papillary endothelial hyperplasia can, in most cases, be seen to merge with definitive thrombus material, in support of the notion that they represent an unusual form of thrombus organization.

Clinical features

Primary lesions of superficial tissues appear as solitary, firm masses, often with red or blue discoloration of the overlying skin or mucosa. The history is typically one of slow growth over a period of several months or years. These occur most commonly within veins of the head and neck and, interestingly, the fingers, but they may also arise elsewhere[3]. In a study of 314 cases, 56% were of the primary form, 40% were associated with other vascular lesions, and 4% appeared extravascularly[3]. Clinical features of the secondary forms are those of the underlying vascular anomaly.

Pathology

Intravascular examples may be limited to the confines of a single thin-walled vein or may arise, often multifocally, within pre-existing vascular lesions such as venous malformations, glomuvenous malformations, spindle cell hemangiomas, and pyogenic granulomas (Fig. 114.2). Foci of intravascular PEH are extremely common in venous malformations and serve to distinguish these low-flow lesions from high-flow arteriovenous malformations. Rarely, the involved vessel wall is ruptured, allowing the proliferative vascular process to spill out into the adjacent stroma. Extravascular examples that on serial sectioning show no evidence of a surrounding blood vessel wall may have arisen within an organizing hematoma[3].

Early lesions show growth of endothelial sprouts into fibrinous thrombus material, dividing it into papillary fronds lined by a single layer of plump endothelial cells with minimal mitotic activity and no significant cytologic atypia. The early fibrin cores of the papillae become collagenized and hyalinized with time, and the endothelial lining becomes thin and attenuated. Lesional papillae may fuse to form an anastomosing meshwork of vessels separated by connective tissue stroma that mimics angiosarcoma (Fig. 114.2, inset). However, the relatively high mitotic rate, striking pleomorphism, and necrosis that characterize angiosarcoma are lacking[4].

Differential diagnosis

The clinical appearance of these lesions is nonspecific, and diagnosis relies on microscopic examination. The most important consideration for the pathologist is well-differentiated angiosarcoma.

A WORKING CLASSIFICATION OF CUTANEOUS VASCULAR ANOMALIES
Reactive conditions
• ***Intravascular papillary endothelial hyperplasia***
• ***Reactive angioendotheliomatosis***
• ***Intravascular reactive angioendotheliomatosis***
• ***Diffuse dermal angiomatosis***
• Eruptive pseudoangiomatosis (self-limited exanthem of bright-red angioma-like lesions, originally described in children, can follow viral infections or vaccines)
• Pseudo-Kaposi sarcoma (acroangiodermatitis of Mali, Stewart–Bluefarb syndrome)
Telangiectasias (see Ch. 106)
• ***Angiokeratoma*** (exception is angiokeratoma circumscriptum, which represents a capillary/lymphatic or capillary malformation)
• Generalized essential telangiectasia
• Cutaneous collagenous vasculopathy
• Unilateral nevoid telangiectasia
• Hereditary hemorrhagic telangiectasia
• Hereditary benign telangiectasia
• Cutis marmorata telangiectatica congenita
• Angioma serpiginosum
• Spider nevus
• Venous lake
Vascular malformations (see Tables 104.2 & 104.5 for associated mutated genes)
• Capillary malformation (CM), includes subtypes nevus simplex, port-wine birthmark, reticulated CM, and geographic CM (see Ch. 104)
• Venous malformation
• Lymphatic malformation (microcystic and macrocystic)
• Mixed capillary/venous/lymphatic malformation
• Arteriovenous malformation
• Capillary malformation–arteriovenous malformation (CM-AVM)
• ***Targetoid hemosiderotic lymphatic malformation*** (previously classified as hobnail "hemangioma" or targetoid hemosiderotic "hemangioma")
• ***Verrucous venulocapillary malformation*** (previously classified as verrucous "hemangioma")
Benign vascular neoplasms and neoplastic-like proliferations
• Infantile hemangioma (see Ch. 103 for details)
• Congenital hemangioma (includes non-involuting congenital hemangioma [NICH], rapidly involuting congenital hemangioma [RICH], and partially involuting congenital hemangioma; see Ch. 103 for details and mutated genes)
• ***Pyogenic granuloma (lobular capillary hemangioma)****[*]
• ***Cherry angioma***
• ***Tufted angioma (likely a superficial form of kaposiform hemangioendothelioma)***
• ***Glomeruloid hemangioma****[*]
• ***Microvenular hemangioma****[*]
• ***Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia [ALHE])****[*]
• ***Multifocal lymphangioendotheliomatosis with thrombocytopenia***[†]
• ***Sinusoidal hemangioma***[‡]
• ***Spindle cell hemangioma***[¶]
• Epithelioid angiomatous nodule (debate as to whether it is a variant of epithelioid hemangioma)
• Papillary hemangioma
• Acquired elastotic hemangioma (capillary-like appearance in association with solar elastosis)
• Poikilodermatous plaque-like hemangioma (pelvic girdle or lower extremities, favors the elderly)
• Cutaneous pseudoangiomatous stromal hyperplasia (primarily encountered in the breast)
• ***Post-radiation atypical vascular lesions of the skin*** (see Table 114.4)
Borderline and low-grade malignant vascular neoplasms
• ***Kaposiform hemangioendothelioma (KHE)***
• ***Papillary intralymphatic angioendothelioma (PILA)*** (Dabska-type hemangioendothelioma, Dabska tumor)
• ***Retiform hemangioendothelioma (RHE)***
• ***Composite hemangioendothelioma (CHE)***
• ***Pseudomyogenic hemangioendothelioma***
• ***Kaposi sarcoma***
Malignant vascular neoplasms
• ***Epithelioid hemangioendothelioma (EHE)***[§]
• ***Angiosarcoma***
Perivascular neoplasms and neoplastic-like proliferations
• ***Glomus tumor (proper)***
• ***Glomuvenous malformation ("glomangioma")***
• ***Glomangiosarcoma***
• ***Infantile-type hemangiopericytoma/myofibromatosis***
• Adult-type hemangiopericytoma
• Glomangiopericytoma
• Myopericytoma
• PEComa (perivascular epithelioid cell tumor)[‖]
*Also viewed as a reactive condition.
†Not clear if a multifocal vascular neoplasm or malformation.
‡Likely a sinusoidal pattern of intravascular endothelial hyperplasia within a pre-existing low-flow vascular malformation.
¶Also viewed as a vascular malformation.
§Reclassified by the WHO as a malignant, rather than intermediate or borderline, vascular tumor.
‖A spectrum of mesenchymal tumors that includes clear cell "sugar" tumor of the lung, angiomyolipoma, lymphangiomyomatosis, clear cell myomelanocytic tumor, and the rare cutaneous tumors with a similar morphology and phenotype; nab-sirolimus approved for treatment of advanced malignant PEComas.

Table 114.1 A working classification of cutaneous vascular anomalies. Entities covered in this chapter are in ***bold italics***.

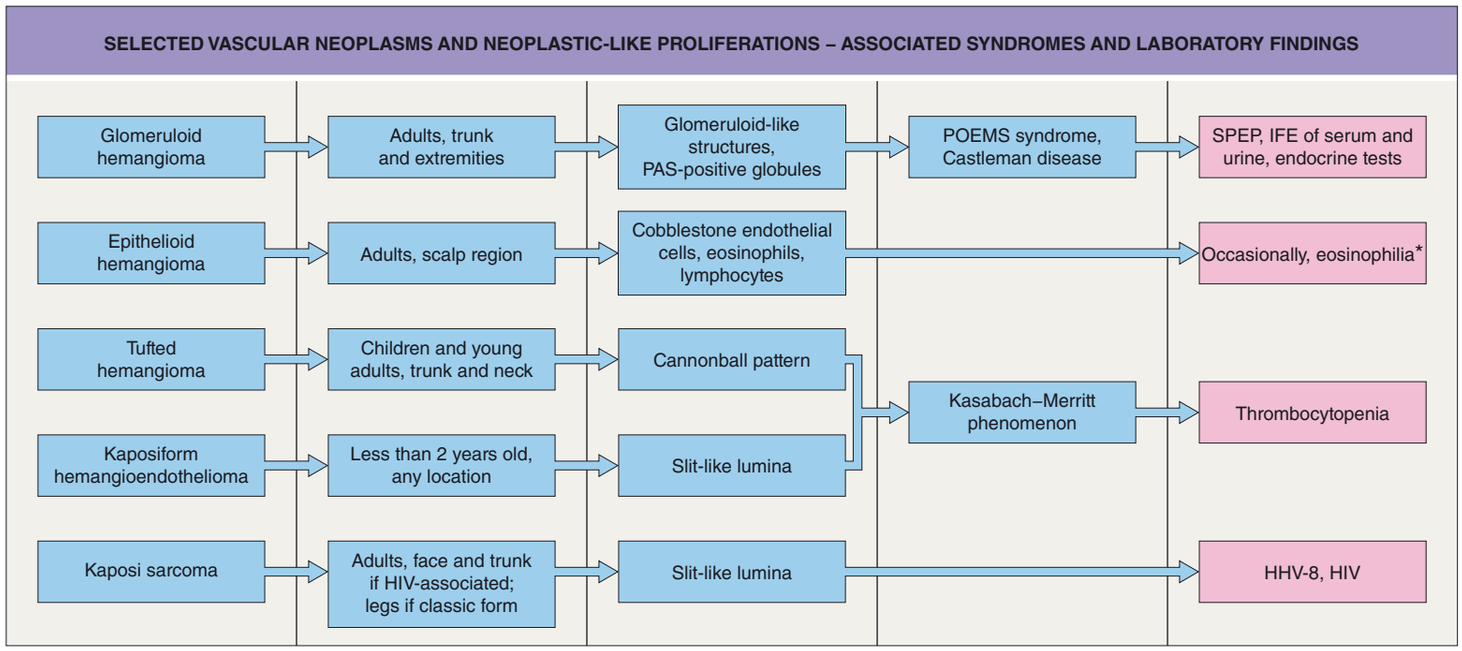

Fig. 114.1 Selected vascular neoplasms and neoplastic-like proliferations – associated syndromes and laboratory findings. *If eosinophilia present, need to consider Kimura disease. IFE, immunofixation electrophoresis; SPEP, serum protein electrophoresis; HHV-8, human herpesvirus 8; HIV, human immunodeficiency virus; PAS, periodic acid Schiff stain.

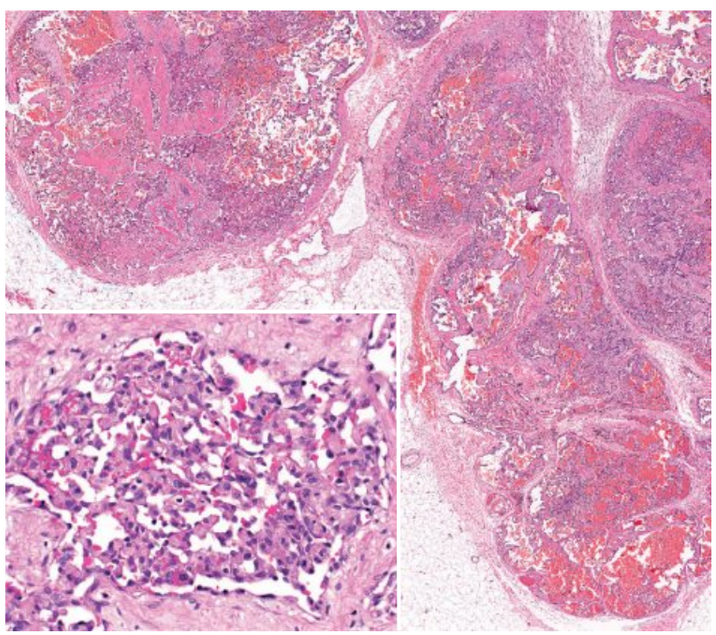

Fig. 114.2 Papillary endothelial hyperplasia (PEH) in a large venous malformation – histopathologic features. Large vascular spaces with remnants of old fibrin thrombi and prominent, irregular recanalization. Networks of recanalizing endothelial cells may mimic angiosarcoma (inset).

Treatment

Surgical excision is usually curative. Local recurrences may occur when the lesion is superimposed on a vascular malformation that may generate new foci of endothelial hyperplasia.

Reactive Angioendotheliomatosis

Key features

- Uncommon, self-limited process occurring exclusively in the skin and characterized histologically by a dense proliferation of small capillaries
- The most common form is predominantly intravascular, resulting in luminal obliteration of pre-existing dermal vessels; many of these patients have vaso-occlusive disorders or systemic infections
- Should be distinguished from *intravascular large cell lymphoma (B or NK/T)*, an angiotropic lymphoma erroneously termed *malignant angioendotheliomatosis* prior to the advent of discriminating immunohistochemistry
- The diffuse dermal angiomatosis variant occurs most commonly on the leg or the breast and is associated with atherosclerosis, cigarette smoking, and large pendulous breasts

Introduction

Angioendotheliomatosis has historically been considered to be a single disease entity, divided into benign and malignant variants. As such, the large pleomorphic cells found within blood vessels in malignant angioendotheliomatosis were thought to be transformed endothelial cells. However, immunohistochemical studies have convincingly demonstrated that these cells are neoplastic lymphocytes. Accordingly, *malignant angioendotheliomatosis* has been renamed *intravascular large cell lymphoma (B or NK/T)* (see Ch. 119). The benign form is a true angioendotheliomatosis and is considered reactive.

Epidemiology

Reactive angioendotheliomatosis is rare and although it can occur at any age, the age of onset often reflects that of any associated systemic disorder. While many cases are idiopathic, this vascular proliferation may be associated with systemic disorders such as bacterial endocarditis, monoclonal gammopathies (including type I cryoglobulinemia), antiphospholipid syndrome, and calciphylaxis as well as renal transplantation, hepatic disease, and rheumatoid arthritis. The diffuse dermal angiomatosis variant occurs most commonly on the leg or the breast[5,6] and is associated with atherosclerosis, cigarette smoking, and large pendulous breasts.

Pathogenesis

Reactive angioendotheliomatosis is a benign, self-limited process. Its frequent association with various systemic conditions has led some investigators to propose that the capillary proliferation may be caused by a circulating angiogenic factor[7]. However, the fact that many of the disorders associated with this process cause vascular occlusion or tissue ischemia suggests that a local, hypoxia-induced increase in vascular endothelial growth factor (VEGF) may be playing a role[8]. In addition, immunological factors may contribute to the proliferative process.

Clinical features

Although erythematous nodules or plaques, often with superimposed petechiae or ecchymoses, are the characteristic primary lesions, the spectrum ranges from erythematous macules to tumor-like masses. Sites of involvement can vary, but the most common is the lower extremities. Focal ulceration may be evident, especially in the diffuse dermal angiomatosis variant (see Fig. 105.20). In this latter variant, reticulated thin violaceous plaques with telangiectasias are often seen (Fig. 114.3A).

Pathology

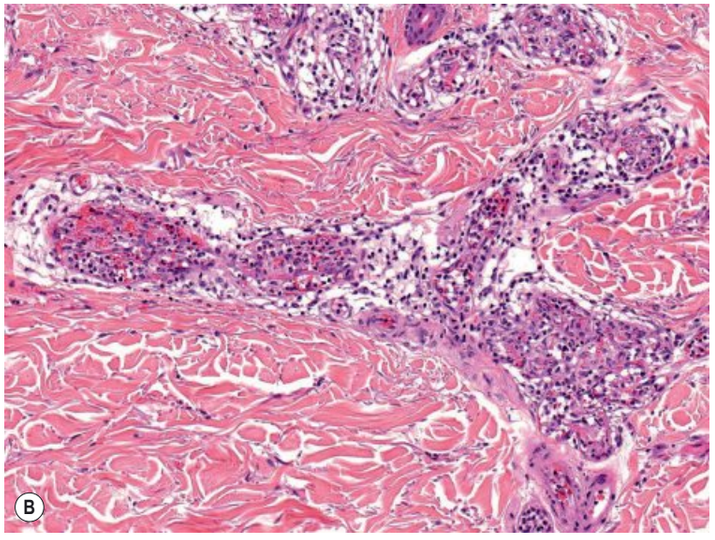
In this predominantly dermal, but also occasionally subcutaneous, process, there is a poorly marginated proliferation of closely packed capillaries lined by plump endothelial cells rimmed by small numbers of pericytes. The pattern of proliferation is highly variable both within and between lesions and is typically described as diffuse and/or lobular[9]. Focally, more dilated capillaries may be present and foci of hemosiderin deposition, fibrin microthrombi, and/or mild chronic inflammation are relatively common. Immunohistochemical positivity for endothelial markers such as CD31 and von Willebrand factor, and focally for pericyte/smooth muscle-associated actins, confirms the cellular composition. Expression of markers of lymphatic endothelial differentiation (e.g. Prox1, podoplanin) is consistently negative[10]. Cytologic atypia is absent and mitotic figures are rare to absent.

The capillary lumina are small and may be occluded by fibrin thrombi and bulging endothelial cells (Fig. 114.3B). In many cases, the proliferating capillaries appear to be contained within a larger, pre-existing vessel, obliterating its lumen, but sometimes the proliferation extends directly between collagen bundles (Fig. 114.3C). Cases associated with cryoglobulinemia typically show intraluminal and intracellular eosinophilic globules, but this finding can also be seen in the absence of cryoglobulinemia.

Differential diagnosis

The clinical differential diagnosis includes vascular tumors (e.g. Kaposi sarcoma, angiosarcoma) as well as other causes of ulceration (see Fig. 105.1). Histologically, one must consider other forms of intravascular endothelial proliferation, including intravascular pyogenic granuloma, papillary intralymphatic angioendothelioma, and intravascular PEH. Intralymphatic histiocytosis can be distinguished by the presence of CD68-positive histiocytes within dilated Prox1- and podoplanin-positive lymphatic vessels[10]. Malignant intravascular proliferations (e.g. intravascular large cell lymphoma [B or NK/T], intralymphatic metastases, intravascular complexes of Merkel cell carcinoma) can be easily distinguished via morphology and immunohistochemistry[11].

Treatment



Evaluation for known associated systemic disorders is important because lesions may regress upon resolution of the underlying condition, e.g. revascularization of an ischemic limb. In case reports, oral isotretinoin has led to improvement, possibly due to its antiangiogenic properties, with consideration of potential side effects[12,13].

Angiokeratomas

Key features

- Small, dark, vascular, and variably keratotic lesions that result from dilation of superficial vessels
- Angiokeratoma circumscriptum is a capillary–lymphatic or capillary malformation
- Angiokeratoma corporis diffusum results from several lysosomal storage disorders and is associated with systemic manifestations

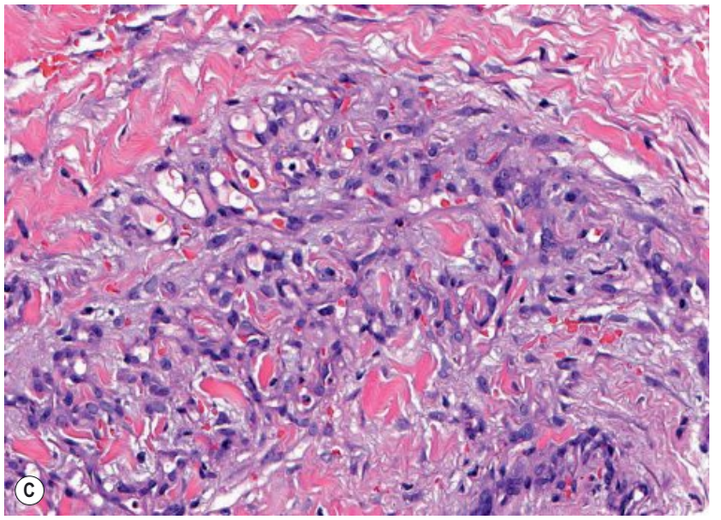


Fig. 114.3 Reactive angioendotheliomatosis – clinical and histopathologic features. A Reticulated violaceous plaques with punctate telangiectasias in a patient with diffuse dermal angiomatosis of the pendulous breast. **B** Intravascular variant with proliferation of grouped capillaries along the course of a dermal blood vessel. The endothelial cells lack atypia and within several capillaries there is an intraluminal proliferation of endothelial cells admixed with erythrocytes occluding the lumina. **C** Diffuse dermal angiomatosis variant with proliferation of hyperplastic endothelial cells without atypical features infiltrating the dermis and forming small vascular lumina. *A, Courtesy Department of Dermatology, Medical University of Graz; B, Courtesy Heinz Kutzner, MD; C, Courtesy Lorenzo Cerroni, MD.*

Introduction

Angiokeratomas are well-circumscribed vascular lesions consisting of superficial vascular ectasia and hyperkeratosis. Five variants have been recognized. With the exception of angiokeratoma circumscriptum (which represents a capillary–lymphatic or capillary malformation), angiokeratomas result from ectatic dilation of pre-existing vessels in the papillary dermis.

Clinical features

Solitary or multiple angiokeratomas

Most commonly, they present as a small, warty, black papule on the lower extremities, but may occur anywhere on the body (Fig. 114.4). The lesions are thought to result from injury to or chronic irritation of the wall of a venule in the papillary dermis. Solitary lesions may be confused with melanoma due to their dark color. Dermoscopy will readily distinguish between these two entities (see Ch. 0).

Genital Angiokeratomas

Synonym: ■ Angiokeratoma of Fordyce

These angiokeratomas may arise in the second or third decade but are most commonly seen in older age groups. In women, angiokeratomas occur most commonly on the labia majora and rarely the clitoris while in men, they develop primarily on the scrotum and rarely the penis[14,15]. The lesions are red–purple to black in color, may be single or multiple, and arise along superficial vessels (Fig. 114.5). In some patients, they may be associated with thrombophlebitis, varicoceles, and inguinal hernias. Vulvar lesions may be associated with vulvar varicosities, hemorrhoids, or increased venous pressure during pregnancy.

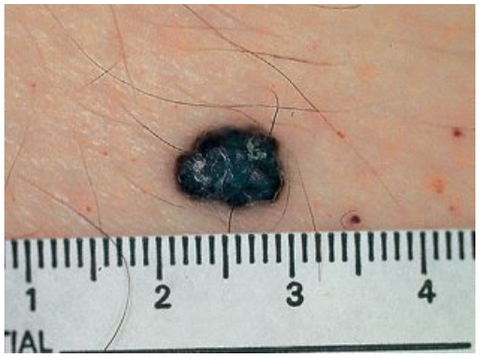

Fig. 114.4 Solitary angiokeratoma. Because of their dark color, these lesions may resemble cutaneous melanoma. Dermoscopy will readily distinguish between these two entities. *Courtesy Jean L. Bolognia, MD.*

Fig. 114.5 Scrotal angiokeratomas. These lesions typically arise along superficial vessels.

Angiokeratoma corporis diffusum

This disorder is characterized by the development of multiple, often clustered angiokeratomas, usually in a bathing trunk distribution. Lesions vary in number (from only a few to numerous) and usually begin to appear during late childhood or adolescence. X-linked recessive Fabry disease is the best-known entity with this clinical presentation and results from a deficiency of the lysosomal enzyme α-galactosidase A (see Ch. 63). This leads to the accumulation of the neutral glycolipid ceramide trihexidose within lysosomes of multiple cell types. Other enzyme deficiencies associated with angiokeratoma corporis diffusum are outlined in Table 63.7.

Angiokeratoma of Mibelli

Lesions usually develop between the ages of 10 and 15 years and are most commonly situated on the dorsal and lateral aspects of the fingers and toes. They may also occur on the dorsa of the hands and feet and rarely on the elbows and knees. Angiokeratoma of Mibelli may be associated with chilblains and acrocyanosis. In rare instances, ulceration of the fingertips can occur. There is a familial predisposition and the disorder may be transmitted in an autosomal dominant fashion with variable penetrance.

Angiokeratoma circumscriptum

This entity usually develops during infancy or childhood as either a plaque of multiple discrete papules (Fig. 114.6) or hyperkeratotic papules and nodules that often become confluent. They occur on the trunk, arms, or legs and are unilateral in most patients. There is a female predominance.

Pathology

Marked dilatation of the papillary dermal vessels is seen in association with an acanthotic, variably hyperkeratotic epidermis. Elongated rete ridges may partially or completely enclose vascular channels, and a collarette may be present at the margin of the lesions. In Fabry disease, vacuoles can be detected within endothelial cells and pericytes. The amount of glycolipid is small and may be difficult to detect in routinely prepared sections. However, the deposits stain positively with PAS and anti-GB3 antibody. They can also be demonstrated by electron microscopy.

Differential diagnosis

Clinically, angiokeratomas should be distinguished from other vascular lesions as well as acral pseudolymphomatous angiokeratomas (see Ch. 121). Darkly colored or thrombosed angiokeratomas may resemble cutaneous melanoma.

Treatment

Patients may request removal for cosmetic reasons. This may be achieved by shave excision, diathermy or laser therapy, the choice of which would largely depend on the size of the lesion.

Fig. 114.6 Angiokeratoma circumscriptum. These grouped red–violet papules had been present since childhood. *Courtesy Jean L. Bolognia, MD.*

Targetoid Hemosiderotic Lymphatic Malformation (Hobnail "Hemangioma")

Synonyms: ■ Targetoid hemosiderotic hemangioma ■ Superficial hemosiderotic lymphovascular malformation ■ Hobnail lymphatic malformation

Key features

- Uncommon acquired vascular lesion that usually presents as a red–blue or brown papule, most commonly on the extremities and often with a history of local trauma
- The papule is sometimes surrounded by a pale ring and then an ecchymotic halo
- Biphasic pattern of dilated, thin-walled vessels with hobnail endothelial cells in the superficial dermis, transitioning to smaller, slit-like vessels in the deeper dermis and lateral portions of the lesion
- Lesional endothelial cells strongly express the lymphoendothelial marker podoplanin and have minimal expression of CD34, consistent with lymphatic differentiation

Fig. 114.7 Targetoid hemosiderotic lymphatic malformation (hobnail "hemangioma"). There is a target-like appearance with a central violet papule surrounded by a pale rim whose color reflects hemosiderin deposition and then a purpuric halo. *Courtesy Department of Dermatology, Medical University of Graz.*

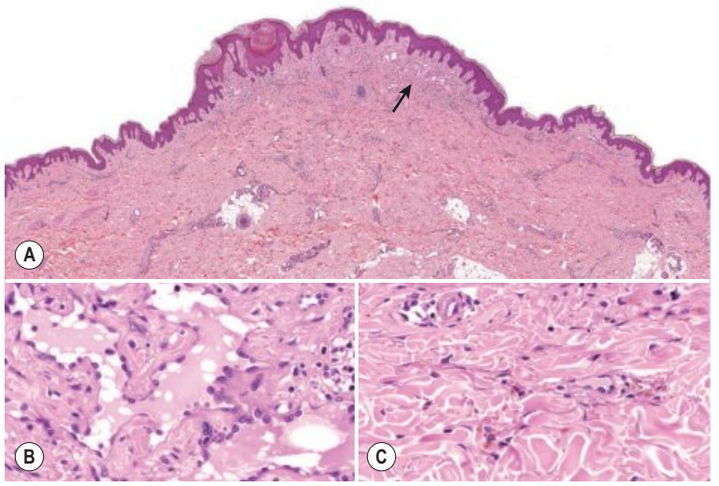

Fig. 114.8 Targetoid hemosiderotic lymphatic malformation (hobnail "hemangioma") – histopathologic features. A Biphasic appearance with dilated superficial dermal vessels lined by hobnailed endothelial cells in the center of the lesion (arrow; **B**), merging with smaller slit-like vessels that dissect between collagen bundles in deeper and lateral portions of the dermis (**C**). *Courtesy Lorenzo Cerroni, MD.*

Introduction and history

The original description in 1988 coined the term *targetoid hemosiderotic hemangioma* to emphasize the targetoid clinical appearance and hemosiderin deposition. Since then it has become apparent that only a minority of these lesions have an ecchymotic halo and hemosiderin deposition is variable. The term *hobnail hemangioma* was proposed to encompass lesions with the characteristic biphasic growth pattern and marked hobnail endothelial morphology, with or without a targetoid clinical appearance and/or marked hemosiderin deposition[16,17]. A benign clinical course has been observed in the over 100 cases that have been reported to date[17,18]. Recently, this "hemangioma" was reclassified as a *targetoid hemosiderotic lymphatic malformation* (THLM)[19].

Epidemiology

There is no sex predilection[17]. In a series of 62 patients, their ages ranged from 6 to 72 years (median, 32 years)[18].

Pathogenesis

This vascular anomaly was thought to represent the benign end of a spectrum of vascular tumors that have hobnail endothelial cells and which includes papillary intralymphatic angioendothelioma (PILA) and retiform hemangioendothelioma (see Table 114.1)[16]. However, the endothelial cells of THLM and PILA, but not retiform hemangioendothelioma, stain positively for several markers of lymphatic differentiation[18,20]. In addition, the endothelial cells of THLM are generally negative for Wilms tumor-1 (WT-1) and have a low Ki-67 proliferation index. The latter explains its reclassification as a vascular malformation based upon International Society for the Study of Vascular Anomalies (ISSVA)-sanctioned restriction of the suffix "angioma" to intrinsically proliferative vascular tumors[19].

Trauma may stimulate the appearance of a THLM, with microshunts between small lesional blood vessels and adjacent lesional lymphatic vessels explaining the presence of erythrocytes within lymphatic vessels and hemosiderin deposits[20].

Clinical features

Most lesions are asymptomatic, solitary, well-circumscribed, red–blue to violet–brown papules that are initially 2 to 3 mm in diameter and then slowly increase in size. In some cases, the papule is surrounded by a thin pale ring and then an ecchymotic halo (Fig. 114.7). The ecchymotic ring may fade and eventually disappear over time, and some lesions undergo cycles of spontaneous regression and recurrence. Favored sites, in decreasing order of frequency, are the lower extremities, upper extremities, back, buttock/hip, and chest wall. Lesions have also been reported on the tongue and gingiva[17].

Pathology

There is a biphasic histologic pattern (Fig. 114.8A), consisting of: (1) dilated, thin-walled vessels containing small numbers of red blood cells and lined by prominent hobnail endothelial cells within the superficial dermis (Fig. 114.8B); and (2) smaller, more slit-like vessels that dissect between collagen bundles in deeper and lateral portions of the dermis (Fig. 114.8C). Extravasated red blood cells and hemosiderin deposits are common but may be absent. Although the superficial vessels occasionally have delicate intraluminal papillary fronds, the more complex, multilayered endothelial tufts of PILA are lacking. The endothelial cells of both the dilated and the slit-like vessels stain positively for the lymphoendothelial marker podoplanin (see Ch. 102), but show little, if any, reactivity for the blood vascular marker CD34[18,20].

Differential diagnosis

The clinical differential diagnosis includes melanocytic nevus, sclerosing hemangioma, and benign vascular neoplasms and proliferations in Table 114.1[17]. Histopathologically, it must be distinguished from patch-stage and lymphangioma-like variants of Kaposi sarcoma, well-differentiated angiosarcoma, retiform hemangioendothelioma, PILA, and microcystic lymphatic malformation.

Treatment

Treatment consists of simple excision. Longitudinal evaluation of 35 patients, ranging from 1 to 4 years, revealed no local recurrence or systemic metastasis[18].

Verrucous Venulocapillary Malformation (Verrucous "Hemangioma")

Synonym: ■ Verrucous venous malformation

Key features

- Rare congenital vascular anomaly that has been reclassified as a vascular malformation
- Somatic missense mutations in *MAP3K3* (mitogen-activated protein kinase kinase kinase 3) detected in some lesions
- Isolated, grouped, or confluent red-to-purple papules with reactive hyperkeratosis; often darkens with age
- Most commonly occurs on the distal extremity and can be complicated by ulceration and bleeding but not local tissue hypertrophy
- Histologically, dilated capillaries and venules are present within the papillary and investing dermis as well as the deep reticular dermis and subcutis; the overlying epidermis is acanthotic

Introduction and history

This rare, but increasingly well-recognized, vascular anomaly was originally thought to be a "hemangioma", but has since been reclassified as a vascular malformation. The debate arose in part because these lesions may show evidence of cellular proliferation during their evolution. Mulliken and colleagues recommended use of the term *verrucous venous malformation*[21] while others prefer the designation *verrucous venulocapillary malformation*, congruent with the predominant component vessels.

Epidemiology

There are no sex, racial, or ethnic predilections.

Pathogenesis

Somatic missense mutations in *MAP3K3* (mitogen-activated protein kinase kinase kinase 3) were detected in 6 of 10 verrucous venulocapillary malformations[21]. The mutant allele frequencies ranged from 6% to 19% in affected tissue and these mutations were not found in unaffected tissue or other types of vascular anomalies. Of note, studies in *MAP3K3* knockout mice had previously implicated MAP3K3 in vascular development.

Clinical features

Verrucous venulocapillary malformations are congenital and present as isolated, grouped, or confluent red-to-purple papules that can sometimes be extensive. The vast majority occur on the distal extremities, particularly the leg (Fig. 114.9A); the trunk is a rare location[22]. They progressively darken and become hyperkeratotic during childhood, often increasingly complicated by ulceration, bleeding, and scarring. They do not regress and are not associated with local tissue hypertrophy or other developmental anomalies.

Pathology

Features can vary with age, in particular the appearance of secondary orthohyperkeratosis and verrucous epidermal hyperplasia, but consistently there are dilated capillaries and venules (without a smooth muscle layer) within the papillary dermis and occasionally the investing dermis around adnexae. There is sparing of most of the reticular dermis, with the dilated blood vessels reappearing in the deep dermis and subcutis, where they are usually smaller in caliber, often grouped, and sometimes have intraluminal thrombi (Fig. 114.9B). The superficial dermal vessels are usually the most obviously dilated with expansion of the dermal papillae (Fig. 114.9C). A purely subcutaneous variant has been described[23].

Endothelial cells consistently express markers of blood vascular differentiation, including CD31 and CD34. Focal positivity for lymphatic endothelial markers, e.g. Prox1, podoplanin, has been observed in some, but not all, studies[24,25]. Mitotic activity is very low. Many verrucous venulocapillary malformations have light, focal immunoreactivity for GLUT1, in contrast to the intense endothelial GLUT1 positivity seen in infantile hemangiomas[26,27]; staining for CD15 and indolamine 2,3 deoxygenase is negative (personal observation).

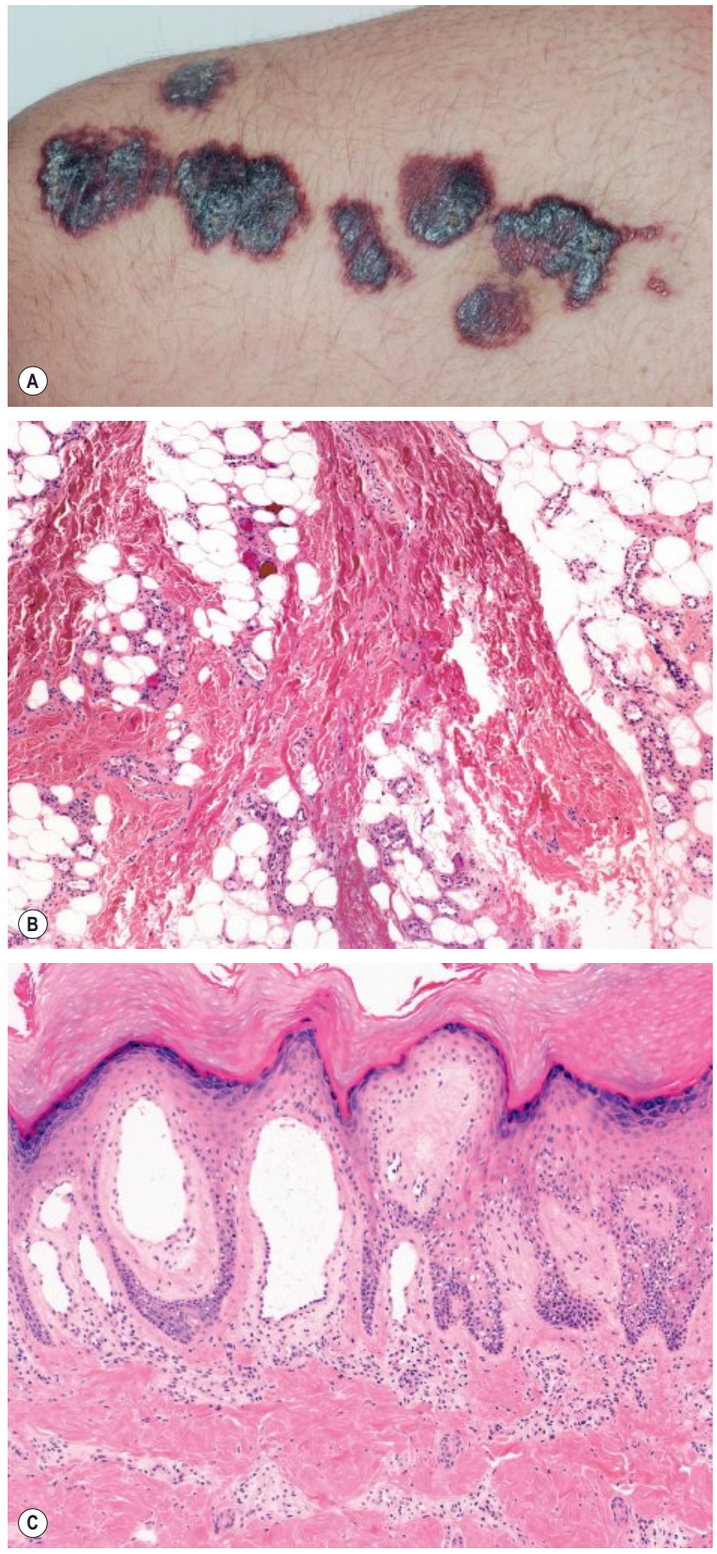

Fig. 114.9 Verrucous venulocapillary malformation (verrucous "hemangioma") – clinical and histopathologic features. A Linear array of purple plaques on the thigh; the thicker portions of the plaques are darker in color with overlying scale. **B** Ectatic venules and capillaries infiltrate the subcutis. **C** Ectatic capillaries and venules expand the papillary dermis; note the hyperkeratosis. *A, Courtesy Julie V. Schaffer, MD.*

Differential diagnosis and treatment

The differential diagnosis includes other venous and venulocapillary malformations, lymphatic and mixed venous–lymphatic malformations (see Ch. 104), non-involuting congenital hemangioma, infantile hemangioma (see Ch. 103), and verrucous epidermal nevus (see Ch. 109). Current first-line therapeutic options include surgical excision

and treatment of the superficial component with pulsed dye, long-pulsed Nd:YAG, and/or carbon dioxide lasers. However, treatment is challenging for extensive lesions. More recently, topical and oral sirolimus have been utilized with variable results[28–30].

Pyogenic Granuloma

Synonyms: ■ Lobular capillary hemangioma ■ Granuloma pyogenicum

Key features

- Rapidly growing, friable, red papule or polyp of skin or mucosa that frequently ulcerates; most common in children and young adults
- Those arising on the gingiva of pregnant women (*granuloma gravidarum*) are considered a separate clinical subgroup, but are histologically indistinguishable
- The characteristic single lesion may spontaneously regress as well as recur whereas multiple lesions can arise, even repeatedly, within pre-existing vascular malformations or congenital hemangiomas
- Neither infectious in etiology nor granulomatous histologically but occasionally associated with trauma or hormonal factors; historically considered a reactive vascular hyperplasia
- Somatic *BRAF* and *RAS* mutations have been detected in sporadic lesions and more often in secondary pyogenic granulomas arising within capillary malformations, pointing to at least a partially neoplastic etiology rather than purely reactive hyperplasia
- Consists of lobules of small benign capillaries set in a fibromyxoid matrix, often distinctly exophytic and bounded by a collarette of hyperplastic epithelium
- Occasionally found in subcutaneous or intravascular locations

Introduction and history

Poncet and Dor are credited with the initial description in 1897, and they believed the cause was a *Botryomyces* infection. The term *granuloma pyogenicum* was coined in 1904 by Hartzell to describe four similar cases that he thought represented a nonspecific granulation tissue-type response to any type of pyogenic agent[31]. Although the etiology of these common lesions remains controversial and potentially heterogeneous, the term *pyogenic granuloma* is clearly a misnomer. There is no evidence to implicate any infectious agent, and the histologic appearance is not granulomatous.

Epidemiology

Pyogenic granulomas (PGs) can develop at any age but are more common in children and young adults. There may be a slight male predominance, but no racial or familial predisposition. Gingival lesions may arise during pregnancy (see Fig. 27.11C). Rarely, neonates develop extensive multifocal PGs.

Pathogenesis

PGs exhibit several clinical features suggestive of reactive neovascularization, including a common association with pre-existing injury or irritation, limited capacity for growth, and a propensity for multiple eruptive lesions that may be localized or disseminated. The occasional appearance of PGs within other vascular anomalies, especially capillary[32] and arteriovenous malformations or congenital hemangiomas, suggests that abnormalities in blood flow or background somatic mutations within the underlying lesion may play a role.

In one study, 8 of 10 PGs arising within a capillary malformation (CM) had a *BRAF* c.1799T>A mutation and 1 of 10 an *NRAS* c.182A>G mutation[33]. All of these secondary PGs also had the underlying CM-specific *GNAQ* c.548G>A mutation, pointing to their derivation from the cells of the CM as well as the independent occurrence of a *BRAF* mutation within the PG[33]. The same *BRAF* c.1799T>A mutation was also found in 3 of 25 sporadic PGs suggesting its possible role as a driver mutation in primary and secondary PGs. *BRAF* c.1799T>A mutation leads to BRAF V600E and immunohistochemical staining for this protein can be used to confirm the presence of BRAF V600E within the endothelial cells of a PG and its absence in adjacent perilesional normal epidermis. Activation of the MAPK signaling pathway (see Fig. 113.1) points to a neoplastic rather than purely reactive process[33], at least for some PGs, taking into account the background level of MAPK signaling due to external factors (e.g., trauma, irritation).

Clinical features

The lesion presents as a solitary red papule or polyp that grows rapidly over the course of several weeks or months, stabilizes, and then may decrease in size (Fig. 114.10). Its final size is rarely >1 cm, and it may persist indefinitely if not removed. Approximately one-third develop following minor trauma. In one series of 289 cases, the most common sites, in decreasing order of frequency, were the gingiva, fingers, lips, face, and tongue[34]. They are extremely friable, frequently ulcerate, and may bleed profusely with minor trauma. Multiple satellite lesions occasionally develop near a primary PG, usually after destruction of that lesion[35]. Rarely, PGs arise within the subcutis, develop intravascularly, or erupt in a disseminated fashion[36]. PGs have been reported in association with vascular malformations (see above) as well as multiple drugs including systemic retinoids[37], indinavir, and BRAF, EGFR, HER2, MEK and mTOR inhibitors. Medication-induced lesions are often in a periungual location and are sometimes referred to as pseudo-PGs.

Pathology

The quintessential cutaneous or mucosal lesion is a well-circumscribed, exophytic, sometimes pedunculated proliferation of small capillaries, often arranged in a lobular pattern (Fig. 114.11). Lesional capillaries are lined by flattened to slightly plump endothelial cells, rimmed by pericytes, and surrounded by a variably edematous fibromyxoid interstitial stroma containing fibroblasts. Endothelial and stromal cell mitotic activity is highly variable and depends on the stage of growth; a variably dense infiltrate of lymphocytes, plasma cells, neutrophils, and mast cells is usually present. Capillary lumina within the lobules vary from small and angular to branching and ectatic, and foci of thrombosis and intravascular PEH may be present. A few larger vessels with smooth muscle walls, usually venous (but often including a small ascending arterial feeder), are frequently present at the base of the lesion. Thick, intervening bands of dense fibrous tissue sharply define the lobularity and help distinguish pyogenic granuloma from other lobular forms of capillary proliferation such as infantile hemangioma. The lateral margins are often defined by epithelial "collarettes".

Differential diagnosis

The diagnosis of PG can be made clinically if the red, bleeding papule is coupled with the characteristic location and history. Otherwise, they can be easily confused with amelanotic melanoma and, in the immunosuppressed patient, bacillary angiomatosis or Kaposi sarcoma. Glomus

tumors, infantile hemangiomas, and irritated melanocytic nevi and warts can all mimic PGs. Histologic confirmation is always helpful in cases where the diagnosis is in question.

Treatment

Shave excision followed by electrosurgery of the base under local anesthesia is sufficient for most lesions. Patients and parents should be alerted to the possibility of recurrence after removal. Excision with suturing may result in less postoperative bleeding and a lower recurrence rate.

Pulsed dye laser has also been shown to be a safe and effective treatment for small PGs and may be particularly useful in children[38]. Topical β-blockers (e.g. timolol) or silver nitrate cauterization may be helpful for targeted cancer therapy-induced pseudo-PGs or small PGs in children. Successful sclerotherapy in nine patients using monoethanolamine oleate was reported, with inconspicuous scar formation and no recurrence[39].

Cherry Angioma

Synonyms: ■ Cherry hemangioma ■ Senile angioma ■ Campbell–De Morgan spot

Key features

- Bright red, dome-shaped to polypoid papules up to several millimeters in diameter that begin appearing during adult life, most commonly on the trunk and upper extremities
- A common, benign lesion found in most individuals by the age of 60 years, sometimes in large numbers
- Consist of dilated, congested capillaries and postcapillary venules within the papillary dermis

Introduction and history

Cherry angiomas are the most common of the acquired cutaneous vascular proliferations. They can be unattractive and when eruptive may rarely herald an underlying systemic abnormality.

Epidemiology

Both sexes are affected equally. Although they may occasionally develop during adolescence, cherry angiomas usually first appear during the third decade of life or later, and then increase in number over time. Most people over 60 years of age have one or more such lesions.

Pathogenesis

An increased number of cherry angiomas often appear during pregnancy and may involute in the postpartum period, suggesting that hormonal factors may be important in their pathogenesis. Two women with hundreds of eruptive cherry hemangiomas, both of whom had increased serum levels of prolactin, have also been reported[40]. Most angiomas that appear in the setting of POEMS syndrome are cherry angiomas, often in association with glomeruloid hemangiomas. Mutually exclusive somatic mutations in three *GNA* genes – *GNA11*, *GNA14*, and *GNAQ* – have been identified in the majority of cherry angiomas[41,42]. Of note, these genes have been associated with a variety of other benign (but not malignant) vascular anomalies, e.g. *GNAQ* and CMs[43]. In ~20% of cherry angiomas, somatic *HRAS* and *KRAS* mutations have been detected[33]. As with PGs, these findings suggest that cherry angiomas are more appropriately considered neoplastic rather than purely reactive in nature, although incidence and phenotypic variability could be influenced by the cell type harboring the mutation and external factors (e.g. trauma, hormones, gammopathy)[33].

Clinical features

Cherry angiomas are round to oval, bright red to purple, dome-shaped papules ranging in size from barely visible to several millimeters in diameter (Fig. 114.12A). Well-developed lesions may be polypoid. They most commonly develop on the trunk and proximal extremities and are rare on the hands, feet, and face. It is not unusual for elderly adults to have 50–100 cherry angiomas on their trunk. Rarely, a segmental distribution pattern, possibly reflecting mosaicism, is seen.

Patients are usually aware of the benign nature of these extremely common lesions and bring them to a physician's attention only when concerned about their appearance. They are generally asymptomatic but may occasionally bleed when traumatized.

Pathology

Histologically, congested, ectatic capillaries and postcapillary venules are seen within the papillary dermis and superficial reticular dermis (Fig. 114.12B,C). Early lesions are characterized by small lumina and plump endothelial cells. With maturation, the vessels dilate and the endothelial cell cytoplasm flattens, often producing slightly hobnailed nuclei. Vessel diameter decreases with descent into the reticular dermis. There is loss of epidermal ridges centrally and peripherally adnexal epithelial collarettes are seen.

Differential diagnosis

The distinctive clinical and dermoscopic findings (see Ch. 0) limit other diagnostic considerations. Glomeruloid hemangiomas, although similar in clinical appearance, can be distinguished histologically. Tiny cherry angiomas may resemble petechiae.

Treatment

Patients may request removal of cosmetically undesirable or chronically traumatized cherry angiomas. This can be accomplished by shave excision, electrodesiccation, or laser ablation, and recurrences are unusual.

Tufted Angioma

Synonyms: ■ Acquired tufted angioma ■ Angioblastoma of Nakagawa ■ Tufted hemangioma

Key features

- Usually presents as an acquired lesion in children and young adults, but may be congenital
- Non-homogeneous pink to red patches and plaques with superimposed papules that spread slowly, often to involve large areas, then stabilize; rarely completely regress
- Most commonly located on neck or trunk
- When congenital can be associated with Kasabach–Merritt phenomenon (syndrome)
- Thought to represent a mild superficial form of kaposiform hemangioendothelioma
- Characterized histologically by tightly packed tufts of tiny capillaries distributed within the dermis and subcutis in a "cannonball" pattern; foci of spindled endothelial cells may be present

Introduction

Tufted angioma has often been lumped erroneously with infantile hemangioma under the generic term "capillary hemangioma". However, a distinction is important given its association with Kasabach–Merritt phenomenon (KMP) in some infants. In older children and adults, it may clinically mimic Kaposi sarcoma. Current opinion is that tufted angioma falls within a spectrum shared by kaposiform hemangioendothelioma (KHE), with the latter usually having deeper involvement of soft tissues. From a practical standpoint, many pathologists favor a unified histopathologic diagnosis for these two variants.

History

Tufted angioma was first described in 1989 by Wilson-Jones and Orkin[44]. Apparently identical lesions had been described many years previously as angioblastoma and progressive capillary hemangioma. The association of tufted angioma with KMP, shared by KHE, is now widely recognized[45].

Epidemiology

Most lesions occur in young adults and children, many during the first year of life. Over 50% present before 5 years of age[44], and ~15% are congenital[44]. Rarely, lesions appear late in life[46]. Although one family with several affected family members has been reported[47], the vast majority of cases are sporadic.

Pathogenesis

Tufted angioma and KHE have a significant degree of overlap in histologic features, with resection specimens of KHE often demonstrating dermal changes that would have been interpreted in small biopsy specimens as tufted angioma. The virtually exclusive association of these two entities with KMP, plus their histologic and molecular overlap, provides convincing evidence that tufted angioma likely represents a more superficial, milder form of KHE (see KHE section for discussion of molecular studies)[45,48–51].

Clinical features

Tufted angiomas appear as mottled red patches or plaques with superimposed angiomatous papules, typically on the neck, trunk or shoulders, that grow slowly by lateral extension over a period of 5 months to 10 years[44] (Fig. 114.13). Occasionally, lesions have an associated growth of lanugo hair or CM-like areas[52]. Platelet trapping (KMP) may develop in congenital cases, although less commonly than in KHE. Lesions eventually stabilize in size, then may persist unchanged, shrink, or leave a fibrotic residuum. Rarely, complete spontaneous regression has been observed[52]. Occasionally lesions are painful, and exacerbations of pain may occur during periods of uncontrolled platelet trapping[53].

Pathology

Tufted angiomas, as originally described in the dermatology literature, are characterized by multiple discrete lobules of capillaries set within the dermis and often the subcutis in a so-called "cannonball" pattern (Fig. 114.14). Borders of the area of tissue involvement are poorly defined. The dermal collagen and subcutis separating capillary lobules may be histologically normal but are often fibrotic. The lobules are composed of tiny capillaries with pinpoint lumina, occasionally containing fibrin microthrombi, that are tightly packed together without intervening stroma (Fig. 114.14, inset), and they frequently bulge into peripherally placed thin-walled vessels. Mitotic figures are rare.

Endothelial cells may be focally spindled, but less prominently than in KHE. The sweeping spindled cell fascicles and epithelioid nodules of KHE are typically absent in tufted angioma[50,54]. Although the number of spindled endothelial cells differs when tufted angioma is compared to KHE, they share an identical phenotype: Prox1$^{\pm}$ (nuclear), podoplanin and LYVE-1^{+} (cytoplasmic), CD31^{+}, CD34^{+}, and smooth muscle actin (SMA)$^{-}$. In both tumors, it has been suggested that the proportion of spindled endothelial cells and degree of podoplanin/Prox1 positivity correlates with aggressiveness and active KMP, but this has not been definitely demonstrated[45,50,54].

Of note, endothelial cells of tufted angioma do not immunoreact for infantile hemangioma-associated antigens such as GLUT1 and Lewis Y antigen[27]. Ultrastructural studies have demonstrated classical Weibel–Palade bodies. In cases associated with KMP, platelet trapping has been confirmed with CD61 immunoreaction[55].

Differential diagnosis

Congenital/early infantile tufted angiomas must be differentiated from infantile hemangiomas, the most common tumors of infancy (see Ch. 103).

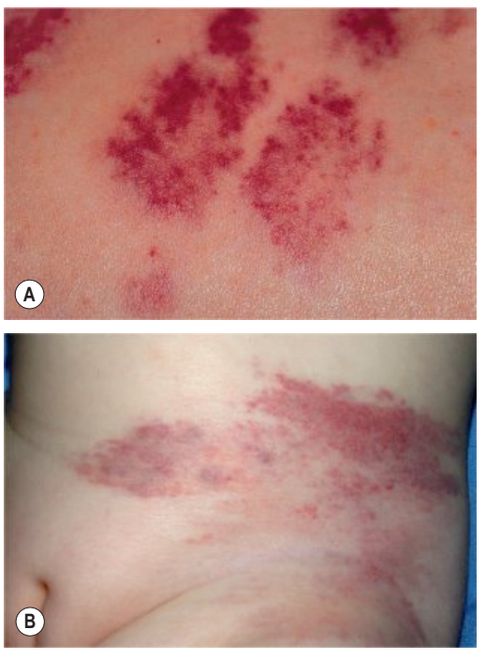

Fig. 114.13 Tufted angioma – clinical features. A Mottled red patches and superimposed papules are typical clinical features. **B** Pink–red to violet plaque in an infant that is broken up into smaller papules. *B, Courtesy Julie V. Schaffer, MD.*

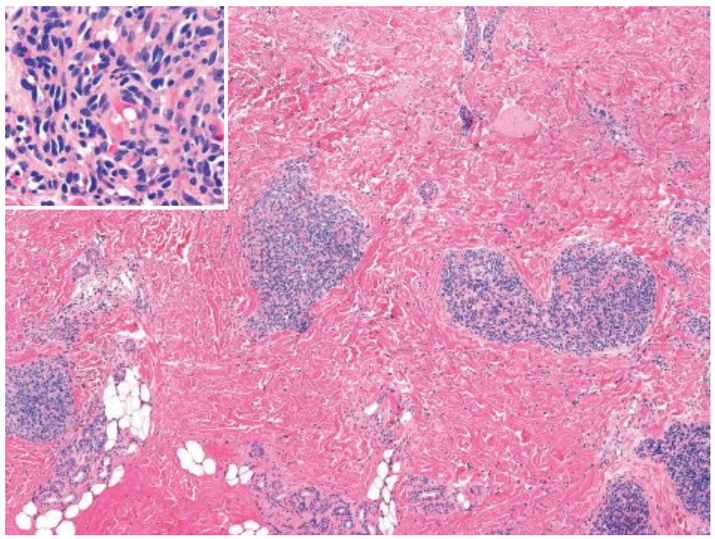

Fig. 114.14 Tufted angioma – histopathologic features. Within the dermis, there is typically a cannonball distribution of dense capillary lobules (inset). *Courtesy Luis Requena, MD.*

The latter are positive for placental capillary-associated endothelial markers (e.g. GLUT1) and show more rapid growth (without lateral extension) during the first year of life, followed by spontaneous, slow involution[27]. Infantile hemangiomas are transiently positive for the lymphatic-associated marker LYVE-1 early in their course, presumably as an expression of their embryonic, cardinal vein-type endothelial phenotype[56], but lack other lymphatic markers such as podoplanin and Prox1[56,57].

Other entities that may mimic the clinical appearance of tufted angioma include pyogenic granuloma arising within a vascular malformation and Kaposi sarcoma. Pyogenic granuloma can be distinguished histologically by its characteristic edematous stroma, granulation tissue-type changes, common presence of inflammation, lack of association with lymphatic markers, and generally larger, more loosely packed lesional vessels. Kaposi sarcoma differs in its lack of tufting, presence of a plasma cell infiltrate, and prominence of fascicles of spindle cells forming slit-like spaces. KHE, although overlapping in histology and likely synonymous in pathogenesis, is traditionally described as a more bulky, deeply seated lesion that tends to infiltrate across multiple tissue planes and has more prominent spindled endothelial cells[50].

Treatment

Complete surgical excision is the treatment of choice for small tufted angiomas, but recurrence is common. Topical sirolimus (rapamycin), an mTOR inhibitor, can be tried (see Ch. 129). Use of the pulsed dye laser has been ineffective[53,58], although the argon tunable dye laser with its higher risk of scarring has been used successfully. Both aggravation and improvement have been reported with the Nd:YAG laser. Historically, high-dose systemic corticosteroids were sometimes employed[59], even though generally ineffective. Interferon-α may produce partial regression, but its use is no longer recommended given the risk of inducing permanent spastic diplegia in infants (see Ch. 103)[58]. For patients with tufted angioma/KHE who develop KMP, first-line therapy consists of oral sirolimus plus prednisolone[60,61]; vincristine plus prednisone is another option[60–62]. Aspirin may also help to control the platelet interaction, pain, and growth of tufted angiomas[53].

Glomeruloid Hemangioma

Key features

- A histologically distinct type of hemangioma that occurs primarily in patients with POEMS syndrome
- In POEMS syndrome, multiple, firm, angiomatous papules or plaques are scattered most often on the trunk and proximal extremities
- Characterized histologically by nests of capillaries within dilated dermal vessels, resembling renal glomeruli
- Likely induced by increased circulating levels of VEGF

POEMS SYNDROME – CLINICAL CRITERIA, CUTANEOUS FINDINGS, AND ASSOCIATED VASCULAR LESIONS
Diagnostic criteria
***M*onoclonal plasmaproliferative disorder** – *and* – **Sensorimotor *p*olyneuropathy** plus at least one other major criterion and one minor criterion
Major criteria
• Sclerotic bone lesions • Castleman disease • Increased circulating levels of VEGF
Minor criteria
• Extravascular volume overload (peripheral edema, pleural effusions, ascites) • Thrombocytosis or polycythemia • Papilledema • *O*rganomegaly (hepatosplenomegaly) or lymphadenopathy • *E*ndocrinopathy (e.g. adrenal, pituitary, gonadal, parathyroid) • Skin changes (characteristic)
Cutaneous findings
• Vascular lesions • More common: diffuse hyperpigmentation, induration, hypertrichosis, hyperhidrosis • Less common: clubbing, livedo reticularis, acrocyanosis, flushing, acquired facial lipoatrophy, leukonychia
Types of cutaneous vascular lesions
• Cherry hemangiomas • Glomeruloid hemangiomas • Other: reactive angioendotheliomatosis, intravascular papillary endothelial hyperplasia, lobular capillary hemangiomas, microvenular hemangiomas

Table 114.2 POEMS syndrome – clinical criteria, cutaneous findings, and associated vascular lesions. Patients with AESOP (*a*denopathy and *e*xtensive *s*kin patch *o*verlying a *p*lasmacytoma) syndrome may fulfill the criteria for POEMS syndrome. Patients with TEMPI syndrome also have a monoclonal gammopathy (M) but they develop telangiectasias (T) as well as elevated erythropoietin and erythrocytosis (E), perinephric fluid collections (P), and intrapulmonary shunting (I). VEGF, vascular endothelial growth factor.

Introduction and history

The term *glomeruloid hemangioma* was coined by Chan et al.[63] in 1990 to describe a distinctive vascular proliferation that occurs primarily in patients with POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy, and *s*kin lesions). Although the majority of patients with POEMS syndrome have an underlying plasma cell dyscrasia, this lesion occurs more commonly in those with multicentric Castleman disease. There is some overlap with reactive angioendotheliomatosis, but glomeruloid hemangioma is discussed separately because of its highly distinctive histologic features and well-recognized clinical association.

Clinical features

The reported incidences of angiomas in patients with POEMS syndrome range from 25% to 45%. These appear as multiple, firm, dome-shaped, red to purple papules or plaques ranging in diameter from a few millimeters to a few centimeters; they are scattered predominantly over the trunk and proximal extremities (see Ch. 53). Additional cutaneous manifestations of POEMS syndrome are outlined in Table 114.2, as are the types of vascular lesions that occur in these patients. True glomeruloid hemangiomas appear to be fairly specific for POEMS syndrome, and rarely they may appear years prior to recognition of the syndrome[64]. In addition, there are reports of a solitary variant that is not associated with POEMS syndrome.

Pathogenesis

Glomeruloid hemangiomas are thought to be reactive, rather than neoplastic. Patients with POEMS syndrome often have increased circulating levels of VEGF[65] such that this elevation represents a major diagnostic criterion (see Table 114.2). Most cases of POEMS syndrome associated with multicentric Castleman disease (~90%) have evidence

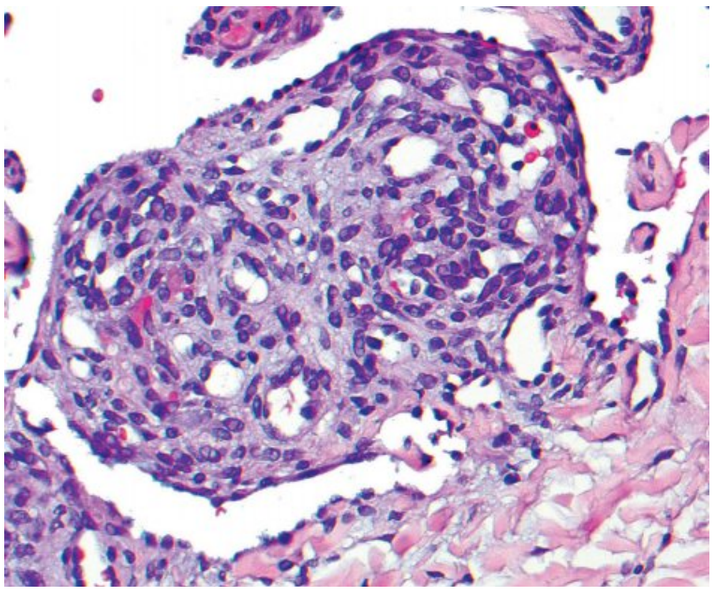

Fig. 114.15 Histology of a glomeruloid hemangioma in a patient with POEMS syndrome. Dilated dermal vessels are filled with congeries of small capillaries reminiscent of renal glomeruli.

of human herpesvirus-8 (HHV-8) infection by PCR. It is suspected that viral interleukin (IL)-6 produced by HHV-8 may indirectly promote angiogenesis by inducing VEGF expression[66]. There was also a case report of a patient with Erdheim–Chester disease and elevated circulating levels of VEGF who developed a glomeruloid hemangioma, further implicating the pathogenic role of VEGF[67].

Pathology

Most of the angiomas seen in patients with POEMS syndrome are found upon histologic examination to be consistent with common cherry angiomas, with numerous dilated dermal capillaries lined by flattened endothelial cells (see above). Only a few demonstrate the distinctive features of glomeruloid hemangioma. These consist of dilated dermal vessels filled by small, well-formed capillary loops that lead to structures reminiscent of renal glomeruli (Fig. 114.15).

The capillaries comprising these glomeruloid formations are lined by flat endothelial cells surrounded by an outer layer of pericytes and are separated by a scant stroma containing large cells with lightly eosinophilic cytoplasm and multiple eosinophilic globules. The latter are PAS-positive, diastase-resistant, and by immunohistochemistry positive for polytypic immunoglobulin, presumably derived from the associated paraprotein[63]. Of note, these interstitial, immunoglobulin-containing cells are of endothelial derivation. Lastly, since many POEMS syndrome patients have both cherry angiomas and glomeruloid hemangiomas, and the cherry angiomas may display focal glomeruloid formation, it is likely that these two histologic subsets reflect variants or different stages of the same process[63].

Differential diagnosis

The clinical differential diagnosis includes other vascular proliferations and tumors (see Table 114.1), while the histologic differential diagnosis of glomeruloid hemangioma is essentially that described above for reactive angioendotheliomatosis. A more recently described entity, *papillary hemangioma*, also enters the histologic differential diagnosis[68]. The latter is characterized by intravascular papillary growths of capillaries, pericytes, and stromal cells within ectatic dermal vessels, accompanied by hyaline globules (features reminiscent of glomeruloid hemangioma), but it differs by being solitary, being confined to the head and neck region, and having neither a true glomeruloid architecture nor an association with POEMS syndrome.

Treatment

Treatment is not required, although shave excision, cryosurgery, electrodesiccation, or pulsed dye laser surgery will remove the vascular tumors.

Microvenular Hemangioma

Synonym: ■ Microcapillary hemangioma

Key features

- An uncommon, acquired, slowly growing, benign vascular tumor of young to middle-aged adults
- Presents as a small, usually solitary, sharply circumscribed red papulonodule or plaque on the trunk or extremities, with a predilection for the forearms
- Consists of small branching capillaries and venules with collapsed lumina and conspicuous pericytes infiltrating the full thickness of the reticular dermis
- May be subject to hormonal influences in some women

Introduction and history

Microvenular hemangioma was first described by that name in 1991 by Hunt, Santa Cruz, and Barr[69], although cases reported as microcapillary hemangiomas are probably identical.

Epidemiology

Reported cases have been in young and middle-aged adults of both sexes. Some cases in women have been temporally related to pregnancy or oral contraceptive use, although this has not been widely corroborated.

Pathogenesis

Microvenular hemangiomas have been noted in patients with POEMS syndrome[40], suggesting that these lesions, like glomeruloid hemangiomas, may be of reactive etiology. Observations that some microvenular hemangiomas affecting women present in association with pregnancy or oral contraceptive use arguably suggest a hormonal influence.

Clinical features

Microvenular hemangioma typically presents as a solitary, purple to red, slowly enlarging papule, plaque, or small nodule on the trunk or extremities (rarely the face). Multiple lesions have occasionally been observed. There appears to be a particular predilection for the forearms, and most lesions are <2 cm in diameter[40]. Although the majority are asymptomatic, mild erythema and tenderness have been reported.

Pathology

Histologically, lesions are poorly circumscribed proliferations of small, relatively monomorphous, branching capillaries and venules involving the full thickness of the reticular dermis. Unlike port-wine birthmarks, in which vascular ectasia is prominent, the vascular lumina of this tumor are inconspicuous and often collapsed. Cells lining the vessels show no atypia, are strongly positive for endothelial markers and WT-1, and are associated with SMA-positive pericytes. The vessels are not as delicate or angulated as the lymphatic-like vessels of Kaposi sarcoma or the vessels of microcystic lymphatic malformations, and they often contain red blood cells. The pericytic component is obvious even in routine H&E-stained sections.

Differential diagnosis

The major histologic differential diagnostic consideration for these acquired lesions is patch-stage Kaposi sarcoma. Kaposi sarcoma differs by the presence of delicate lymphatic-like vessels, plasma cells, eosinophilic globules, interstitial fascicles of spindle cells, and positivity for HHV-8.

Treatment

Surgical excision has been effective in reported cases.

Epithelioid Hemangioma

Recommended Synonym: ■ Angiolymphoid hyperplasia with eosinophilia (ALHE) subtype of epithelioid hemangioma

Historical Synonyms: ■ Angiolymphoid hyperplasia with eosinophilia ■ Pseudopyogenic granuloma ■ Inflammatory angiomatous nodule ■ Papular angioplasia ■ Inflammatory arteriovenous hemangioma ■ Intravenous atypical vascular proliferation ■ Nodular angioblastic hyperplasia with eosinophilia and lymphofolliculosis ■ Histiocytoid hemangioma

Key features

- Benign angiomatous nodules or plaques, often multiple and grouped; usually located in the head and neck region, especially around the ears
- May be painful, pruritic, or pulsatile, and often recur after excision
- Characterized histologically by proliferations of capillary-sized vessels with epithelioid endothelial cells surrounding larger, thick-walled vessels, accompanied by eosinophils and lymphocytes
- Associated with arteriovenous shunts and sometimes trauma
- Kimura disease now considered to be a separate clinicopathological entity

Introduction and history

Epithelioid hemangioma was initially described as *angiolymphoid hyperplasia with eosinophilia (ALHE)* in 1969 by Wells and Whimster and subsequently referred to as *histiocytoid hemangioma*. Although originally thought to be a late stage of Kimura disease, it is now generally accepted that these represent two separate entities.

Epidemiology

Epithelioid hemangioma occurs in young to middle-aged adults without sex or ethnic predilection. Previous reports of a female predominance are not supported by more recent series. A history of trauma can be elicited in some patients[70].

Pathogenesis

Both the WHO and the ISSVA classify epithelioid hemangiomas as benign vascular tumors[71,72]. Genetic heterogeneity correlates with morphologic subtypes and locations, supporting the concept that distinct entities exist within the "epithelioid hemangioma" group. Lesions arising within deep soft tissue and bone often demonstrate *FOS* or *FOSB* rearrangements[73,74] while these rearrangements are not observed in cutaneous lesions[74]. The latter display several features that suggest a significant reactive, as opposed to neoplastic, component; for example, there is frequently mural damage to or rupture of large intralesional vessels, suggesting that trauma and/or arteriovenous shunting may play a pathogenic role[70]. In addition, cutaneous epithelioid hemangiomas have been observed in association with pre-existing arteriovenous fistulas and malformations. It is possible that cutaneous epithelioid hemangiomas represent a heterogeneous group of histologically overlapping disorders, some neoplastic and others reactive due to arteriovenous (AV) shunting. There are rare reports of *TEK* (*TIE2*) mutations in epithelioid hemangiomas, but additional studies have not corroborated this finding[75].

Clinical features

Epithelioid hemangiomas typically present as papules or nodules that are tan, brown, pink, or dull red in color and are located predominantly in the head and neck region, especially around the ears and on the forehead and scalp (Fig. 114.16). Less commonly, lesions have been observed in the mouth and on the trunk, distal extremities, vulva, and penis. Most papulonodules are dermal or subcutaneous in location; occasionally, epithelioid hemangiomas involve deeper soft tissues or bone or arise from vessels[4]. Approximately half of the patients with dermal or subcutaneous papulonodules have multiple lesions, generally in a clustered pattern[4]. The skin lesions can be either asymptomatic or painful, pruritic or pulsatile[70]. Some patients have regional lymph node enlargement and peripheral eosinophilia.

Fig. 114.16 Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia) – clinical features. Multiple pink papulonodules are often seen on the scalp.

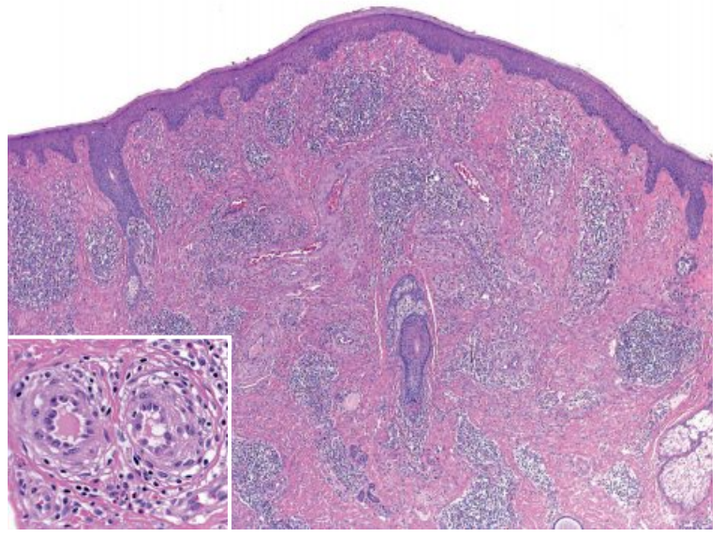

Fig. 114.17 Histology of epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia) – histopathologic features. Dermal proliferation of vessels accompanied by dense inflammatory infiltrates. Enlarged endothelial cells with cytoplasmic vacuolization protrude into the lumen of the central blood vessels, producing a scalloped or "cobblestone" appearance (inset); note also the infiltrate of lymphocytes and eosinophils surrounding the vessels. *Courtesy Lorenzo Cerroni, MD.*

Pathology

Typical lesions involving the dermis and subcutaneous tissue are of the ALHE subtype and present as well-circumscribed, vaguely lobular proliferations of capillary-sized vessels surrounding larger central blood vessels. There is a variably dense perivascular inflammatory infiltrate rich in lymphocytes and eosinophils (Fig. 114.17). Scattered ectatic lymphatic vessels are variably present. Mast cells and plasma cells are usually also present, and nodular lymphoid aggregates, with or without germinal centers, may be prominent, particularly in subcutaneous lesions. The stroma is fibrous, and the larger vessels have thick walls with prominent myxoid degeneration.

Many of the vessels, particularly the larger ones, are lined by enlarged endothelial cells with cytoplasmic vacuolization that protrude into the lumen, producing a scalloped or "cobblestone" appearance (Fig. 114.17, inset). These epithelioid endothelial cells are responsible for use of the descriptors epithelioid and, previously, histiocytoid. Inflammatory infiltration of medium- to large-sized arteries, with variable luminal occlusion, damage to elastic laminae, and even mural rupture, is common. In older lesions, fibrosis is more prominent, with a reduction in the inflammatory and vascular elements. Over 50% of cases of cutaneous epithelioid hemangioma have strong diffuse immunopositivity for FOSB although they lack molecular rearrangements[76].

Differential diagnosis

Epithelioid hemangioma may resemble cutaneous lymphoid hyperplasia, lymphoma cutis, sarcoidosis, epithelioid hemangioendothelioma, epithelioid angiosarcoma, Kimura disease, and richly vascularized metastatic tumors. Kimura disease is now considered to be a separate entity that is usually located on the posterior neck and histologically has much larger lymphoid follicles.

Treatment

Although rare instances of spontaneous regression have been reported, surgical excision is generally required. About one-third of lesions recur after excision[4], sometimes due to incomplete excision of an underlying nidus of AV shunting, e.g. an AV malformation or AV fistula. Intraoperative bleeding can be problematic. Various lasers (e.g. CO_2, pulsed dye, copper vapor) have been used with variable success. In a small case series, treatment with polidocanol sclerotherapy (for the deep vascular component) plus radiofrequency ablation was reportedly successful[77]. Other reported therapies include intralesional corticosteroids, oral propranolol, and radiation therapy.

Multifocal Lymphangioendotheliomatosis with Thrombocytopenia

Synonym: ■ Congenital cutaneovisceral angiomatosis with thrombocytopenia

Key features

- Cutaneous vascular lesions are typically present at birth, along with visceral involvement and chronic mild to moderate thrombocytopenia
- Numerous, widely distributed, red–brown to burgundy, flat or indurated papules and plaques, often with central pallor
- Gastrointestinal bleeding is common and may be life-threatening
- Distinctive histopathological features that resemble benign lymphangioendothelioma, with variable expression of lymphatic-associated markers

Introduction and history

Initially described in 2004 by North et al.[78], the term *multifocal lymphangioendotheliomatosis with thrombocytopenia* (MLT) reflected its highly characteristic histology, multifocal tissue involvement, consistent expression of the lymphatic-associated marker LYVE-1, and associated thrombocytopenia. Based upon a similar series of cases, the term *congenital cutaneovisceral angiomatosis with thrombocytopenia* (CCAT) was proposed[79]. In the current ISSVA classification, MLT is listed as a "provisionally unclassified vascular anomaly"[72].

Epidemiology

MLT is a sporadic disorder with no known racial or sex predilections. Although lesions are usually apparent at birth, they often slowly enlarge and increase in number over time.

Pathogenesis

It is not yet clear if MLT is best classified as a tumor or malformation. Lesional endothelial cells coexpress CD34 and LYVE-1 and may focally express podoplanin, making blood–vascular versus lymphatic–vascular differentiation ambiguous[80]. As with KHE/tufted angioma, this mixed endothelial phenotype may be linked to the associated selective thrombocytopenia (see below)[45,48,78].

Clinical features

Cutaneous lesions, often numbering in the hundreds at birth, are flat or indurated, red–brown to burgundy papules or plaques (Fig. 114.18A), often with pallor and occasionally scar-like areas centrally. Both a slow progression of pre-existing lesions and the appearance of new lesions is typical, without evidence of regression. Similar lesions in the gastrointestinal tract lead to severe gastrointestinal bleeding and anemia, beginning during infancy. Some patients have extensive pulmonary involvement complicated by hemoptysis; less often, other sites are affected, e.g. muscle, synovium, liver, spleen, kidney, bone[48,79,81]. The thrombocytopenia is chronic but fluctuates and is mild-to-moderate, especially in infants. Serum fibrinogen levels and PT/PTT are essentially normal.

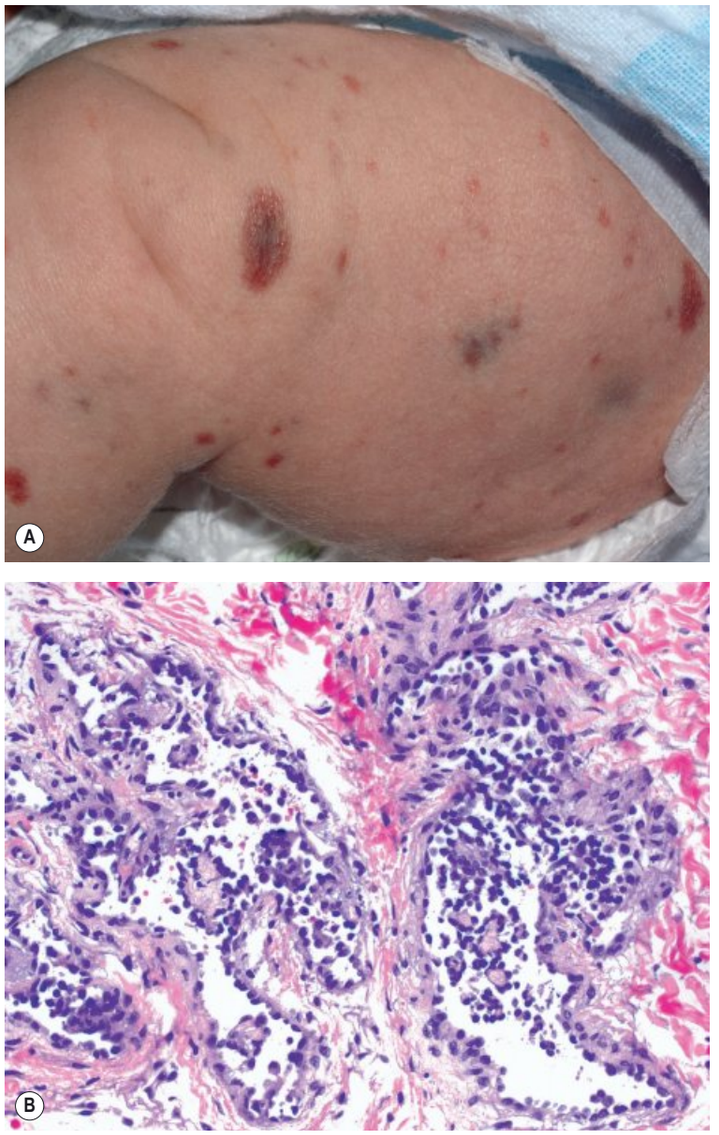

Fig. 114.18 Multifocal lymphangioendotheliomatosis with thrombocytopenia. A Multiple red–brown to red–purple papules and plaques in a widespread distribution. **B** Thin-walled vessels focally form intraluminal papillary projections. When the projections are complex, the endothelium that lines them can appear to float within the vascular lumen. *A, Courtesy Julie V. Schaffer, MD.*

Pathology

Thin-walled vessels are scattered throughout the dermis and subcutis and are lined by a monolayer of slightly hobnailed endothelial cells that focally form papillary projections (Fig. 114.18B). Some of the papillary formations are complex and appear to float within the lumina. However, lumina, especially the smaller ones, are largely devoid of red blood cells. Endothelial cells show strong immunopositivity for CD31, CD34, and LYVE-1, light to absent positivity for podoplanin, and negativity for GLUT1[78]. Mitotic figures are rare or absent, although Ki-67 expression may be increased.

Differential diagnosis

This entity must be differentiated from a "blueberry muffin baby" (see Table 121.4) as well as other disorders with multifocal vascular lesions that present during infancy or childhood, including multifocal infantile hemangiomas, blue rubber bleb nevus syndrome, glomuvenous malformations, and Maffucci syndrome. However, the skin lesions of MLT

are unique in their clinical and histologic appearance and are far more numerous than would be typical for any of these vascular disorders except for multifocal infantile hemangiomas.

Treatment

Gastrointestinal bleeding may spontaneously stabilize or require segmental resection to control. Corticosteroids, sirolimus, everolimus, vincristine, thalidomide, and bevacizumab have been reported to be of possible value in some, but not all, cases[78,79,82–84].

Sinusoidal Hemangioma

Synonyms: ■ Variant sinusoidal hemangioma ■ Sinusoidal venous malformation

Key features

- Relatively rare, small, well-demarcated acquired lesion most commonly seen in the subcutis of middle-aged women and traditionally described as a variant of "cavernous hemangioma" (venous malformation)
- Probably malformative with a delayed presentation, rather than neoplastic or reactive in etiology
- Histologically distinguished by dilated, interconnecting venous channels exhibiting a prominent sieve-like or sinusoidal pattern
- Similar sinusoidal patterns are seen focally in many venous malformations
- May be confused with well-differentiated angiosarcoma, but distinguished from the latter by lack of significant cytologic atypia, infiltrative growth, and endothelial multilayering

Introduction and history

In 1991, sinusoidal hemangioma was described as a distinctive subset of so-called "cavernous hemangioma" (historic term as now recognized to be a venous malformation). In contrast to typical venous malformations of childhood, sinusoidal hemangiomas presented during adulthood and had an unusually prominent sinusoidal or sieve-like histologic pattern. Some authors believe that sinusoidal hemangioma may represent PEH within a pre-existing vascular malformation.

Epidemiology

These adult-onset lesions have most commonly been observed in middle-aged women and are relatively rare. The not uncommon occurrence in breast subcutaneous tissue has emphasized the need to differentiate these lesions from angiosarcoma.

Pathogenesis

Because of the typical presentation during adulthood, a neoplastic or reactive etiology has been suggested. However, the strong histologic parallels with venous malformations of childhood suggest that these mitotically quiescent vascular lesions are probably congenital developmental disorders that become evident later in life due to remodeling, thrombosis, recanalization, and progressive vascular dilation. Focal sinusoidal patterns have also been described in congenital venous malformations.

Clinical features

Sinusoidal hemangiomas, as traditionally defined, are relatively well-demarcated, solitary, deep dermal or subcutaneous papulonodules that are freely mobile. The color varies from red (superficial lesions) to bluish or skin-colored (subcutaneous lesions). They most commonly develop in adult women and favor the arms and torso (including the breast). Longitudinal studies have revealed no evidence of metastasis or of local recurrence following resection.

Pathology

Generally well-defined lobules of dilated, thin-walled veins with scant mural smooth muscle form characteristic interconnected, "emphysematous", sieve-like spaces. Lining endothelial cells are flattened, single-layered, and mitotically inactive. Organizing thrombi are common, with occasional superimposed changes of PEH. There is no significant cytologic atypia. Central infarction and necrosis have been reported.

Differential diagnosis

Given the typical presentation during adulthood and anastomosing vascular pattern, the most clinically significant simulant is well-differentiated angiosarcoma. The latter is distinguished by a more infiltrative pattern, endothelial multilayering, mitotic activity, and cytologic atypia.

Treatment

Complete surgical resection, which is facilitated by its typical obvious demarcation, is curative.

Spindle Cell Hemangioma

Synonym: ■ Spindle cell hemangioendothelioma (not recommended)

Key features

- Blue–red nodules typically develop within the dermal and subcutaneous tissue of the distal extremities of young adults and children and tend to multiply locally
- Occurs in Klippel–Trenaunay syndrome and especially Maffucci syndrome; in the latter setting, the spindle cell hemangiomas often have somatic *IDH1/2* mutations
- Composed of thin-walled cavernous veins containing organizing thrombi, interspersed with fascicles of spindle cells and occasional aggregates of vacuolated epithelioid cells
- Originally interpreted as a low-grade angiosarcoma (*spindle cell hemangioendothelioma*), but now viewed as a benign lesion without metastatic potential (*spindle cell hemangioma*)
- Currently regarded by many as a vascular malformation complicated by thrombosis and irregular vascular collapse

Introduction and history

This entity was first described by Weiss and Enzinger in 1986 as *spindle cell hemangioendothelioma* given its spindle cell morphology and the fact that one case from their series of 26 had metastasized to a regional lymph node. Results of larger studies with extended follow-up have led to the current view that this tumor has no inherent malignant potential[4,85]. In 1996, Perkins and Weiss suggested that it be renamed *spindle cell hemangioma*[85].

Epidemiology

Spindle cell hemangiomas usually occur in children and young adults, although in a series of 78 patients[85], the ages ranged from 8 to 78 years, with a median age of 32 years. However, those presenting during late adulthood appear to represent previously occult, longstanding lesions. There is no sex predilection. These hemangiomas occur in association with varicose veins and various vascular malformations, including in patients with Klippel–Trenaunay syndrome (capillary–venous or capillary–venous–lymphatic malformation)[86] and Maffucci syndrome (venous malformation)[87].

Pathogenesis

In the 2014 ISSVA classification scheme, spindle cell hemangioma is categorized as a benign vascular tumor[72]. Nonetheless, it has long been thought to represent a vascular malformation altered by thrombosis and irregular vascular collapse[4,85]. Its association with vascular malformation syndromes (see above) further supports this hypothesis. Typical development of multiple nodules over time within a given anatomic region suggests intravascular propagation[85].

In patients with Maffucci syndrome, somatic alterations in 2p22.3, 2q24.3, and 14q11.2 have been described[87], and in tumoral tissue, including spindle cell hemangiomas and endochondromas, heterozygous

somatic mutations in *IDH1* (rarely *IDH2*) were detected in 10 of 13 patients[88]. The latter encode NADP(+)-dependent isocitrate dehydrogenases and mutations can lead to epigenetic modifications (see Ch. 54)[87,89]. *IDH1/2* mutations have also been reported in sporadic spindle cell hemangiomas (in the absence of Maffucci syndrome), suggesting that these mutations are specifically linked to the vascular lesion rather than Maffucci syndrome[90].

Clinical features

Most spindle cell hemangiomas begin as a solitary, firm, red–blue nodule in the subcutaneous tissue and dermis of the distal upper or lower extremity, then slowly develop multifocally within a localized area (Fig. 114.19). Rarely there is involvement of skeletal muscle and occasionally tumors develop on the trunk, head and neck, or proximal limbs. They may be asymptomatic or painful, and ~60% recur following resection[85].

Pathology

Hemorrhagic, often multiple, nodules are seen within the dermis and subcutaneous tissue and are composed of two basic histologic elements (in variable combinations): (1) thin-walled, cavernous spaces containing organizing thrombi; and (2) more cellular areas containing spindle cells and occasional aggregates of vacuolated epithelioid cells (Fig. 114.20). The spindled areas stain focally for actin, form slit-like vascular spaces, and appear to consist of fibroblastic cells, pericytes, and collapsed vessels[4]. The epithelioid interstitial cells, as well as the flattened cells lining the cavernous spaces, stain positively for endothelial markers[86]. Cavernous vessels may show foci of intravascular PEH and phleboliths consistent with the presence of organizing thrombus material. Frequently, remnants of residual vascular walls rim the lesion, suggesting intravascular development.

Fig. 114.19 Spindle cell hemangioma – clinical features. Clustered blue–red multifocal nodules are typical.

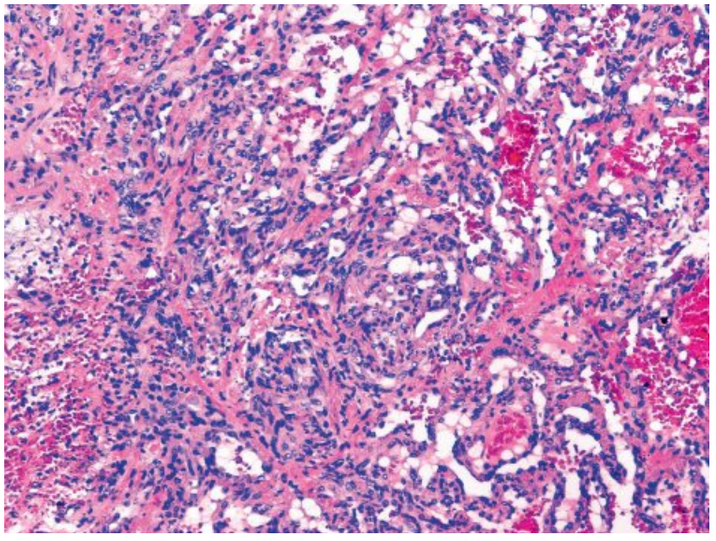

Fig. 114.20 Spindle cell hemangioma – histopathologic features. Partly dilated, partly collapsed vessels lined by spindled and epithelioid cells.

Differential diagnosis

These tumors may resemble nodular lesions of Kaposi sarcoma, but the latter lack cavernous vascular spaces and vacuolated epithelioid endothelial cells and are positive for HHV-8. The frequent presence of foci of secondary intravascular PEH within a spindle cell hemangioma may lead to misdiagnosis. A primary lesion of intravascular PEH is solitary and lacks epithelioid endothelial cells (see above).

Treatment

Based upon the large series of Perkins and Weiss[85], simple surgical excision is successful in some patients (~40%). The frequent local recurrences may reflect the inherent multifocality, with growth within vessels leading to discontinuous locoregional sites[85]. There is one report of the successful use of intralesional and intra-arterial IL-2, with no signs of recurrence at 24 months[91].

BORDERLINE AND LOW-GRADE MALIGNANT VASCULAR NEOPLASMS

Kaposiform Hemangioendothelioma

Synonyms: ■ Infantile kaposiform hemangioendothelioma ■ Kaposi-like infantile hemangioendothelioma

Key features

- Rare infiltrative tumor of infancy and childhood that crosses tissue planes and can involve the skin, subcutis, and deeper soft tissues
- Depending upon level of involvement, presents as an ill-defined, often indurated, violaceous stain, plaque, or bulging mass; may wax and wane but does not spontaneously involute
- Locally aggressive and occasionally multifocal along lymphatic pathways, but thought not to truly metastasize
- Overlapping histologic features (e.g. expression of mixed blood vascular and lymphatic endothelial markers) and likely synonymous in pathogenesis with tufted angioma, with the latter designation traditionally ascribed to more superficial lesions
- Complete surgical excision is recommended where feasible
- In some patients is associated with Kasabach–Merritt phenomenon (syndrome), requiring treatment with sirolimus or vincristine plus prednisone

Introduction and history

Kaposiform hemangioendothelioma (KHE) was described as such by Zukerberg et al.[49] in 1993, although equivalent lesions had been previously reported as "hemangioma with Kaposi's sarcoma-like features"[92] and "Kaposi-like infantile hemangioendothelioma". Many lesions of this type were previously misdiagnosed as infantile hemangioma.

Epidemiology

Most tumors present in children <2 years of age, and some are congenital. In one literature review of patients with skin involvement[93], the average age at presentation was 43 months. Tumors that are bulky and congenital are most likely to be associated with Kasabach–Merritt phenomenon (KMP), with KMP said to only develop in those patients with congenital/early infantile lesions. Patients with more deeply seated tumors, particularly in the retroperitoneum, are also at increased risk for KMP[93]. Occasionally KHE has been described in adults, all to date without evidence of KMP[94]. There is no sex predilection.

Pathogenesis

KMP was originally defined as life-threatening thrombocytopenic purpura occurring in the setting of an enlarging "hemangioma".

Decades later, with improved categorization of vascular tumors and malformations, it became clear that KMP develops in association with tufted angioma and KHE[45,49] – not the common infantile hemangioma. Rarely, KMP occurs in patients with a congenital fibrosarcoma or congenital hemangiopericytoma.

In KMP, there is profound sustained thrombocytopenia, sometimes accompanied by microangiopathic hemolytic anemia and secondary consumption of fibrinogen and coagulation factors (see Ch. 22). It differs from the localized chronic consumptive coagulopathy that may complicate large venous or venous–lymphatic malformations in which platelet counts are normal or only slightly decreased, but D-dimers are elevated and in more severe cases, fibrinogen levels are low.

As noted previously, KHE and tufted angioma, given their striking overlap histologically and mutual association with KMP, are widely thought to be, at a minimum, closely related and are likely biologically synonymous[45,49,50,92,95,96]. Molecular studies provide a degree of support for this concept, although further investigation is clearly warranted. For example, when 5 KHEs and 2 tufted angiomas were compared to a variety of vascular malformations (n=14) via next generation sequencing and genome-wide methylation analysis, a similar methylation cluster pattern was present in KHEs and tufted angiomas, indicating that they are epigenetically related and distinct from the vascular malformation cluster; an *NRAS* mutation was also found in one tufted angioma and a *RAD50* mutation in one KHE[51]. Of note, no *GNA14* mutations, which are present in benign vascular lesions such as cherry hemangiomas, were detected[51]. This is in contrast to a second study in which *GNA14* mutations were observed in 3 cases of KHE/tufted angioma[97]. Thus, to date there is no consistent mutational pattern in these tumors as *PIK3CA* mutations have also been described in single case reports.

Platelet trapping within the vascular beds of these lesions is thought to play a role in the selective thrombocytopenia of KMP. The strong endothelial expression of Prox1, LYVE-1, and focally podoplanin (all lymphatic-associated antigens) as well as for the blood vascular marker CD34 supports the concept that these tumors have a mixed, partially lymphatic endothelial phenotype. This mixed endothelial phenotype may explain the propensity for platelet trapping as podoplanin is the natural ligand of CLEC-2, a platelet-bound receptor[98].

The paradoxical worsening of KMP observed in some patients following platelet transfusions suggests that platelet activation within the tumor may stimulate vascular proliferation[45], presumably by release of platelet-associated angiogenic agonists. In theory, a self-sustaining cycle of platelet trapping and tumor growth may exist.

Clinical features

KHE usually involves the skin, subcutis, and deeper soft tissues (Fig. 114.21). Cutaneous and subcutaneous forms present as locally infiltrative vascular stains or plaques that can develop nodules. Deeper soft tissue lesions can appear as bulging, indurated masses or may be undetectable on physical examination. KHE occasionally presents as a bulky body cavity or retroperitoneal mass and rarely with bony or splenic involvement. Patients with KMP often have purpura and ecchymoses.

Due to rare reports of spread along (or perhaps multifocal involvement of) local lymphatic chains, KHE is categorized as an "intermediate (locally aggressive)" soft tissue tumor by the WHO[71]. To date, no true distant metastases have been reported, although to date one patient did have spread to regional lymph nodes[99].

The two most common causes of death from KHE are complications of thrombocytopenia and direct tumor infiltration[93]. Clinical evaluation of suspected cases, for instance new-onset vascular tumors in children >3 months of age[93], should include magnetic resonance imaging (MRI), a complete blood cell count, coagulation studies to detect coexistent KMP, and, if not prohibited by severe thrombocytopenia, biopsy for histopathologic diagnosis. By MRI, KHE is usually diffusely enhancing and T2 hyperintense, with ill-defined margins that cross tissue planes.

Following treatment of KMP, residual KHE has been subclassified into: type I – resembles a port-wine birthmark and may overlie fibrotic infiltration; type II – minor soft tissue swelling and telangiectasias; and type III – sclerotic or infiltrative, depending upon depth.

Pathology

KHE is characterized by ill-defined, frequently coalescing nodules composed of fascicles of moderately plump spindled endothelial cells with eosinophilic to clear cytoplasm and bland nuclei that form elongated, slit-like lumina containing erythrocytes, reminiscent of Kaposi sarcoma (Fig. 114.22A). The spindle cells often encompass nests of more epithelioid endothelial cells and pericytes that are surrounding platelet-rich microthrombi (which can be highlighted by CD61 immunostaining). At the margin of the lesion, the spindle cells may infiltrate into the surrounding adipose tissue and between collagen bundles, or they may be encased by desmoplastic stroma. The spindle cells are strongly immunoreactive for the pan-endothelial marker CD31, the blood vascular marker CD34, and the lymphatic endothelial markers podoplanin (Fig. 114.22B), LYVE-1, VEGFR-3, and Prox1[50].

Mitotic activity is variable, but generally low. Focally, lobules of small, rounded capillaries lined by flat endothelia merge with the spindled areas. Extravasated erythrocytes and hemosiderin granules are typically present, and tumor cells may contain intracytoplasmic erythrocyte fragments and hyaline globules. Often there is a prominent component of dilated vessels with a lymphatic morphology that intermingles with the tumor lobules, but these vessels are often most obvious within the marginal soft tissues. Residual KHE, i.e. remaining after successful medical treatment, represents a dormant, often sclerotic, version of the original disease process.

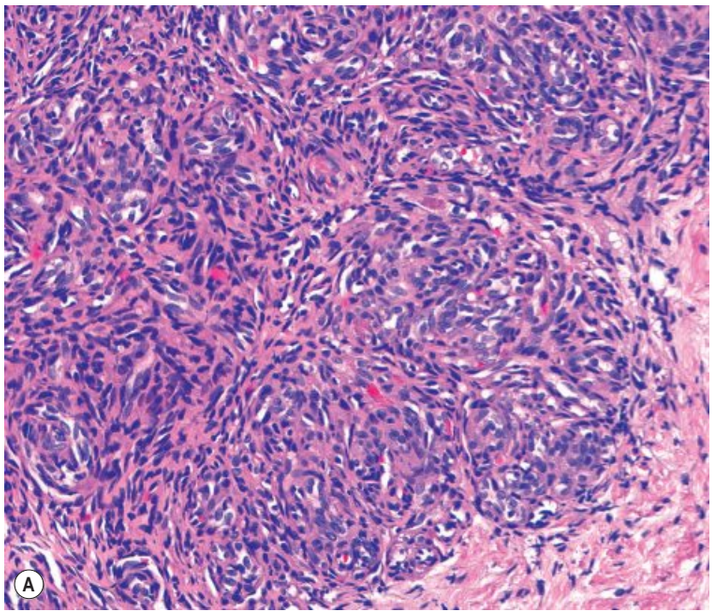

Fig. 114.21 Kaposiform hemangioendothelioma complicated by Kasabach–Merritt phenomenon in a 5-week-old boy. Progressive induration and ecchymosis developed rapidly over a 24-hour period. An eczematous eruption is also evident. *Courtesy Julie V. Schaffer, MD.*

Differential diagnosis

In addition to tufted angioma, the differential diagnosis includes infantile hemangioma, congenital hemangiomas (e.g. rapidly involuting [RICH], non-involuting [NICH]), and Kaposi sarcoma. Infantile hemangiomas, unlike KHE, express an unusual and complex endothelial phenotype shared only by placental capillaries, most commonly manifested by immunohistochemical staining for GLUT1[26,27]. Infantile hemangiomas also lack both fascicles of spindle cells and foci with a mixed lymphatic–blood vascular phenotype. Tufted angioma is thought to be a milder, more superficial form of KHE that is distinguished by a relative scarcity of endothelial spindling and an absence of pericyte-rich epithelioid nodules. Kaposi sarcoma, which is rare in children (outside of Africa), lacks the lobularity of KHE, characteristically contains plasma cell infiltrates, and is positive for HHV-8.

Treatment

Tufted angiomas and KHEs that are localized and superficial can be cured by wide local excision. However, tumors in deeper soft tissues, the mediastinum, or retroperitoneum are often large and unresectable. As with tufted angioma, first-line therapy for associated KMP consists of sirolimus[60,61] or vincristine[62] plus prednisone. Treatment of small lesions without KMP is controversial.

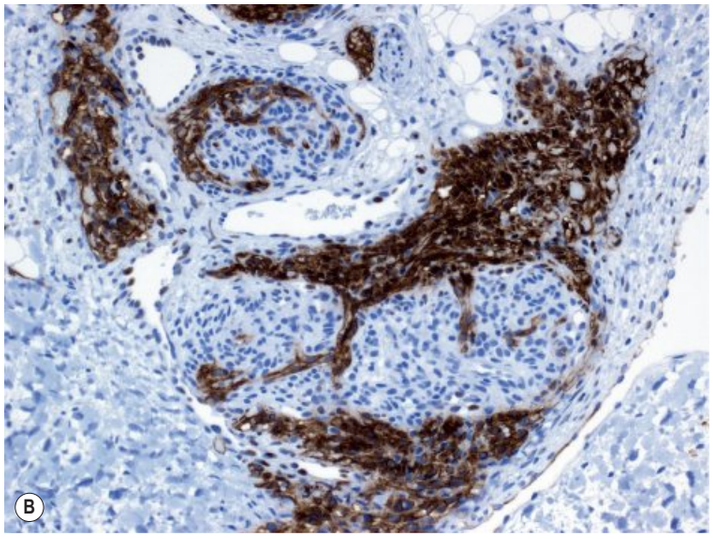

Fig. 114.22 Histology of kaposiform hemangioendothelioma. A Fascicles of spindled endothelial cells forming slit-like lumina surround nests of more epithelioid areas rich in pericytes. **B** The endothelial cells show evidence of lymphatic differentiation, here evidenced by positivity for podoplanin.

Papillary Intralymphatic Angioendothelioma (PILA)

Synonyms: ■ Dabska-type hemangioendothelioma ■ Dabska tumor ■ Endovascular papillary angioendothelioma ■ Malignant endovascular papillary angioendothelioma ■ Hobnail hemangioendothelioma

Key features

- Rare neoplasm with at least partial lymphatic differentiation and very low metastatic potential that occurs primarily in children
- Enlarging dermal or subcutaneous mass or plaque, often on distal extremities
- Histologically defined by prominent papillary intralymphatic growth and peculiar rosette-like clusters of hobnail, columnar endothelial cells

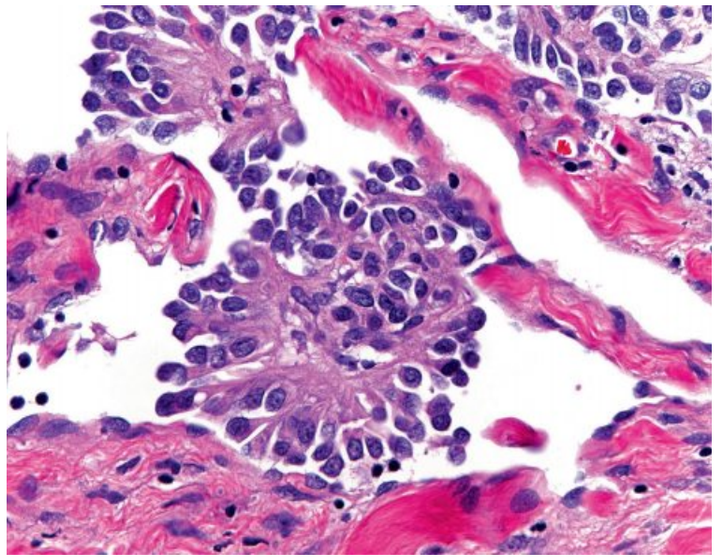

Fig. 114.23 Histology of papillary intralymphatic lymphangioendothelioma (PILA). Rosette-like intravascular clusters of hobnailed, columnar endothelial cells.

Introduction and history

Maria Dabska first described tumors of this type as *malignant endovascular papillary angioendothelioma* in 1969 based on a series of six cases, all in children. Two patients in this original series had lymph node metastases, and one of them later developed distant metastases and died. Subsequently reported cases have behaved in a benign fashion, although follow-up for some has been limited[100]. Based on the prominent presence of lymphatic vessels, the tentative potential for malignant or borderline clinical behavior, and the defining presence of papillary intravascular proliferation, the currently favored designation for this tumor is *papillary intralymphatic angioendothelioma* (PILA)[100]; this term has also been adopted by the WHO[71]. Because of their shared hobnail endothelial morphology and similar biologic behavior, Weiss and Goldblum[4] have suggested that the term *hobnail hemangioendothelioma* be used to embrace both PILA and retiform hemangioendothelioma. However, the lack of convincing evidence of lymphatic differentiation in the latter has seriously undermined any potential relatedness of these two entities[101].

Epidemiology

Compilations of reported cases have shown no clear sex predilection, with ~75% of patients being children and the remainder primarily young adults. Tumors may be present at birth. A more recent series of 12 patients in which the mean age was 30 years suggests a wider age range[100].

Clinical features

These tumors most commonly originate within the soft tissues of an extremity and rarely other sites such as bone or spleen. Lesions can present as either enlarging, diffuse, firm swellings of skin and subcutaneous tissue or as soft intradermal plaques; sometimes there is also a pink or blue discoloration of the skin. The size range is wide (up to 40 cm)[100]. A number of cases appear to have arisen within pre-existing lymphatic malformations.

The WHO currently classifies PILA as an intermediate (rarely metastasizing) vascular tumor[71], and in the 2014 ISSVA classification scheme[72] it is considered a locally aggressive or borderline tumor.

Pathology

The unifying microscopic feature is presence within the dermis and/or subcutis of intercommunicating, thin-walled vessels lined by hobnail endothelial cells, with the latter forming characteristic intraluminal papillary projections that focally assume a rosetting or matchstick-like pattern (Fig. 114.23). Lesional vessels are variable in size. Hyaline papillary stromal cores stain positively for collagen type IV, and, in some cases, focal actin-positive pericytes may be present within the papillary projections[100]. Lymphocytes may cluster along the endothelial lining of

the vessels and infiltrate into the surrounding stroma; large lymphoid aggregates are common. There is strong endothelial immunopositivity for VEGFR-3 and podoplanin in the hobnail endothelial proliferations of these tumors[102], indicative of lymphatic differentiation. CD34 expression is low.

Differential diagnosis

PILA must be differentiated histologically from other entities with hobnail endothelial architecture, including targetoid hemosiderotic lymphatic malformation, hemangioma with dabskoid features, retiform hemangioendothelioma, and well-differentiated angiosarcoma. Targetoid hemosiderotic lymphatic malformation is a smaller, more superficial dermal process, without exuberant papillary tufts. Retiform hemangioendothelioma usually occurs in adults and intravascular papillary tufts are infrequent and poorly developed. Of note, regional lymph node disease has been documented in both PILA and retiform hemangioendothelioma. Angiosarcoma, even when well differentiated, may display intravascular papillary growths that suggest PILA, but classic hobnail endothelial cells are absent. In children, angiosarcomas are extremely uncommon and are usually visceral (especially cardiac or pericardial).

Treatment

Optimal therapy is relatively conservative surgical excision with clear margins, supplemented by close follow-up. Local recurrences following excision are common (~40%).

Retiform Hemangioendothelioma (RHE) and Composite Hemangioendothelioma (CHE)

Synonym: ■ Hobnail hemangioendothelioma for RHE (no longer recommended)

Key features

- Rare neoplasms with very low metastatic potential and a wide age range that favor young adults
- Present as a slowly growing exophytic tumor or multinodular plaque that is often on the distal extremity
- A morphologic spectrum characterized in RHE by a diffuse infiltration of the dermis and/or subcutis by elongated vessels with hobnail endothelial cells arborizing in a pattern resembling normal rete testis that in CHE is admixed with other vascular patterns
- Rearrangements of *YAP1* are common, in particular *YAP1–MAML2* fusions
- Local recurrence following excision occurs in ~60% of cases but regional lymph node spread is rare; a neuroendocrine variant of CHE is more aggressive

Introduction and history

RHE was first described as an entity in 1994 by Calonje et al.[16] based on a series of 15 cases and was interpreted as a low-grade angiosarcoma. RHE is currently classified by the WHO and ISSVA as a vascular tumor of intermediate (rarely metastasizing) type[71] and a locally aggressive or borderline vascular tumor[72], respectively. Very rarely, there is a complex admixture of the features of RHE with a variety of other distinct vascular patterns, especially epithelioid changes reminiscent of epithelioid hemangioendothelioma, resulting in CHE[103,104].

Epidemiology

RHE and CHE occur most commonly in young adults, although the age range is wide. There is no clear sex predilection.

Pathogenesis

As noted in the previous section, use of the term *hobnail hemangioendothelioma* (not to be confused with hobnail "hemangioma") to encompass both PILA and RHE has been proposed[4]. However, increasingly convincing evidence that RHE endothelial cells, unlike those of PILA, usually do not express lymphatic markers has weakened this proposal. In an RHE from an apparently immunocompetent patient, HHV-8 sequences were detected[105].

More recently, 5/13 (38%) of RHEs and 3/11 (27%) of CHEs arising within soft tissue were found to have rearrangements of *YAP1*, with five (including all three CHEs) having a *YAP1–MAML2* fusion. Such findings support the inclusion of RHE and CHE within a morphologic spectrum[106]. Additional reported gene fusions in neuroendocrine CHEs are *PTBP1–MAML2* and *EPC1–PCH2*[106,107].

Clinical features

The clinical appearance of both RHE and CHE is not specific and the vascular nature may not be suspected clinically. RHE typically presents as a solitary, slow-growing, reddish blue plaque, exophytic mass or dermal/subcutaneous nodule, most commonly on the extremities. Most CHEs also appear on the distal extremities, typically appearing as a nodular mass or ill-defined swelling. Rarely, these tumors occur in viscera.

In the original series of RHEs, nearly 60% recurred locally, and 1 of 14 patients followed longitudinally developed lymph node involvement[16]. To date, there have been no RHE-related deaths. Following surgical excisions, there may be multiple recurrences of CHEs, with the potential for lymph node metastasis. Those CHEs that contain angiosarcoma-like areas are much less aggressive than conventional angiosarcomas[104] while a "neuroendocrine" variant of CHE that coexpresses synaptophysin and endothelial markers is more clinically aggressive with distant metastases in 50% of cases[107].

Pathology

RHE is one of a small group of vascular anomalies characterized by endothelial cells with a so-called hobnail appearance; this group also includes targetoid hemosiderotic lymphatic malformation and PILA. Overall, there is a diffuse infiltration of the reticular dermis and/or subcutis by an arborizing network of elongated, thin-walled vessels forming a pattern reminiscent of normal rete testis. The margins are ill-defined. Higher magnification of the lesional vessels reveals a lining of bland endothelial cells with prominent apical nuclei that protrude into the lumina in a hobnail or "matchstick" fashion. Mitotic figures are rare, and cytologic atypia is minimal, or rarely, mild. Solid foci of spindle cells expressing endothelial markers are often present, as are occasional intravascular papillae. Unless the tumor arises within the background of a vascular malformation, cavernous lymphatic-like vessels are absent as are the prominent intravascular proliferations characteristic of PILA. The endothelial cells of RHE consistently express pan-endothelial markers such as CD31 and ERG, but usually do not express lymphatic markers such as podoplanin, VEGFR3, and Prox1[101].

CHEs are infiltrative tumors that by definition must be composed of at least two morphologically distinct vascular tumor patterns, most commonly resembling RHE and epithelioid hemangioendothelioma, but occasionally resembling spindle cell hemangioma, angiosarcoma, or vascular/lymphatic malformations[103]. CHEs consistently express CD31 and ERG and variably express podoplanin[103]. The more aggressive "neuroendocrine" variant contains, in addition to RHE-like areas, a strikingly nested pattern of epithelioid-to-slightly spindled endothelial cells plus solid sheets of epithelioid endothelial cells unaccompanied by the myxochondroid to hyalinized matrix characteristic of epithelioid hemangioendothelioma and epithelioid hemangioma[107].

Differential diagnosis

Important entities to exclude are epithelioid hemangioendothelioma and low-grade angiosarcoma. The former is distinguished by epithelioid endothelial cells with glassy cytoplasm embedded in a myxochondroid matrix. Well-differentiated angiosarcomas are distinguished by subtle cytologic atypia, multilayered endothelial cells, mildly increased mitotic activity, and lack of hobnail endothelial cells.

Treatment

Wide excisional biopsy with follow-up is appropriate. However, local recurrence is common.

Pseudomyogenic Hemangioendothelioma

Key features

- Rare neoplasm with intermediate biologic potential and male predominance that favors young adults and the lower extremities
- Solitary, or more commonly multiple, nodules that cross tissue planes – usually the skin, often skeletal muscle, and less often bone
- Infiltrative sheets and fascicles of loosely arranged spindled to polygonal cells with abundant eosinophilic cytoplasm resembling a myoid tumor or epithelioid sarcoma
- Immunohistochemical staining: ERG$^+$; AE1/AE3$^+$; CD31$^+$ (less consistently); FOSB$^+$ (diffuse nuclear); CD34$^-$; podoplanin$^-$, LYVE-1$^-$, Prox1$^-$; desmin$^-$; S100$^-$; EMA$^-$
- Associated with *SERPINEE1–FOSB* fusions or, more commonly in solitary lesions, with *ACTB–FOSB* fusions; both lead to upregulation of FOSB expression

Introduction and epidemiology

Pseudomyogenic hemangioendothelioma (PMHE) was first included as an entity in the 2013 WHO Classification of Soft Tissue and Bone and was classified as a tumor of intermediate biologic potential. The age range is wide, but most commonly diagnosed in the second to fifth decades. There is a male predominance.

Pathogenesis

Two gene fusions – *SERPINEE1–FOSB* and *ACTB–FOSB* – have been identified in PMHEs. Both result in upregulation of FOSB expression[108,109]. The FOS family of proteins (e.g. FOS, FOSB) dimerize with JUN proteins to form the AP-1 transcriptional factor complex that has been implicated in the genesis of multiple tumor types.

Clinical features

Most patients present with subcutaneous nodules, often multiple, that involve the skin and skeletal muscle. The lesions tend to cross tissue planes and favor the distal lower extremities. They may resemble dermatofibromas, nodular fasciitis, or a vascular neoplasm[110]. While solitary lesions are more likely to have *ACTB–FOSB* fusions rather than *SERPINE1–FOSB* fusions, genetic variants appear similar clinically[108,111]. Local recurrence following resection occurs in ~60% of patients but lymph node and distant metastases are uncommon[111].

Pathology

The architecture of dermal PMHE ranges from loosely fascicular to focally plexiform or storiform, with infiltrative borders. There are sheets, nests, and short intersecting fascicles of plump spindled cells with ample eosinophilic cytoplasm and vesicular nuclei with prominent nucleoli within the mid and deep reticular dermis, often with extension along connective tissue septa into the subcutis[110]. Focally, clusters of more epithelioid, rounded cells with slightly atypical vesicular nuclei and rhabdomyoblast-like appearance may be present. The epidermis can be normal or hyperplastic. There is consistent coexpression of endothelial markers and cytokeratins, including expression by most tumor cells of CD31, ERG, FLI-1, and cytokeratin AE1/AE3[110]. In nearly all cases, there is diffuse nuclear FOSB expression.

Differential diagnosis

The histologic differential diagnosis of PMHE includes epithelioid sarcoma, epithelioid hemangioendothelioma, and epithelioid angiosarcoma[110]. Unlike PMHE, epithelioid sarcoma shows moderate cytologic atypia and is EMA$^+$, CD34$^+$, INI-1$^-$, and CD31$^-$. Epithelioid hemangioendothelioma has epithelioid cells with prominent cytoplasmic vacuolization, myxohyaline stroma, CD34 positivity, and characteristic *WWTR1–CAMTA1* fusions. Epithelioid angiosarcoma has marked cytologic atypia, frequent mitotic figures, and positivity for CD34. Diffuse nuclear FOSB immunostaining points to the diagnosis of PMHE[111].

Treatment

Treatment options include simple surgical excision, amputation (multifocal disease), chemotherapy[112], and radiotherapy. Partial responses to everolimus[113] and sirolimus[114] have been reported.

Kaposi Sarcoma

Key features

- It is controversial whether Kaposi sarcoma (KS) represents neoplasia or hyperplasia; all clinical variants are viewed as a virally induced disease, with HHV-8 the causative agent
- A multifocal systemic disease with four principal clinical variants: (1) chronic or classic KS; (2) African endemic KS, including a fulminant lymphadenopathic type; (3) KS due to iatrogenic immunosuppression; and (4) AIDS-related epidemic KS
- Cutaneous lesions can vary from pink patches to dark violet plaques, nodules, or polyps, depending on clinical variant and stage
- The histologic features of KS do not vary significantly between clinical subtypes, but do vary with stage of the lesion
- Most cases in children, with or without HIV infection, are of the lymphadenopathic type and are rapidly fatal due to visceral dissemination
- Because of multifocality, treatment with chemotherapy and/or radiation is favored over surgery

Introduction and history

In 1872 Moritz Kaposi described five men with an unusual multifocal sarcoma of the skin which he termed "idiopathic multiple pigmented sarcoma of the skin". This disease entity became known as *Kaposi sarcoma* and historically has been considered a chronic, protracted disease primarily affecting elderly men, generally Jewish (Ashkenazi) or of Mediterranean/Eastern European descent. Despite occasional reports regarding its occurrence in organ transplant recipients and its endemic form in Africa, KS received little attention until it became epidemic among men who have sex with men and was recognized as a sign of acquired immunodeficiency syndrome (AIDS). A new human herpesvirus (HHV-8), also referred to as KS-associated herpesvirus, was recognized as the probable inductive agent of all clinical variants of KS. The mechanisms that control the clinical variability of KS are likely to involve a number of interrelated factors modulated by the patient's immune status and have yet to be fully defined.

Epidemiology

The epidemiologic aspects of the four major types of Kaposi sarcoma are outlined in Table 114.3.

Pathogenesis

Immunohistochemical and ultrastructural studies have firmly established the endothelial nature of KS, but it remains controversial whether this endothelial phenotype is vascular, lymphatic, or perhaps a composite of both. Moreover, many, if not most cells forming the substance of a plaque or nodule of KS are spindled cells distinctly unlike normal endothelial cells in morphology, although expressing pan-endothelial markers like CD31. These spindled cells also coexpress markers of blood vascular differentiation (CD34) and lymphatic differentiation (VEGFR-3[102,115], podoplanin[116], LYVE-1[117]). A seminal discovery was that, *in vitro*, Kaposi sarcoma herpesvirus (taxonomical name HHV-8) can infect both lymphatic and blood vascular endothelial cells and induce transcriptional reprogramming, leading to expression of lymphangiogenic molecules in infected blood vascular endothelial cells[118] and a more blood vascular profile in infected lymphatic endothelial cells[119]. This potentially explains the mixed lymphatic/blood vascular phenotype of KS, but also emphasizes the difficulty in precisely assigning endothelial cell derivation based solely on marker studies[120].

HHV-8 can also induce aberrant expression of mesenchymal markers in endothelial cells (endothelial-to-mesenchymal transition) via Notch-dependent signaling[121]. This may provide an explanation for why poorly differentiated KS endothelial cells express mesenchymal and macrophage as well as endothelial markers[122]. Of note, there is also evidence that HHV-8 may cause a mesenchymal-to-endothelial transition, transforming mesenchymal stem cells into KS endothelial cells[123]. The relative contributions of these transitions in cellular differentiation to the pathogenesis of KS remain unclear.

EPIDEMIOLOGIC ASPECTS OF THE FOUR MAJOR TYPES OF KAPOSI SARCOMA
Classic
• Predominantly in individuals of Jewish (Ashkenazi) descent and/or of Mediterranean/Eastern European descent • Male : female (M : F) ratio varies from 15 : 1 (older literature) to 3 : 1 or 1 : 1 (more recent observations) • Two-thirds of patients develop disease after the age of 50 years
African endemic
• Incidence amongst Black Africans ranges from 1% to 10%, with a clear male predominance • Accounts for up to 9% of all reported cancers in equatorial Africa • The lymphadenopathic variant affects primarily children, with a M : F ratio of approx. 1 : 1
Due to iatrogenic immunosuppression
• Individuals are immunosuppressed secondary to systemic medications, e.g. calcineurin inhibitors, prednisone, cytotoxic agents, JAK inhibitors • Cyclosporine is associated with a higher incidence and more rapid onset of disease • Lesions can regress following cessation of immunosuppressive therapy • Estimated incidences of post-transplantation KS in Western countries and the Near East are <1% and 4%, respectively • Men are slightly more often affected than women
AIDS-related epidemic
• Occurs primarily in men who have sex with men • To a lesser degree, seen in female partners of affected men and in women from certain regions of Africa and the Caribbean who became HIV-infected via heterosexual contact • Up to 40% of men who have sex with men with AIDS can develop KS, compared with <5% in other risk groups and 4% in children • Can flare in the setting of immune reconstitution inflammatory syndrome • Occasionally develops in HIV-infected patients receiving chronic antiretroviral therapy, perhaps due to immunosenescence

Table 114.3 Epidemiologic aspects of the four major types of Kaposi sarcoma (KS). A fifth type has been proposed – nonepidemic KS in HIV-seronegative men who have sex with men. *Adapted from Dispenzieri A. Blood Rev 2007;21:285–99.*

Fig. 114.24 Classic Kaposi sarcoma. Red macules and patches on the plantar surface of the foot, with violaceous plaques on the ankle.

Fig. 114.25 Kaposi sarcoma in a patient with AIDS. Multiple violet to violet–brown plaques that are usually more widely distributed than in classic KS. On the uppermost trunk, there are several oval lesions whose long axes are parallel to skin tension lines. *Courtesy Luis Requena, MD.*

It also remains unclear whether KS is essentially hyperplastic or neoplastic in nature, or both. While some studies employing X-chromosome inactivation (methylation) patterns have supported singular, presumably disseminated, clones[124], others utilizing the same methodology in examining sets of multiple lesions from single patients have found either oligoclonal composition within a given lesion or dissimilar, presumably independently developing, clones[125]. Despite these lingering uncertainties about both endothelial phenotype transitions and clonality, it is noteworthy how much compelling molecular, clinical, and epidemiological evidence has accumulated to confirm that infection with HHV-8 causes, or at least strongly influences, the development of KS[126]. This virus is known to be present in most patients with all clinical types of KS, and seroreactivity to HHV-8 is not present to a significant degree in the normal population. The HHV-8 genome, when detected in the blood of HIV-positive men, strongly predicts their subsequent development of KS.

HHV-8 contains homologs of cellular genes that can stimulate cell proliferation, inflammation, and angiogenesis and perhaps inhibit apoptosis[127]. *In vitro*, HHV-8 enhances the proliferation of primary endothelial cells or extends their life span, while not producing complete oncogenic transformation[128]. The host immune response and cytokines (particularly fibroblast growth factor) released by the virally infected cells may further support tumor growth in an autocrine and paracrine manner[129–131]. The role of inflammation in KS is supported by the observation that in patients with AIDS, pre-existing KS can get worse, at least transiently, in the setting of the immune reconstitution inflammatory syndrome (IRIS; see Ch. 78)[132].

Clinical features

Classic KS typically presents as slowly growing, pink to red–violet macules on the distal lower extremities that may coalesce to form large plaques (Fig. 114.24), or develop into nodules or polypoid tumors. Initially unilateral lesions progress to a more widely disseminated multifocal pattern. Early lesions may regress, while others evolve, leading to lesions in different stages at the same time. Patients with longstanding KS may have lesions in the mouth and gastrointestinal tract that are usually asymptomatic as well as lymphedema.

African endemic KS can be classified into four subgroups: nodular, florid, infiltrative, and lymphadenopathic. The nodular variant resembles classic KS in course and appearance, whereas the florid and infiltrative types are more biologically aggressive. The lymphadenopathic type is notably different in several regards: it predominantly affects children, the primary tumors involve the lymph nodes (although skin and mucosal lesions may also be present), and its course is fulminant and fatal.

KS due to iatrogenic immunosuppression (transplantation-associated KS) is generally clinically similar to classic KS. It may resolve completely upon removal of immunosuppressive therapy. KS associated with prolonged high-dose immunosuppression may behave in a more aggressive fashion, causing death in patients who develop internal involvement.

AIDS-related epidemic KS most commonly affects HIV-infected patients with advanced immune impairment and $CD4^+$ T cell counts of <500 cells/cubic millimeter[133]. Clinical features of KS in the HIV-infected patient are protean. While some patients experience only a single lesion, others have disseminated cutaneous disease. Individual lesions range from faint erythematous macules, papules, and plaques to purple–black tumors and nodules. Macules and plaques are frequently oval to lanceolate and may array along lines of cleavage of the skin (Fig. 114.25). Coalescing papules and plaques occasionally form extensive armor-like constricting plaques that may impair the function of extremities and cause lymphedema.

While any skin surface may be involved, the trunk and midface (particularly the nose) are common sites, causing significant cosmetic disfigurement (see Ch. 78). Bluish to violaceous macules, plaques, and tumors can arise intraorally. Plaques and tumors at any site may

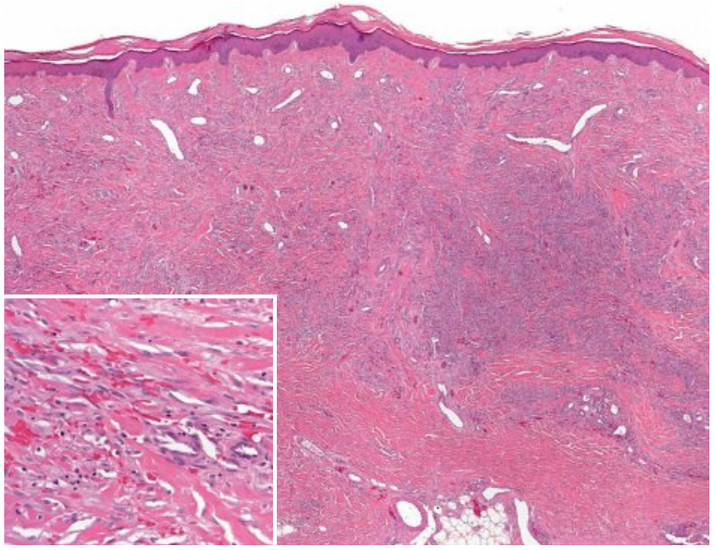

Fig. 114.26 Histology of Kaposi sarcoma – plaque stage. In the reticular dermis, there is a spindle cell vascular proliferation characterized by slit-like vascular spaces with extravasated erythrocytes (inset). *Courtesy Lorenzo Cerroni, MD.*

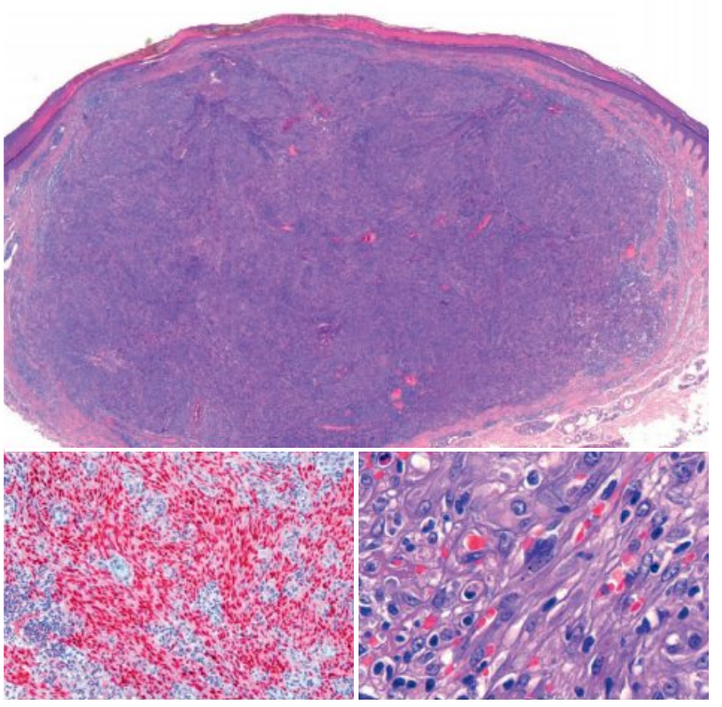

Fig. 114.27 Histology of Kaposi sarcoma – nodular stage. Nodular dermal proliferation of spindled and epithelioid cells admixed with extravasated erythrocytes (right inset). Note the positivity for the latency-associated nuclear antigen (LANA-1) of HHV-8 (left inset). *Courtesy Luis Requena, MD.*

ulcerate and become secondarily infected. KS frequently involves the viscera, including the gastrointestinal tract, lymph nodes, and lungs. The prognosis of pulmonary disease is grave.

Pathology

The histologic appearance of KS does not vary significantly between the different clinical subtypes, but does vary with stage of the lesion. The *patch* stage is characterized by a superficial dermal proliferation of small, angulated vessels lined by inconspicuous endothelial cells, suggestive of lymphatics. These delicate but "jagged" vessels tend to separate collagen bundles and are accompanied by a sparse infiltrate of lymphocytes and plasma cells as well as small numbers of spindle cells expressing endothelial markers. In the more advanced *plaque* stage, the vascular proliferation extends to include the deeper dermis and may involve the subcutis (Fig. 114.26). The spindled endothelial cell population also expands among the ramifying small vessels.

In the *nodular* phase, there is replacement of dermal collagen by these spindled endothelial cells. Pleomorphism and significant numbers of mitotic figures are absent. The spindle cells form intersecting fascicles and are separated by characteristic slit-like spaces containing erythrocytes (Fig. 114.27). The resulting sieve-like pattern of vascular spaces is highly characteristic of KS. Intracellular and extracellular hyaline globules are thought to represent degenerated erythrocytes[4]. The tumor nodules are often rimmed by ectatic or crescentic vessels, hemosiderin deposits, lymphocytes and plasma cells, and may be compartmentalized by fibrous bands. Some tumors contain prominent ectatic meshworks of vessels and have been referred to as "lymphangioma-like" KS. Tumors with a frankly sarcomatous appearance, nuclear pleomorphism, and brisk mitotic activity may occur either as a late stage within previously indolent lesions or as an initial presentation, with the latter most commonly observed in African endemic cases.

Demonstration of expression of the latency-associated nuclear antigen (LANA-1) of HHV-8 has proved to be a highly sensitive and specific marker of KS and other HHV-8-associated disorders such as multicentric Castleman disease and primary effusion lymphoma in both HIV-positive and HIV-negative patients (see Fig. 114.27, left inset)[134,135]. Immunohistochemical detection of this antigen in vascular tumors is more diagnostically useful than detection of the HHV-8 genome by PCR since a few non-KS vascular tumors in both immunocompromised and immunocompetent patients have been found to be positive for HHV-8 by PCR, but not for LANA-1 by immunohistochemical staining, presumably due to detection of HHV-8 within blood cells circulating through the tumors[134].

Differential diagnosis

For patch stage KS, the clinical differential diagnosis includes capillary malformations, an early stage of several of the vascular tumors in Table 114.1, and when on the lower extremities, changes secondary to venous hypertension. Histologically, patch stage KS must be distinguished from stasis changes, well-differentiated angiosarcoma, and benign vascular proliferations and tumors; positivity for LANA-1 points to the diagnosis of KS.

Histologically, the most important differential diagnostic considerations in nodular stage KS are KHE, spindle cell hemangioma, and moderately differentiated angiosarcoma, all of which are negative for LANA-1 of HHV-8. Although KS and spindle cell hemangioma are both characterized by proliferations of spindle cells, KS lacks the cavernous spaces of the latter. KHE is almost exclusively a disease of infancy and childhood and is distinguished from KS by a strongly lobular architecture and lack of plasma cell infiltrates. Angiosarcoma is characterized by endothelial atypia and mitotic activity, both absent in KS.

Late-stage KS may both clinically and histologically resemble pseudo-Kaposi sarcoma, i.e. acroangiodermatitis of Mali that is related to chronic venous insufficiency and Stewart–Bluefarb syndrome that can be associated with an arteriovenous malformation. These reactive, hyperplastic entities differ from KS in that the hyperplasia can be seen to derive from pre-existing vasculature and staining for HHV-8 is negative. Late-stage KS lesions can also be confused histologically with a number of non-vascular spindle cell sarcomas such as fibrosarcoma and leiomyosarcoma. In these cases, demonstration of CD31 immunoreactivity helps confirm the vascular differentiation of KS.

Other entities that can mimic KS clinically but which can be easily distinguished on the basis of histologic features include cutaneous metastases, leukemia or lymphoma cutis, venous and lymphatic malformations, and the cutaneous manifestations of polyarteritis nodosa and erythema elevatum diutinum.

Treatment

In many patients with KS, obtaining a complete cure may be an unrealistic expectation, since recurrence rates are high. Treatment of visible lesions, even in HIV-positive patients with widely disseminated disease, improves appearance, heightens self-esteem, and provides patients with a sense of control in an otherwise difficult situation. In older immunocompetent patients with static disease, observation and close follow-up is an option. Surgery is only useful for tissue diagnosis and removal of solitary lesions. Cryotherapy, laser surgery, photodynamic therapy, intralesional vinblastine or vincristine, and topical alitretinoin, timolol and

imiquimod as well as low-dose oral propranolol have been used to treat superficial patches and plaques[136,137,137a]. Cryotherapy must usually be sufficiently vigorous to cause epidermal ulceration, and the resulting scar seems to replace the vascular proliferation of KS. Extensive, multifocal disease often requires systemic treatment (see below).

Radiation therapy is an option for multifocal, but relatively localized, cutaneous KS. Reported regimens include single-dose radiation (8 to 12 Gy) delivered to an extended field and total skin electron beam therapy (4 Gy fractions weekly) for 6 to 8 weeks (see Ch. 139). Radiation therapy also plays a role in the treatment of localized oral KS, but may have a briefer effect in AIDS-related KS than in classic KS[138].

Rapidly progressive KS (defined by development of 10 or more new cutaneous lesions per month), pulmonary KS, symptomatic visceral involvement, and significant lymphedema are indications for systemic chemotherapy. Liposomal anthracyclines, paclitaxel, and vinblastine are used singly or in combination; less often vincristine, gemcitabine, vinorelbine, etoposide, and/or bleomycin are administered[139,140]. High-dose interferon-α is sometimes employed, but its use is frequently limited by side effects[141]. Immunomodulatory drugs (IMiDs) that inhibit growth of blood vessels such as pomalidomide have also been used successfully for cutaneous and oral KS. Additional potential therapies include sirolimus (see below) and tyrosine kinase inhibitors (e.g. pazopanib). Antiretroviral therapy has clearly helped to alleviate AIDS-related KS, probably indirectly by decreasing viral load and by increasing the CD4 count, but the exact mechanism is unclear. As noted previously, flares of KS can occur as a manifestation of IRIS (see Ch. 78), but this does not necessarily translate into a poor prognosis.

Organ transplant patients with KS pose a particular therapeutic challenge, that of balancing the risk of graft rejection with the benefit of improvement in KS. In addition to reduction of immunosuppression[142], substitution of sirolimus for cyclosporine can also lead to clinical improvement of KS. In 15 renal transplant recipients, this substitution led to resolution of all of the KS lesions in all of the patients, both clinically (by 3 months) and histologically (by 6 months). The authors observed neither episodes of rejection nor changes in kidney graft function[143]. This observation has been independently corroborated by additional studies, albeit not always with equally impressive response rates[144]. It is not yet clear if the beneficial effect of sirolimus reflects lessened immunosuppression or possibly a more direct antitumor effect related to inhibition of HHV-8-induced effects (e.g. PI3K and AKT phosphorylation)[120]. Organ transplant patients with KS also respond to conventional local and systemic therapies used in other forms of KS.

MALIGNANT VASCULAR NEOPLASMS

Epithelioid Hemangioendothelioma

Key features

- Malignant, but relatively indolent, vascular tumor that typically arises in adults
- Skin involvement uncommon and usually associated with more deeply seated disease
- Histologically, cords and nests of epithelioid endothelial cells within a myxoid or hyalinized stroma
- Although ~30% of patients develop metastases within regional lymph nodes, lung, liver, or bone, <50% of patients with metastases die of their disease

Introduction and history

Traditionally, the term *hemangioendothelioma* denoted a vascular tumor of intermediate malignant potential. The original description of *epithelioid hemangioendothelioma* (EHE) incorporated this definition as these tumors can give rise to metastases but their biologic behavior may be relatively indolent[145]. The WHO and ISSVA have recently reclassified EHE as a malignant, rather than intermediate or borderline, vascular tumor. Only angiosarcoma shares that designation (see Table 114.1)[71,72], although EHE is clearly associated with a better prognosis than classic angiosarcoma.

Epidemiology

EHE typically arises in adults, but in a younger age group than angiosarcoma[146]. Occurrence in preadolescent children is exceedingly rare. Unlike angiosarcoma, women appear to be affected slightly more frequently than men.

Pathogenesis

EHE is a clonal neoplastic proliferation of endothelial cells. Most classical cases have a t(1;3)(p36.3;q25) translocation which generates a WWTR1–CAMTA1 fusion protein that is likely an early causative event in oncogenesis[147–149]. *WWTR1* (3q25) encodes a transcriptional coactivator[150] while *CAMTA1* (1p36) encodes a calmodulin-binding transcription activator[151,152]. There is a *WWTR1–CAMTA1* fusion-negative subset of EHE that arises primarily in young adults; compared to classic EHE, more well-developed vascular structures and voluminous eosinophilic cytoplasm are present[153]. This subset contains an alternative gene fusion, *YAP1-TFE3*[153].

To date, the *WWTR1–CAMTA1* and *YAP1–TFE3* fusions have not yet been detected in other neoplasms, in particular the morphologic mimics of EHE such as epithelioid angiosarcoma, epithelioid sarcoma-like hemangioendothelioma, and epithelioid hemangioma. However, it is not yet certain that these fusions are unique to EHE[147,148]. Notably, both the *WWTR1–CAMTA1* and *YAP1–TFE3* gene fusions are reliably detected by FISH and/or RT-PCR[154].

Clinical features

Most tumors present as a slightly painful mass within deep soft tissues, but lesions can develop in the skin, viscera, or bone and are multifocal in up to 50% of patients[155]. Skin involvement is usually associated with an underlying soft tissue or bone tumor, but purely cutaneous examples do occur[145], primarily on the extremities. Skin tumors can be multinodular, and they need to be distinguished from cutaneous metastasis from a visceral primary tumor[156]. Some cases are closely associated with or arise from a vessel, usually a vein. Occlusion of that vessel may lead to secondary symptoms (e.g. edema, thrombophlebitis).

Overall, ~30% of patients develop metastases within the regional lymph nodes, lung, liver, or bone, and <50% of patients with metastases have died of their disease. One study of 30 patients suggested that dermal tumors may have a better prognosis than more deeply seated lesions[145].

Pathology

Similar to its more common counterparts involving soft tissue and bone, cutaneous EHE has an infiltrative growth pattern of epithelioid tumor cells with eosinophilic cytoplasm that form poorly canalized nests and cords within a distinctive myxohyaline stroma (Fig. 114.28). An important clue to their endothelial origin is the presence of small

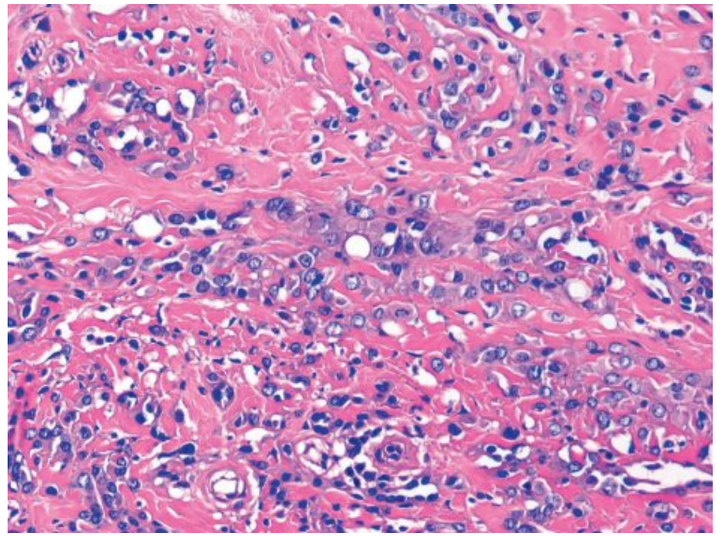

Fig. 114.28 Histology of epithelioid hemangioendothelioma. Poorly canalized cords and nests of endothelial cells forming small intracytoplasmic vacuoles as a sign of primitive vascular differentiation. *Courtesy Luis Requena, MD.*

intracytoplasmic vacuoles containing red blood cells. The nuclei are vesicular with little or no atypia and contain small, inconspicuous nucleoli. An angiocentric growth pattern may be present, but is less commonly observed in cutaneous tumors. Unlike epithelioid hemangioma, inflammation is sparse. Mitotic rate is variable and only weakly correlates with clinical outcome[145].

The tumor cells of EHE are positive for endothelial markers such as ERG, CD31, and CD34 and may also be positive for podoplanin, LYVE-1, and Prox1 (at least focally), suggesting lymphatic or mixed lymphatic–blood vascular differentiation[157,158]. Electron microscopy shows that EHE cells, unlike normal endothelial cells, contain abundant cytoplasmic intermediate filaments[159]. These filaments can cause immunopositivity for cytokeratins and/or smooth muscle antigen, leading to misdiagnosis[146].

Differential diagnosis

The differential diagnosis is broad and includes epithelioid sarcoma, metastatic signet ring adenocarcinoma, melanoma, and epithelioid angiosarcoma. An essential criterion for diagnosis of EHE is immunohistochemical evidence of endothelial differentiation[145]. Differentiation from epithelioid angiosarcomas may be problematic and relies upon recognition of the typical architectural pattern of EHE throughout the lesion plus an absence of the more atypical cells of angiosarcoma that frequently show apoptosis and abnormal mitotic figures in addition to the lack of *WWTR1-CAMTA1* or *YAP1-TFE3* gene fusions.

Treatment

Appropriate therapy involves wide local excision without adjuvant chemotherapy or radiotherapy, given the typically low-grade nature of these tumors. Regional lymph nodes should also be evaluated since these represent a common site for metastases. Anecdotally, stabilization of disease has been observed with interferon, celecoxib, and thalidomide[150]. Updated clinical practice guidelines were published in 2021[160].

Angiosarcoma

Synonyms: ■ Malignant hemangioendothelioma ■ Hemangiosarcoma ■ Lymphangiosarcoma

Key features

- Uncommon malignant neoplasm of endothelium, accounting for <1% of all sarcomas
- Unlike most sarcomas, has a predilection for skin and superficial soft tissue
- Most commonly affects the scalp and face of the elderly and areas of chronic lymphedema or radiodermatitis; rare in children
- Cutaneous forms are usually well to moderately differentiated lesions composed of anastomosing vessels that dissect between bundles of collagen
- Approximately 50% of cases express markers of lymphatic differentiation
- Prognosis is extremely poor, with <15% of patients surviving 5 years
- Most long-term survivors received early radical ablative surgery

Introduction and history

The term *angiosarcoma* has traditionally been used to denote all biologically high-grade malignant neoplasms of endothelial derivation, regardless of the evidence of lymphatic or blood vascular differentiation. However, even though EHE has recently been reclassified as a malignant, rather than intermediate or borderline, vascular tumor[71,72], it has a much better prognosis than angiosarcoma as well as distinct molecular underpinnings. Therefore, EHE is not considered an angiosarcoma variant.

Angiosarcomas were first described systematically by Caro and Stubenrauch in 1945. Only 3 years later, Stewart and Treves described the association between angiosarcoma and post-mastectomy lymphedema. The cutaneous form of angiosarcoma that primarily affects the face and scalp of the elderly was characterized by Wilson-Jones in 1964.

Epidemiology

Angiosarcomas are unusual neoplasms that occur more often in White men and develop primarily in middle-aged or older adults, with the highest incidence in individuals >70 years of age[161]. Those rare examples that occur during childhood or adolescence are more likely to arise in or around viscera (especially the heart or pericardium)[162] or in association with other disease states[163], including chronic or congenital lymphedema, chronic radiodermatitis, and immunosuppression.

Pathogenesis

Angiosarcomas are clonal proliferations of malignantly transformed cells expressing endothelial differentiation. When compared with other sarcomas, distinct upregulation of vascular-specific receptor tyrosine kinase genes, including *TIE1*, *KDR*, *FLT1* and *TEK*, has been observed in angiosarcomas[164]. Furthermore, high-level *MYC* amplification (chromosome 8q24) is consistently seen in radiation-induced and lymphedema-associated angiosarcomas[165,166]. *MYC* amplification leads to upregulation of the miR-17-92 cluster, which downregulates thrombospondin-1, a potent inhibitor of angiogenesis[167]. The *WWTR1–CAMTA1* gene fusion typically seen in EHE has not been detected in angiosarcomas, including epithelioid angiosarcomas[148]. Mechanisms underlying the association between chronic lymphedema and angiosarcoma remain uncertain. Theories include induction of neoplastic change by unknown carcinogens in accumulated lymphatic fluid and the idea that areas with chronic lymphedema are "immunologically privileged sites" due to loss of afferent lymphatic connections.

Radiotherapy has been shown to be an independent risk factor for angiosarcoma development, best exemplified in breast cancer patients (see below). Environmental chemical exposures linked to angiosarcoma, particularly of the liver, include vinyl chloride, thorium dioxide, arsenic, radium, and anabolic steroids[168]. Lastly, neither HHV-8 infection nor cumulative sun exposure appears to be associated with angiosarcoma.

Clinical features

The most common form of angiosarcoma is cutaneous angiosarcoma (without lymphedema) in the elderly. Approximately 70% of these tumors occur in patients over 40 years of age, with the highest incidence in those >70 years of age. About 50% involve the head and neck (Fig. 114.29). Lesions typically present as a deceptively benign-appearing bruise-like patch on the central face, forehead, or scalp. Facial swelling and edema may be present. More advanced lesions are violaceous nodules that bleed easily and may ulcerate. The area of involvement spreads centrifugally, eventually covering large portions of the head and neck. The prognosis is invariably poor, with a less than 15% survival over a 5-year period[161]. In contrast, pediatric cutaneous angiosarcomas tend to be small, unifocal, and favor girls and the lower extremity[163].

Fig. 114.29 Angiosarcoma. Erythematous and purple hemorrhagic plaques as well as grouped vesicles with clear or hemorrhagic fluid (reminiscent of microcystic lymphatic malformation) are present. There is also induration and a pink hue to the left side of the face in addition to evidence of previous excisions and radiotherapy. *Courtesy Lorenzo Cerroni, MD.*

Angiosarcomas that arise in the setting of chronic lymphedema present as firm, coalescing violaceous nodules or an indurated plaque on a background of brawny, non-pitting edema. More than 90% of all angiosarcomas associated with lymphedema arise after mastectomy and lymph node dissection (Stewart–Treves syndrome). In these cases, the inner aspect of the upper arm is the most common site of involvement. Other forms of chronic lymphedema are associated with angiosarcoma, including congenital, filarial, traumatic, and idiopathic. The duration of lymphedema prior to appearance of angiosarcoma ranges from 5 to 25 years.

Even though the incidence is very low (<0.05% in a recent survey of breast cancer patients)[169], the greater use of breast-sparing surgery paired with irradiation has translated into an increase in post-irradiation sarcomas. The latter arise within breast parenchyma and overlying skin, with an average post-treatment interval of 6 years. Post-irradiation angiosarcomas appear as infiltrative plaques or nodules in or near the area of irradiated tissue and share the poor prognosis of all forms of angiosarcoma (Fig. 114.30). These are aggressive, infiltrative, multicentric tumors that enlarge incessantly. Local recurrence and metastasis to regional lymph nodes and lung are common.

Angiosarcomas of skin and soft tissue have also been reported in association with benign and malignant nerve sheath tumors[170], defunctionalized arteriovenous shunts in renal transplant patients[171], long-term exposure to various foreign materials[172], xeroderma pigmentosum[173], and bilateral retinoblastoma[174].

MRI, which shows a nonspecific decreased or variable signal intensity in T1 images, an increased signal in T2 images, and enhancement with gadolinium, is more useful than CT in accurately delineating the extent of local disease, including involvement of neurovascular structures and joints. It is also the imaging modality of choice for evaluating tumor response to preoperative radiation or chemotherapy.

Pathology

Angiosarcomas involving the skin, although highly variable in degree of endothelial differentiation both between and within individual tumors, do not vary in histology as a class; the latter includes those of the "usual type" not associated with lymphedema, those associated with chronic lymphedema, and those associated with chronic radiodermatitis. Well-differentiated areas display an anastomosing network of sinusoidal vessels, often bloodless, lined by a single layer of endothelial cells of slight to moderate nuclear atypia. These exhibit a highly infiltrative pattern, splitting apart collagen bundles and groups of adipose cells. In less well-differentiated areas, the endothelial cells with more pronounced nuclear pleomorphism and mitotic activity pile up and form papillary projections (Fig. 114.31). In poorly differentiated areas, luminal formation may be non-apparent and mitotic activity may be high, mimicking other high-grade sarcomas, carcinoma, or melanoma. Hemorrhage and blood-filled cavities may be present.

Most angiosarcomas stain positively for CD31, CD34, ERG, c-MYC, and Fli-1[175–177], with CD31 and ERG generally considered the most useful markers. Immunohistochemical detection of factor VIII-related antigen, although highly specific for endothelial cells, lacks sensitivity for vascular neoplasms and is negative or very weak even in well-differentiated angiosarcomas.

In tumors associated with chronic lymphedema, networks of small lymphatics lined by endothelial cells with hyperchromatic nuclei may ramify through adjacent soft tissues and have been interpreted as premalignant change. Angiosarcomas developing in this setting may retain lymphatic characteristics (Fig. 114.32). While angiosarcomas arising within a background of chronic lymphedema are often presumed to originate from lymphatics, many angiosarcomas outside of this setting are thought to have mixed lineage due to expression of lymphatic markers, e.g. podoplanin, Prox1 (usually to a minor degree), in addition to pan-endothelial markers and markers more typical of blood vascular endothelium (e.g. CD34)[178]. Until this issue is further clarified, use of the more generic term *angiosarcoma*, rather than *lymphangiosarcoma* or *hemangiosarcoma*, seems prudent.

More recently, a category of purely "lymphatic-type angiosarcoma" was proposed based on a distinctive subset of 21 tumors arising within

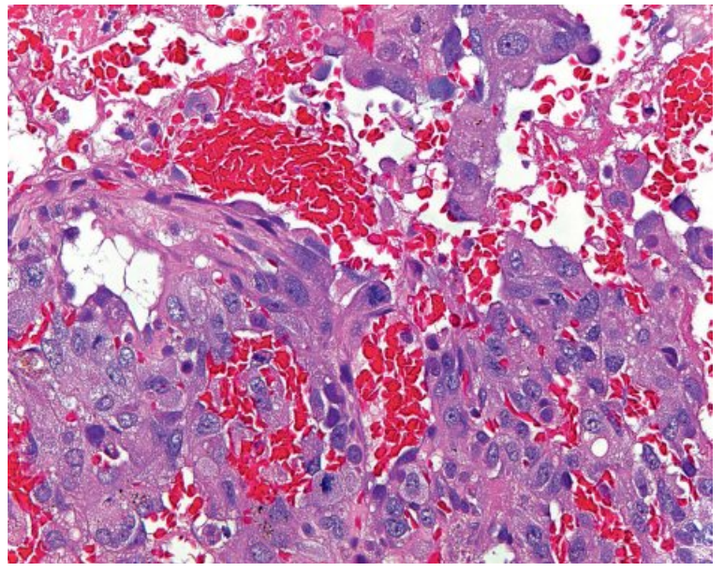

Fig. 114.31 Histology of angiosarcoma. Ill-defined vascular spaces filled with erythrocytes and lined by atypical, piled-up endothelial cells.

Fig. 114.30 Post-radiation angiosarcoma. Red–violet patches and plaques on the breast. The clinicopathologic differential diagnosis is primarily post-radiation atypical vascular proliferation of the skin, an entity that may represent a precursor of post-radiation angiosarcoma (Table 114.4). *Courtesy Celia Requena, MD.*

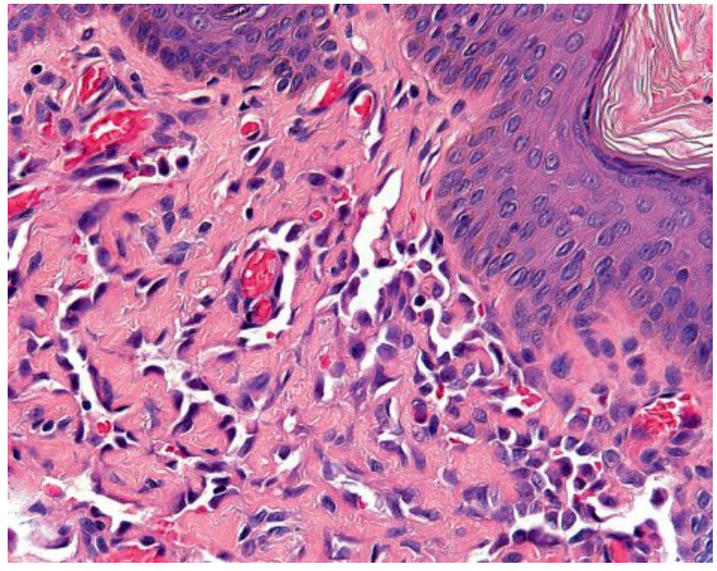

Fig. 114.32 Histology of angiosarcoma with lymphatic characteristics ("lymphangiosarcoma"). Some of the vascular channels are angular and lack erythrocytes. Also note the hyperchromatic atypical endothelial cells.

FEATURES OF RADIATION-INDUCED ANGIOSARCOMA OF THE BREAST (COMPARED TO POST-RADIATION ATYPICAL VASCULAR LESIONS OF THE SKIN)
Clinical features: • thicker and more indurated plaques
Histopathologic features: • cellular atypia • multilayering of vessels • positivity for c-MYC • high Ki-67 proliferation index

Table 114.4 Features of radiation-induced angiosarcoma of the breast (compared to post-radiation atypical vascular lesions of the skin).

the skin and subcutis of the head and neck region in adults. The tumors were defined by the growth characteristics of angiosarcoma (low-to-high grade), cytologic features of lymphatic differentiation (e.g. hobnail-type endothelium), dense intratumoral and peritumoral T cell infiltrates, and diffuse endothelial expression of at least one lymphatic marker – most commonly podoplanin (89%) and/or Prox1 (100%). Although somewhat reminiscent of RHE histologically, this angiosarcoma subgroup displayed more cytologic atypia and a more aggressive course (albeit less aggressive than conventional angiosarcoma).

Highly aggressive angiosarcomas with an epithelioid appearance occasionally occur in the skin[179], although this variant is more common in deep soft tissues. These so-called "epithelioid angiosarcomas" consist of large, rounded cells with prominent eosinophilic nucleoli in which the only morphologic evidence of vascular differentiation may be the presence of occasional intracytoplasmic vacuoles. Cytokeratin positivity is present in about one-third of epithelioid angiosarcomas[180,181], making distinction from carcinoma problematic. Fortunately, this distinction can be accomplished by demonstration of coexistent CD31 and/or ERG expression. The proportion of purely epithelioid cutaneous angiosarcomas appears to be higher among pediatric cases (90%) compared to adult cases (30%)[182].

Differential diagnosis

Early recognition and histologic diagnosis are crucial in the treatment of angiosarcoma. In sites of previous radiation, it can be difficult to distinguish angiosarcomas from atypical vascular lesions. Well-differentiated angiosarcomas, which display only slight cytologic atypia despite their high-grade biologic behavior, may also closely resemble microcystic lymphatic malformation. Other vascular neoplasms that must be distinguished from angiosarcoma histologically include PILA, RHE, epithelioid hemangioendothelioma, and KHE/tufted angioma. Intravascular proliferation of atypical endothelial cells is not a feature of KS and HHV-8 is negative in angiosarcoma. Nuclear staining for c-MYC can be useful for distinguishing angiosarcoma (positive in the majority of cases) from its mimickers (negative). Distinguishing post-radiation atypical vascular lesions of the skin from radiation-induced angiosarcoma of the breast can sometimes be challenging (Table 114.4).

Treatment

Surgical excision with wide margins is indicated. Even with negative margins by histologic examination, the recurrence rate and chance of metastatic disease are high. This may in part reflect the tendency for multifocality. Systemic therapies are limited and include taxanes (+/– radiotherapy) and anthracyclines[183,184]. There are also isolated reports of the successful use of IMiDs, targeted therapies (e.g. pazopanib), and immune checkpoint inhibitors. Radiotherapy alone may be palliative, but does not improve survival. Complete and partial responses to propranolol plus vinblastine-based metronomic chemotherapy were observed in seven patients with advanced angiosarcoma[185].

PERIVASCULAR NEOPLASMS AND NEOPLASTIC-LIKE PROLIFERATIONS

Glomus Tumors and Glomuvenous Malformations

Synonyms: ■ Glomus tumor: solitary glomus tumor, solid glomus tumor ■ Glomuvenous malformation: glomangioma, infiltrating glomus tumor, multiple glomus tumors

Key features

- A heterogeneous group of benign tumors and malformations characterized by the presence of glomus cells
- Two major subgroups are *glomus tumor* and *glomuvenous malformation (*previously termed "glomangioma")
- The glomus tumor typically presents in young adults, is a *solitary*, *painful* papule or nodule on the extremities with a predilection for subungual sites, and consists of a relatively *solid proliferation of glomus cells* associated with *small vessels*
- The less common glomuvenous malformation typically presents in infancy or childhood, is often *multiple* and *asymptomatic* and histologically resembles a venous malformation in which *dilated vessels* are rimmed by a *few glomus cells*
- Histologic variants in which glomus cells merge with well-differentiated smooth muscle cells are referred to as glomangiomyomas
- Extremely rare atypical and malignant forms have been described

Introduction

Tumors distinguished by the presence of benign glomus cells have been subclassified in the past into a number of descriptive types, such as solid, solitary, multiple, adult, pediatric, and diffuse. Current evidence supports division of these tumors into two major disparate categories: (1) the glomus tumor proper, a cellular lesion that tends to be well circumscribed, solitary, and subungual; and (2) the glomuvenous malformation (GVM), a frequently multifocal lesion, traditionally termed a "glomangioma", that most commonly presents in infants or children and histologically resembles a venous malformation in which lesional vessels are rimmed by glomus cells.

Epidemiology

Solitary glomus tumors can occur at any age, but are most common in young adults. Although these tumors in general show no sex predilection, subungual lesions are more common in women. GVMs are less common (accounting for 10%–20% of all glomus cell lesions) and typically present in children without sex predilection; many are evident at birth.

Pathogenesis

The fact that the most common site of occurrence of glomus tumors (the subungual region of the finger) corresponds to one of the densest areas of distribution of the normal glomus body suggests that many glomus tumors represent neoplastic proliferations originating from pre-existing normal glomus cell populations. However, the occasional occurrence of glomus tumors at sites where normal glomus bodies may not be found, including bone, gastrointestinal tract, trachea, and nerve, suggests that some glomus tumors may arise from pluripotent mesenchymal cells or even ordinary smooth muscle cells.

Despite the shared presence of benign glomus cells, glomus tumors and GVMs differ widely in clinical and histopathologic features and are likely unrelated in pathogenesis. The resemblance to venous malformations plus the early presentation of GVMs strongly supports their now widely accepted malformative etiology as well as abandonment of the traditional term *glomangioma*.

Familial GVM is inherited in an autosomal dominant fashion, with patients tending to have multiple lesions that continue to appear later in life, sometimes in response to trauma[186]. At least 40 different germline mutations in *GLMN*, which resides on chromosome 1p22.1 and encodes glomulin, have been detected; glomulin may function as an immunophilin ligand[187–190]. In one study, the most common *GLMN* mutation was present in ~45% of families[191]. The frequent multifocality, incomplete but high (~90%) penetrance, and delayed development in familial GVM suggest a paradominant inheritance pattern in which somatic mutations likely serve as "second hits". Interestingly, in a recent study of 28 cases of familial GVM, second hits were identified in 16 lesions. Although these included a few intragenic mutations and deletions as well as one interstitial deletion containing *GLMN*, the majority of identified mutations represented acquired uniparental isodisomy, with a breakpoint region near the centromere at 1p13.1–1p12. The latter led to duplication of the germline *GLMN* mutation

at 1p22.1 without causing quantitative loss of other genes[192]. It is assumed that somatic mutations within or affecting *GLMN* are the likely cause of sporadic GVMs.

Knock-out mouse studies have shown that glomulin is essential for the viability and appropriate development of the embryonic vasculature during vascular remodeling[193]. In embryonic and adult mice, glomulin is expressed primarily in vascular smooth muscle cells[194].

Clinical features

The ***glomus tumor*** is a benign lesion that usually presents in young adults (20–40 years of age) as a small (<2 cm), blue–red papule or nodule in the deep dermis or subcutis of the distal upper or lower extremities. They are tender to touch, and may be associated with severe paroxysmal pain in response to temperature changes and pressure. The hand, especially the nail beds and palm, is most commonly affected (Fig. 114.33), but cutaneous lesions can also occur at other sites. Unusual extracutaneous glomus tumors have been reported in the gastrointestinal tract, bone, mediastinum, trachea, mesentery, cervix, and vagina. Extremely rare instances of malignant transformation within glomus tumors, with documented metastasis, have been described[195].

Radiographs are of limited usefulness in diagnosis, but subungual tumors often show bony erosion and may show increased distance between the nail and the dorsum of the phalanx. MRI is frequently the primary diagnostic imaging modality of choice (Fig. 114.34), followed by contrast-enhanced CT. Glomus tumors are strongly enhancing masses by both CT and MRI.

GVMs may be present at birth or become evident during childhood or adolescence and tend to be multiple. They are generally asymptomatic lesions that vary widely in appearance, from multiple, soft, red to blue nodules that may be widely distributed or confluent to multifocal, pink to deep blue plaque-like lesions (Figs. 114.35 & 114.36); occasionally, single punctate lesions are seen. Although they clinically resemble venous malformations, GVMs differ in appearance from the latter in a number of aspects[196]: they tend to be more nodular or cobblestone-like in appearance, more blue and less compressible, and they do not swell with exercise or dependency. Lesions typically thicken and become more blue in color with time. Although less painful than the glomus tumor, GVMs may be tender to palpation, and bouts of pain may occur in association with menstruation and pregnancy. All reported cases have behaved in a benign fashion.

Pathology

The common ***glomus tumor*** is a generally well-circumscribed proliferation of solid sheets and clusters of uniform glomus cells focally clustering around a variable number of capillary-sized, endothelium-lined vessels (Fig. 114.37). The stroma can be myxoid or hyalinized and may contain numerous small nerve twigs. A dense fibrous pseudocapsule may be present. The glomus cells are distinctive in their uniformly rounded or polygonal shape, centrally placed and rounded nuclei, and pale eosinophilic cytoplasm. PAS staining reveals basement membrane material around individual tumor cells. Mitotic figures may be present, but are normally configured. In that glomus cells represent modified smooth muscle cells with myofilaments, there is consistent expression of vimentin and muscle actin isoforms, and variably reported expression of desmin. Examples demonstrating gradual transition from rounded glomus cells to elongated, well-differentiated smooth muscle cells have been termed glomangiomyomas[197].

Although the great majority of glomus tumors display no significant cytologic atypia, some have atypical or frankly malignant features. Based on an analysis of 52 atypical and malignant glomus tumors[198], a histopathologic classification of glomus tumors with unusual features has been proposed, with *malignant glomus tumors* defined as those of large size (>2 cm) and deep location, or those with marked atypia and a high mitotic rate (≥5/50 HPF), or those with atypical mitotic figures. Malignant examples show a compressed rim of benign glomus

Several aggregates of vascular structures in the dermis and superficial subcutaneous fat, most of which are filled with erythrocytes. The vascular walls are composed of one or more layers of round, monomorphous glomus cells (inset). *Courtesy Lorenzo Cerroni, MD.*

tumor around the malignant areas in about one-half of cases, consistent with malignant transformation from a pre-existing benign tumor. In some cases, the presence of nuclear pleomorphism without mitoses is thought to represent a degenerative phenomenon ("ancient" changes), and tumors with these characteristics have been termed "symplastic" glomus tumors.

GVMs consist of large, dilated, thin-walled veins in the dermis and subcutaneous tissue, histologically equivalent to those comprising venous malformations, but surrounded by one or more layers of uniform, cuboidal glomus cells (Fig. 114.38). Some microscopic fields may lack the glomus cells and be indistinguishable from common venous malformations. They are less circumscribed than solitary glomus tumors and may be distributed as separate nodules in the same anatomic area. Like venous malformations without glomus cells, many GVMs contain organizing thrombi or phleboliths.

Differential diagnosis

Solitary glomus tumors may clinically be confused with other painful nodules such as eccrine spiradenomas and leiomyomas which can readily be distinguished from glomus tumors histologically and immunohistochemically. From a histologic point of view, solid forms of hidradenoma may closely resemble glomus tumors, especially when sweat ducts contain erythrocytes, but can be distinguished by their keratin expression. Cellular glomus tumors are occasionally mistaken for pseudoangiomatous intradermal nevi, but the latter are positive for melanocytic markers.

GVMs must be distinguished from ordinary venous malformations that lack glomus cells by histologic examination, although several clinical features of these lesions also help make this distinction (see section above). It is likely that many cases of the so-called blue rubber bleb nevus syndrome, a familial disorder characterized by multiple venous malformations, actually represent examples of multiple GVMs.

Treatment

Solitary glomus tumors can be treated successfully by local surgical excision. Other options include electrodesiccation and sclerotherapy.

GVMs are less amenable to surgery than are common glomus tumors, due to their more extensive and multifocal nature. In a series of large facial "glomangiomas"[196], MRI was the best modality for definition of the extent of the lesions and their relationship to other anatomic structures. In this same series, surgical resection reduced the area of discoloration and improved facial contour, while sclerotherapy was less effective than for venous malformations[196]. Laser surgery employing CO_2, KTP, Nd:YAG, and pulsed dye lasers may also be helpful. In a retrospective study of 17 patients with GVMs who were treated with dual wavelength pulsed dye–Nd:YAG laser therapy, a reduction of at least 60% was observed[196]. Residual lesions following subtotal resections may slowly re-expand[196].

Infantile Hemangiopericytoma

Synonym: ■ Congenital hemangiopericytoma

Key features

- Benign neoplasm of perivascular myoid differentiation that usually presents at birth or in the first years of life
- Closely related to infantile myofibromatosis
- Clinical appearance is that of single or multiple dermal and subcutaneous nodules that may be alarmingly large at birth or grow rapidly
- Differs in both histology and clinical behavior from adult-type hemangiopericytoma, which rarely involves the skin
- Histologically, multilobulated tumor with cellular areas of spindle cells and antler-like branching blood vessels, merging with less cellular areas containing plump myofibroblasts
- Behaves in a benign fashion, despite frequent focal necrosis and increased mitotic activity

Introduction and history

The concept of hemangiopericytoma as an entity has been controversial since these tumors were described in 1942 by Stout and Murray, who considered them to be composed mainly of pericytes. Congenital or infantile hemangiopericytoma was recognized as a separate entity from adult-type hemangiopericytoma in 1976 by Enzinger and Smith

due to its distinguishing clinical and histologic features. Classic adult-type hemangiopericytomas will not be discussed here because of their extreme rarity in superficial tissues.

Epidemiology

Infantile hemangiopericytomas are uncommon tumors that typically appear in the first year of life and are usually congenital. There is a male predominance by ~2:1. Examples in older children have occasionally been reported.

Pathogenesis

The frequent zonal pattern of myofibroblastic differentiation in infantile hemangiopericytomas has led to the proposal that infantile hemangiopericytoma and infantile myofibromatosis may lie upon a continuous spectrum of myofibroblastic lesions[199]. In addition, a family of adult tumors with perivascular myoid differentiation has been described that overlaps histologically with infantile myofibromatosis and includes two newer entities, termed *glomangiopericytoma* and *myopericytoma*. Granter et al.[200], in support of similar observations by Requena and colleagues[201], have proposed that this widening spectrum of tumors and their distinctive cellular components might be better explained by derivation from a pluripotent periendothelial cell capable of differentiating along smooth muscle, pericytic, and glomus cell lines, rather than from myofibroblasts.

Clinical features

Infantile hemangiopericytomas are nodules that primarily occur in the subcutaneous and dermal tissues of the head and neck. Congenital examples may be alarming in size at birth or grow rapidly thereafter. Multicentric cases have been reported and have in some instances been misinterpreted as examples of distant metastasis. Although benign behavior appears to be the rule, large tumors may be problematic if they hemorrhage or threaten vital structures. Lesions in the tongue and in deeply seated sites, such as the mediastinum and abdomen, have been reported. Rare multisystemic forms in neonates may be lethal. Local recurrence after excision is common, although spontaneous tumor regression has also been documented.

Pathology

Infantile-type hemangiopericytomas, unlike the adult type, are usually dermal or subcutaneous in location and are often multilobulated. They typically show a biphasic growth pattern in which primitive hemangiopericytomatous areas resembling the adult tumors (short spindle cells arranged around thin-walled, branching vessels) blend with less cellular areas containing plump myofibroblast-like cells set within a collagenous matrix. Focal necrosis and significant mitotic activity may be present, but are not indicative of poor prognosis.

Differential diagnosis

Infantile hemangiopericytomas demonstrate nonspecific clinical and radiologic features and require histologic examination for definitive diagnosis. They may be confused clinically with an infantile hemangioma due to rapid postnatal growth, and large congenital lesions may suggest a rapidly involuting congenital hemangioma or infantile fibrosarcoma. Further diagnostic considerations include infantile myofibromatosis and subcutaneous pyogenic granuloma.

Treatment

Conservative treatment following establishment of the diagnosis via histologic examination is generally recommended given the potential for spontaneous regression. Complete surgical resection is a reasonable option in some cases, although there appears to be a conflicting tendency of these tumors to both locally recur and spontaneously regress.

Malignant Peripheral Nerve Sheath Tumor 2087
Merkel Cell Carcinoma 2087
Heterotopic Neural Tissue of the Skin 2090
Primitive Neuroectodermal Tumors 2092

In the past, neural tumors were often misdiagnosed histopathologically because of confusing classifications. As a result, their clinical relevance was poorly understood. Clinically, cutaneous neural tumors often look alike and most of them are benign. However, their correct diagnosis can be helpful in recognizing important clinical syndromes and this can contribute to better patient management[1].

CLASSIFICATION, TERMINOLOGY, AND HISTOGENESIS

Cutaneous neural tumors can be classified into two major groups: those derived from peripheral nerves and those derived from ectopic or heterotopic neural tissue (Table 115.1). The former group were classically subdivided into true nerve sheath neoplasms and hamartomatous tumors, although this classification may be specious due to evidence that most hamartomas are driven by clonal expansion of a neoplastic cell population[2,3].

Cutaneous neural tumors tend to differentiate toward one or more elements of the nervous system; as a result, they recapitulate to varying degrees the morphogenesis of normal peripheral nerves. Therefore, knowledge of the organization of the normal peripheral nerve (Fig. 115.1) is crucial to understanding the histogenesis of cutaneous neural tumors[2].

The basic element of a peripheral nerve is the nerve fiber, which is composed of an axon and its surrounding Schwann cell layer. A peripheral nerve can be compared to a conventional telephone cable, in which each axon and its surrounding Schwann cell layer correspond to a telephone wire and its insulation, respectively. Nerve fibers are bundled within nerve fascicles by the perineurium, a sheath composed of specialized perineurial cells (see Fig. 115.1). Inside the nerve fascicle, the space between individual nerve fibers is referred to as the endoneurium. The bundles of nerve fascicles are further encased in a supportive fibrous sheath called the epineurium. To a variable extent, this architectural arrangement is recognizable in many cutaneous neural neoplasms.

The most important constituent cells are the Schwann cell, the perineurial cell, and the various nonspecific mesenchymal cells, such as fibroblasts and mast cells. These cells are capable of proliferation and malignant transformation. Other elements of the peripheral nerve, which are cell parts or products (i.e. axons and myelin, respectively), cannot duplicate. Schwann cells are derived from the neural crest and perineurial cells appear to be modified fibroblasts of mesodermal origin. This difference in histogenesis is also reflected in the distinct antigenic expression of these cells. Schwann cells express S100 protein and SOX10 but not perineurial markers (e.g. epithelial membrane antigen, GLUT1, claudin-1), whereas perineurial cells stain positively for perineurial markers but not S100 protein and SOX10. Axons contain a specific type of intermediate filament called neurofilament, and myelinated axons contain myelin basic protein, both of which can be detected by immunohistochemistry. These and other immunohistochemical markers often can help to establish the correct diagnosis.

In the following sections, each clinically relevant neural neoplasm is discussed (Tables 115.2–115.4).

NEUROMAS

Key features

Traumatic neuroma

- Develops at the site of previous trauma
- Skin-colored papule or nodule that is often painful or sensitive
- Circumscribed histologically, but not encapsulated
- Regenerative proliferation of axons and Schwann cells within fibrous scar tissue

Solitary circumscribed neuroma

- Formerly known as "palisaded encapsulated neuroma"
- Solitary papule or nodule, usually on the face of adults
- Circumscribed histologically; partially or completely encapsulated
- Compactly arranged fascicles of spindle cells with only vague palisading of nuclei

Introduction

Neuromas are proliferations of neural tissue in which the ratio of axons to Schwann cells is only slightly less than the normal 1 : 1 ratio. There are two major subtypes: *traumatic (or amputation) neuroma* and *solitary circumscribed neuroma* (SCN). Traumatic neuromas are complex regenerative proliferations of nerve fibers that follow injury. SCN, formerly known as palisaded encapsulated neuroma, is a benign peripheral nerve sheath tumor whose development is not preceded by apparent tissue injury.

History

The current view of traumatic neuroma was introduced by Huber and Lewis based on the concept of Wallerian degeneration. SCN was described by Reed and co-workers in 1972[4].

Epidemiology

Traumatic neuromas are relatively uncommon but can occur at any age and in either sex. They are more prevalent in professions with a high probability of physical injuries. SCN develops spontaneously and gradually without obvious preceding trauma. These tumors appear during adulthood (mean age, 45 years), and there is no sex predisposition or association with known tumor predisposition syndromes[2–4].

Pathogenesis

The term "neuroma" refers to a benign nerve sheath tumor characterized by a relatively balanced proliferation of Schwann cells and axons, resulting in an axon to Schwann cell ratio close to the normal 1 : 1 ratio[5].

CLASSIFICATION OF CUTANEOUS NEURAL AND NEUROENDOCRINE TUMORS	
Tumors of the peripheral nerve sheath and related structures	**Neural heterotopias**
Neuromas	Meningeal
• Traumatic (amputation) • Solitary circumscribed (palisaded encapsulated) • Multiple mucocutaneous (non-encapsulated) • Epithelial sheath	• Meningocele • Rudimentary meningocele (type 1 meningioma)
	Neuroglial
	• Nasal glial heterotopia ("nasal glioma")
Schwannomas	**Neuroblastic/ganglionic tumors**
• Common • Ancient • Cellular • Plexiform • Epithelioid • Microcystic/reticular • Psammomatous melanotic (malignant melanotic schwannian tumor)	• Primary primitive neuroectodermal tumor • Neuroblastoma • Ganglioneuroma
	Miscellaneous neural and neuroendocrine tumors
Neurofibromas	• Meningioma (type II and type III) • Primary low-grade neuroendocrine carcinoma of the skin (primary cutaneous carcinoid tumor) • Neuroendocrine carcinoma of the skin (Merkel cell carcinoma) • Pigmented neuroectodermal tumor of infancy
• Common (localized cutaneous) • Diffuse • Intraneural (localized) • Plexiform • Ancient (with cytological atypia) • Atypical neurofibromatous neoplasm of uncertain biologic potential (ANNUBP)	
Nerve sheath myxoma* Granular cell tumor Perineurioma • Soft tissue • Sclerosing • Other variants Hybrid peripheral nerve sheath tumor Malignant peripheral nerve sheath tumor	

*Cellular neurothekeoma is now regarded as a distinct entity with no evidence of neural differentiation.

Table 115.1 Classification of cutaneous neural and neuroendocrine tumors.

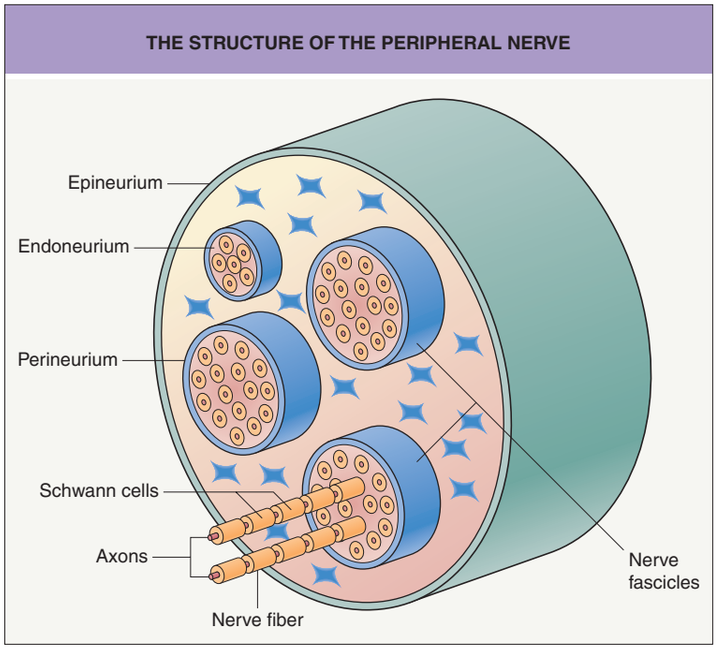

Fig. 115.1 The structure and components of the peripheral nerve.

Fig. 115.2 Traumatic neuroma. A painful, firm papule that appeared after a deep puncture injury.

Traumatic neuromas represent exuberant proliferations of nerve fibers that develop in response to an extrinsic nerve injury. Ideally, a severed nerve is reestablished via an orderly growth of axons and proliferating Schwann cells from the proximal to the distal end of the nerve[6]. If the two nerve ends are not maintained in close apposition, the reparative process fails, resulting in a tangle of irregularly proliferating proximal nerve fascicles embedded within scar tissue.

In SCN there is a coupled proliferation of Schwann cells and axons within the confinement of the perineurium. Its exact pathomechanism remains to be determined. Although a reactive process following minor tissue injury (e.g. facial acne) has been postulated, no definite traumatic origin has been demonstrated[2].

Clinical Features

Traumatic neuromas are usually solitary, skin-colored or reddish purple, firm papules or nodules at sites of wounds, surgical scars, and amputations[7,8] (Fig. 115.2). On the lower extremities, they may be multiple[7]. Early lesions are asymptomatic, but after a few months they gradually become painful, frequently with a lancinating character. Variable tingling and itching can be associated with the pain.

In neonates and young infants, similar lesions may be located on the lateral surface of a normal digit, most commonly the ulnar side of the fifth digit. Such tumors, also referred to as "rudimentary supernumerary digits", have traditionally been regarded as traumatic neuromas secondary to amputation of supernumerary digits *in utero*[9] (see Fig. 64.24). However, on histologic examination, there is no evidence of a pre-existing supernumerary digit, leading some authors to propose that these lesions may represent true congenital malformations.

SCNs present as asymptomatic, rubbery to firm, skin-colored to pink papules or nodules ranging in diameter from 2 to 6 mm[4]. Approximately 90% are located on the face, primarily around the nose, but they also occur on the cheek, chin, lips, and oral mucosa[10]. The remaining 10% occur elsewhere, including the trunk and extremities.

In MEN2B, also referred to as multiple mucosal neuroma syndrome or MEN type 3, numerous soft, skin- or mucosa-colored papules and nodules appear on the eyelid margins, mucosal lips, tongue, and conjunctivae, as well as the nasal and laryngeal mucosae (see Fig. 63.2). Additional findings include pheochromocytomas, medullary carcinoma of the thyroid, gastrointestinal ganglioneuromatosis, rare perinasal cutaneous neuromas, and palpable foci of dermal hyperneury (see Table 63.2). Multiple mucocutaneous neuromas with a predilection for the face and distal extremities may also be a manifestation of the PTEN hamartoma tumor syndrome (see Tables 63.3 & 63.4).

Pathology

Traumatic neuromas are usually well-circumscribed nodules located at any level of the dermis or the subcutis. They are encased by a fibrous sheath, although the distal end can be poorly defined. The proliferation is composed of a chaotic, poorly organized tangle of fascicles of various

CLINICAL FEATURES OF BENIGN NEURAL NEOPLASMS							
	Traumatic (amputation) neuroma	**Solitary circumscribed neuroma (SCN)**	**Schwannoma**	**Neurofibroma**	**Nerve sheath myxoma**	**Cellular neurothekeoma***	**Granular cell tumor**
Incidence	Uncommon	Rare	Uncommon	Very common	Rare	Rare	Rare
Age	Any	Adults (30–60 years)	Adults (30–50 years)	Adults (20–60 years)	Any	Early adulthood (mean age, 24 years)	Adults (30–50 years)
Sex	M:F = 1:1	M:F = 1:1	M:F = 1:1	M:F = 1:1	M:F = 1:1	F:M = 2:1	F>M
Number	Usually solitary	Usually solitary	Usually solitary (>90%)	Usually solitary	Usually solitary	Usually solitary	Usually solitary (10% multiple)
Location	At sites of trauma, surgical scars, amputations	90% face, 10% elsewhere	Flexor aspect of an extremity, head	Trunk, head (solitary type)	Distal extremities	Predominantly on head and upper extremities	25% tongue, 75% elsewhere, mainly head and neck
Size	0.5–2.0 cm	0.2–0.6 cm	0.5–3.0 cm	0.2–2.0 cm	0.5–1.0 cm	0.5–3.0 cm	0.5–3.0 cm
Clinical appearance	Skin-colored to reddish purple, firm papule or nodule	Skin-colored or pink, rubbery to firm papule or nodule	Soft, skin-colored to pink or yellow, smooth-surfaced nodule or tumor	Skin-colored, soft or rubbery papule or nodule, sometimes pedunculated	Soft, skin-colored papule or nodule	Pink, red, or brown, firm papule or nodule	Skin-colored to brownish red, firm papulo-nodule; may have ulcerated or verrucous surface
Symptoms	Variable; tingling, pruritus, lanci-nating pain	Asymptomatic	Asymptomatic; occasionally painful or tender; rarely paresthesias; occasionally freely movable	Asymptomatic; "buttonhole" sign may be present	Asymptomatic	Usually asymp-tomatic, rarely painful or pruritic	Asymptomatic or occasionally tender or pruritic
Association	NA	Multiple (non-encapsu-lated) neuromas in MEN2B (mucosal) and PTEN hamartoma tumor syndrome (mucocuta-neous)	Neurofibromatosis type 2, schwan-nomatosis	If multiple, may be sign of one of the various forms of neurofibro-matosis (see Ch. 61)	NA	NA	Multiple tumors more frequently occur in African-Americans and RASopathies (NF1, Noonan syndrome, Noonan syndrome with multiple lentigines)
Clinical differential diagnosis	Hypertrophic scar, derma-tofibroma, foreign body granuloma, granular cell tumor, neurothekeoma, phantom limb pain (amputation)	Basal cell carcinoma, adnexal tumor, IDN, neurofibroma, schwannoma, nerve sheath myxoma; when multiple, adnexal tumors (see Fig. 111.5)	Neurofibroma, lipoma, angio-lipoma, cyst (epidermoid, pilar, dermoid, ganglion), IDN, adnexal tumors (including sebaceous), SCN, leiomyoma	IDN, soft fibroma, schwannoma, fibrolipoma, SCN, nerve sheath myxoma, anetoderma, lipoma, cyst (epidermoid, pilar)	IDN, neuro-fibroma, schwannoma, lipoma, cyst (myxoid, ganglion, epidermoid, pilar)	Dermatofibroma (including sclerosing heman-gioma variant), adnexal tumor, hypertrophic scar, keloid, granular cell tumor, SCN, fibrosed dermal or compound melanocytic nevus	Tongue: irritation (traumatic) fibroma, verruca, SCC Elsewhere: dermatofibroma, regressing verruca, adnexal tumor, prurigo nodularis, fibrosed melano-cytic nevus, SCC
Other	"Rudimentary supernu-merary digit" is considered a variant (Ch. 64)		Melanotic schwannoma is a distinct entity and may be associated with Carney complex	Plexiform variant is pathogno-monic for NF1		Gene expression profile suggests fibrohistiocytic differentiation	Visceral forms occur; true malignant trans-formation rare

*Cellular neurothekeoma is no longer considered to be a neural neoplasm.

Table 115.2 Clinical features of benign neural neoplasms. NA, not applicable; IDN, intradermal melanocytic nevus; MEN2B, multiple endocrine neoplasia, type 2B; NF1, neurofibromatosis type 1; SCC, squamous cell carcinoma.

sizes and shapes (Fig. 115.3). Between the fibers are variable amounts of fibrous tissue with or without inflammatory cells and mucin[5]. The constituent cells are Schwann cells and accompanying perineurial cells with spindle-shaped nuclei and cytoplasm. Special stains show several axons in an irregular, haphazard pattern[1,2].

SCNs present as well-circumscribed, ovoid or round nodules within the mid dermis, although some lesions may extend into the subcutis; occasionally, there is a multinodular, plexiform growth pattern. The tumor appears at least partially encapsulated by a thin connective tissue sheath composed of perineurial cells[10] (Fig. 115.4). The parenchyma consists of interwoven fascicles of spindled cells. Fascicles are compactly and relatively uniformly arranged, occasionally separated by clefts. The stroma is relatively monomorphous, and in contrast to traumatic neuromas, there is no evidence of inflammation, granulation tissue, or scarring[5].

HISTOLOGIC DIFFERENTIAL DIAGNOSTIC FEATURES OF COMMON CUTANEOUS NEURAL NEOPLASMS				
	Traumatic neuroma	**Solitary circumscribed neuroma**	**Schwannoma**	**Neurofibroma (localized cutaneous variant)**
Location in the skin	Any level of dermis or subcutis	Mid dermis, occasionally extending into subcutis	Deep dermis or subcutis	Any location in the dermis
Growth pattern	Usually well circumscribed but may be poorly defined at the distal end	Well circumscribed, nodular, rarely plexiform	Well circumscribed, nodular or ovoid	Poorly to well circumscribed
Encapsulation	Usually encased by a fibrous sheath	Yes, by perineurium	Yes, by perineurium	Not encapsulated in the dermis
Architecture	Chaotic, poorly organized tangle of fascicles of various sizes and shapes	Compactly arranged fascicles; frequent clefts between fascicles	Hypercellular areas (Antoni A), fascicles in various patterns, hypocellular areas (Antoni B), edematous, myxoid	Fine fibrillary lattice of haphazardly arranged spindle cells in variably dense matrix
Constituent cell types	Schwann cells, perineurial cells, fibroblasts, mast cells, macrophages	Schwann cells (99%), perineurial cells (in capsule only)	Schwann cells (99%), perineurial cells (in capsule only)	Schwann cells, perineurial cells, fibroblasts, mast cells
Cytologic features	Spindle cells with indistinct cytoplasmic contours and tapered slender nuclei	Spindle cells with indistinct cytoplasmic contours and tapered slender nuclei	Spindle cells with indistinct cytoplasmic contours and slender nuclei	Spindle cells with slender nuclei, plump fibroblasts
Nuclear palisading	None	Usually present, but indistinct	Yes (Antoni A areas)	Rarely
Verocay bodies	None	None	Often	None
Nerve fibers (axons)	Yes; abundant, irregular pattern	Yes; abundant, often in a parallel arrangement	Yes; very rare, more frequent at the site of the connecting nerve	Yes; rare, scattered
Other important features	Nerve of origin frequently present, extensive fibrosis	Nerve of origin frequently present, no fibrosis	Mast cells; may have extensive degenerative changes (e.g. hyalinization, hemorrhage) in Antoni B areas ("ancient changes")	Variable fibrosis and myxoid changes, mast cells, occasional blood vessels
Histopathologic differential diagnosis	Hypertrophic scar, neurofibroma, schwannoma, palisaded encapsulated neuroma	Traumatic neuroma, schwannoma, angioleiomyoma, myofibroma	Palisaded encapsulated neuroma, angiomyoma, fibrous histiocytoma, traumatic neuroma	Melanocytic nevus with neuroid differentiation, dermatofibroma, hypertrophic scar, dermatofibrosarcoma protuberans, traumatic neuroma

Table 115.3 Histologic differential diagnostic features of common cutaneous neural neoplasms.

IMMUNOHISTOCHEMICAL STAINING OF CUTANEOUS NEURAL NEOPLASMS AND THE MAJOR TUMORS IN THE DIFFERENTIAL DIAGNOSIS							
Neoplasm	**Immunohistochemical stain**

*Similar pattern of immunoreactivity may be observed with GLUT1 and claudin-1
†Very sparse axons may be demonstrated in serial immunostained sections
‡In some variants, staining pattern may be variable
¶The rare perineurial variant is S100(–) / SOX10(–) / EMA(+)
^Positive in psammomatous melanotic schwannomas.
^^In the pigmented variant (Bednar tumor), scattered S100-/SOX10-/Melan-A-positive dendritic melanocytes are seen but the neoplastic cells are negative.

Table 115.4 Immunohistochemical staining of cutaneous neural neoplasms and the major tumors in the differential diagnosis. EMA, epithelial membrane antigen; Melan-A, melanocyte-related antigen; NF, neurofilament; S100, S100 protein; SMA, smooth muscle actin. +, positive; –, negative.

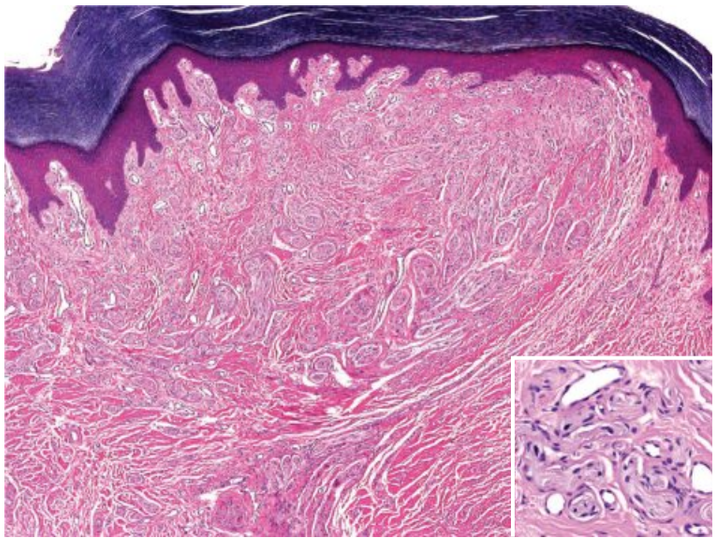

Fig. 115.3 Traumatic neuroma. Acral lesion with a chaotic proliferation of nerve fascicles is embedded in a fibrous stroma. Note nerve fascicles within a fibrotic stroma (inset). *Courtesy Lorenzo Cerroni, MD.*

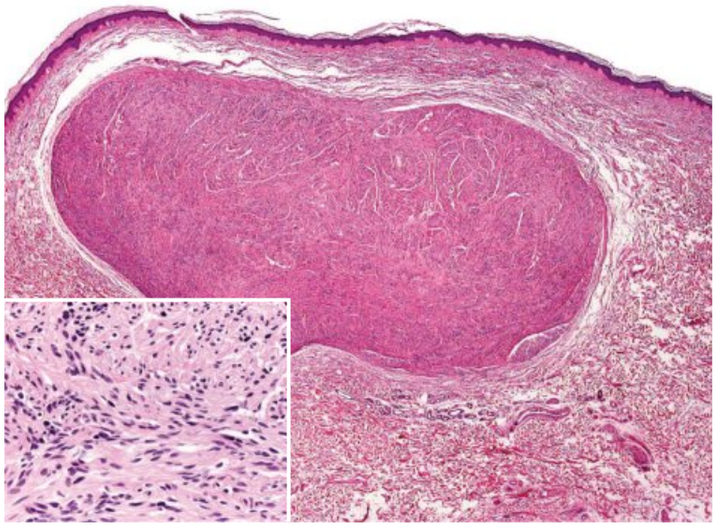

Fig. 115.4 Solitary circumscribed neuroma. The well-circumscribed dermal nodule appears encapsulated. Note nerve fascicles (inset). *Courtesy Lorenzo Cerroni, MD.*

The nuclei of the spindle-shaped tumor cells are elongated and wavy with tapered ends and an evenly basophilic chromatin pattern. Occasionally, a parallel arrangement of the nuclei is present, but distinct palisading or Verocay body formation is unusual[11–13]. No appreciable nuclear pleomorphism or mitotic activity is observed. In contrast to schwannomas, abundant axons throughout the tumor nodules may be highlighted via special stains[11] (Fig. 115.5).

Mucosal neuromas in MEN2B consist of non-encapsulated, tortuous proliferations of nerve bundles with a prominent perineurium, while dermal hyperneury is characterized by an increased number of enlarged and haphazardly arranged dermal nerves. Epithelial sheath neuroma represents a more recently described entity in which there is hyperplasia of mature nerve fascicles within the dermis (akin to dermal hyperneury), but each fascicle is surrounded by an aberrant sheath of squamous epithelium instead of normal perineurium; these features must be distinguished from perineural invasion by malignant tumors[14].

Differential Diagnosis

The diagnosis of traumatic neuroma is usually suspected by the history of a painful or symptomatic papulonodule at a site of injury and is confirmed by pathologic examination. Clinically, SCNs may resemble a BCC, adnexal tumor, intradermal melanocytic nevus, or neurofibroma (see Table 115.2). The diagnosis usually depends upon histologic examination (see Table 115.3).

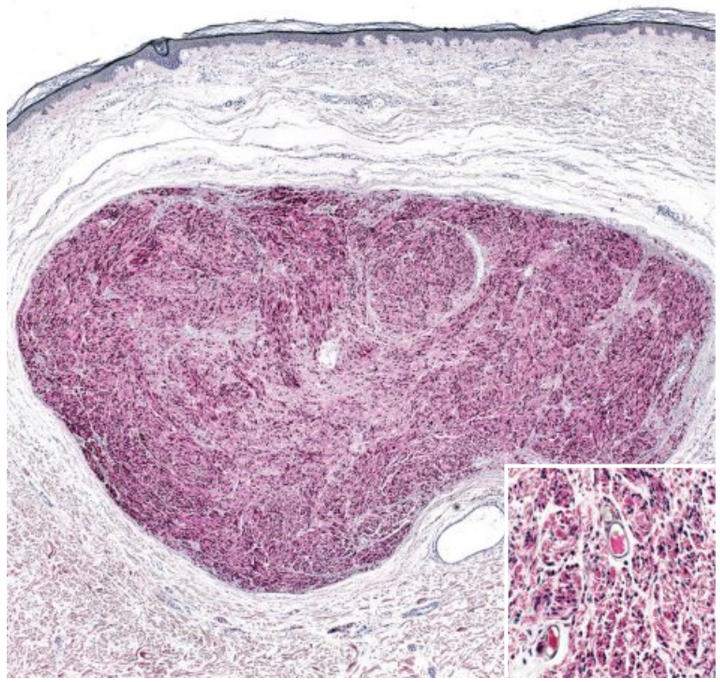

Fig. 115.5 Solitary circumscribed neuroma. Diffuse positivity for S100 within the dermal nodule. Note expression of S100 by the nerve fascicles (inset). *Courtesy Lorenzo Cerroni, MD.*

Treatment

Surgical excision of traumatic neuromas is recommended, with an attempt to reposition the proximal nerve stump into a scar-free area[7]. SCNs are easily excised, and some can even be enucleated from the surrounding dermis or subcutaneous tissue[4].

SCHWANNOMA

Synonyms: ■ Neurilemmoma ■ Neurolemmoma ■ Schwann cell tumor ■ Acoustic neuroma

Key features

- Solitary papulonodule that usually appears on the flexural aspect of an extremity, along a peripheral nerve
- Occasionally painful or tender
- Deep dermal or subcutaneous location
- Histologically, there is an encapsulated spindle cell proliferation with biphasic Antoni A and B areas, palisading of nuclei, and Verocay bodies; rare axons are present

Introduction

Schwannomas are benign encapsulated nerve sheath neoplasms nearly entirely composed of differentiated Schwann cells.

History

Stout coined the term "neurilemoma", referring to the closely applied sheath and covering of the tumor[15]. Because nearly the entire tumor is composed of Schwann cells, the designation "schwannoma" is preferred.

Epidemiology

Schwannomas may occur at any age, with a peak incidence during the fourth to sixth decades of life. There is no sex or racial predilection. Approximately 90% of schwannomas are solitary and occur sporadically[2]. Multiple schwannomas can be a manifestation of neurofibromatosis type 2 (NF2) or schwannomatosis, with both disorders having a mosaic (segmental) form. Patients with NF2, an autosomal dominant disorder, can develop meningiomas and bilateral vestibular schwannomas ("acoustic neuromas") (see Table 61.5)[2,16–19]. The latter tumors are unusual in schwannomatosis which is sporadic in the majority of patients (see below).

Psammomatous melanotic schwannoma (also more recently referred to as "malignant melanotic schwannian tumor") is a variant that typically arises from spinal and autonomic nerves[20]. This tumor may occur sporadically as well as in the setting of Carney complex (see Ch. 112). *Primary cutaneous* psammomatous melanotic schwannomas are exceedingly rare and appear to have a more indolent behavior than extracutaneous counterparts.

Pathogenesis

Because a schwannoma is a neoplastic proliferation of periaxonal or endoneurial Schwann cells, it develops as an encapsulated mass within the confines of the perineurium. Normal nerve fascicles are passively displaced to the periphery, with the bulk of the tumor appearing devoid of other normal peripheral nerve components[2]. Only after careful dissection can the attached nerve trunk be demonstrated.

Loss of expression of merlin, the oncosuppressor protein encoded by *NF2*[21,22], leads to the development of schwannomas. *Somatic* inactivating mutations in *NF2* occur in 50%–75% of sporadic schwannomas, while *germline* inactivating mutations lead to NF2. Both inherited and sporadic (~40% of patients) schwannomatosis are associated with germline mutations in either *SMARCB1* or *LZTR1*, coupled with somatic biallelic inactivation of *NF2* in each tumor[17–19]. The development of psammomatous melanotic schwannomas, either sporadically or in association with Carney complex, is related to inactivation of *PRKAR1A*.

Clinical Features

Schwannomas present as solitary, soft, skin-colored to pink or yellow, smooth-surfaced, dermal or subcutaneous papulonodules (Fig. 115.6). In general, their diameter ranges between 0.5 and 3 cm[23]. They are most commonly found on the flexor aspect of extremities along a larger nerve trunk, followed by the head and neck region[24]. Tumors are usually asymptomatic, but occasionally pain and tenderness occur, in particular if forceful movements place the attached nerve under tension. Motor disturbances and paresthesias are extremely rare[25].

Pathology

Schwannomas are well-circumscribed, nodular or ovoid tumors composed of differentiated Schwann cells. They are located in the deep dermis or subcutis and are almost always encapsulated. The tumors are composed of hypercellular (also called Antoni A-type tissue) and hypocellular (Antoni B-type tissue) areas[2]. Within areas of Antoni A-type tissue, there is proliferation of spindle cells with indistinct cytoplasmic contours and uniform nuclei[26]. Nuclear palisading is a typical finding and palisaded nuclei arranged in double rows can result in characteristic "Verocay bodies"[2,3] (Fig. 115.7). Mitotic figures are absent or rare.

Antoni B-type tissue areas have characteristic large, irregularly spaced vessels with thickened fibrotic walls, as well as variable degrees of edematous, mucinous, cystic, xanthomatous, and fibrotic changes within the hypocellular stroma. Such degenerative changes, which are often associated with some degree of cytologic atypia, are the predominant feature in so-called *ancient schwannomas*. These latter tumors should not be confused with *cellular schwannomas*, a histologic subtype composed largely of Antoni A-type tissue but lacking Verocay bodies, that rarely occur in the skin[27]. Axons are sparse in schwannomas and may be best detected at the tumor's periphery in proximity to nerve attachments[28].

Additional less common subtypes of schwannomas include plexiform, epithelioid (frequently associated with loss of SMARCB1 expression), and microcystic/reticular schwannomas[29–31]. In psammomatous melanotic schwannoma, a mixture of spindled and epithelioid cells that resembles syncytial tissue is seen. The cells have variable pleomorphism and nuclear atypia, and focal areas may demonstrate typical neural organization, i.e. nuclear palisading and whorl formation. Melanin deposition is often heavy, obscuring cytologic details. Psammomatous structures, consisting of eosinophilic laminated and whorled structures with variable calcification, are a frequent and characteristic finding. The cells stain positively for S100 protein and SOX10 and in psammomatous melanotic schwannomas also stain positively for Melan-A, HMB-45, and tyrosinase[32].

Differential Diagnosis

The clinical differential diagnosis includes neurofibroma, lipoma, angiolipoma, adnexal tumor, cyst (epidermoid, pilar, dermoid, ganglion), and intradermal melanocytic nevus. The diagnosis is made by histopathologic examination. Clinically, a psammomatous melanocytic schwannoma may resemble a blue, combined, or atypical melanocytic nevus.

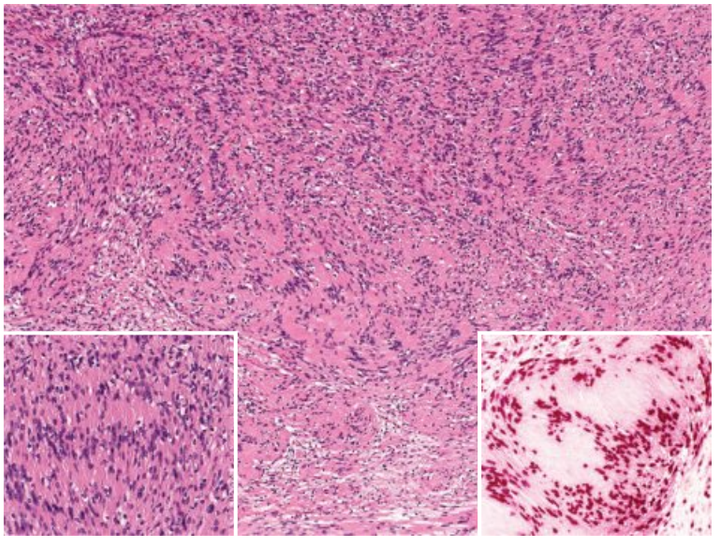

Fig. 115.7 Solitary cutaneous schwannoma. Hypercellular areas often show nuclear palisading and Verocay bodies. Detail of Verocay bodies and the nuclear expression of SOX10 (insets). *Courtesy Lorenzo Cerroni, MD.*

Treatment

Schwannomas are benign and a simple excision is curative. If the clinical diagnosis is suspected, the tumor should be removed by enucleation, preserving normal nerve function.

NEUROFIBROMA

Variants/synonyms: ■ Solitary neurofibroma – sporadic neurofibroma, solitary nerve sheath tumor ■ Plexiform neurofibroma

Key features

Solitary type

- Skin-colored to tan–violet papule or nodule
- May be pedunculated or have the "buttonhole" sign
- Predilection for the trunk and head
- Spindle cell proliferation with variable mixture of the components of the peripheral nerve, including residual axons
- Fibrosis and mucinous changes are common

Plexiform type

- Pathognomonic of NF1
- Large, occasionally pigmented, bag-like mass
- Favors the trunk and proximal extremities
- The plexiform variant has similar cytologic constituents as the solitary or sporadic type, but carries a risk of malignant transformation

Introduction

Neurofibromas are benign nerve sheath tumors composed of a complex proliferation of neuromesenchymal cells (Schwann cells, perineurial cells, fibroblasts, and mast cells), along with residual interspersed axons[2]. Cutaneous neurofibromas are common, especially as solitary lesions. The presence of multiple neurofibromas raises the possibility of one of the several types of neurofibromatosis, including the mosaic form (see Ch. 61). Plexiform neurofibromas are pathognomonic of NF1.

History

Neurofibromas were originally described as fibrous tumors by von Recklinghausen. A neuroectodermal origin was suggested by Verocay and eventually confirmed by immunohistochemical and ultrastructural studies.

Epidemiology

Localized cutaneous neurofibromas are the most common peripheral nerve sheath tumors, and have neither age nor sex preference. Diffuse and plexiform neurofibromas are considered to be of congenital origin.

Pathogenesis

Neurofibromas differ from schwannomas in that several cell types are involved in their histogenesis. Regardless of the histologic subtype of neurofibromas (e.g. localized cutaneous, diffuse, plexiform), the basic process is proliferation of the entire "neuromesenchyme", which includes Schwann cells, perineurial cells, endoneurial fibroblasts, and mast cells[2]. Axons are easily found in neurofibromas, although the axon to Schwann cell ratio is significantly lower than the normal 1 : 1 ratio. Within a neurofibroma, only a subpopulation of Schwann cells is neoplastic, carrying a clonal biallelic inactivation of *NF1*. Nullizygosity ($NF1^{-/-}$) of Schwann cells is a prerequisite, but is not sufficient, for neurofibroma formation; the latter may require the promoting effect of a $NF1^{+/-}$ microenvironment, in particular *NF1*-haploinsufficient mast cells[33] (see Fig. 61.2). The pathogenesis of sporadic cutaneous neurofibromas remains unclear, as most of them show retained expression of neurofibromin[34].

Clinical Features

Clinically, *localized cutaneous* neurofibromas present as asymptomatic, skin-colored, soft or rubbery papulonodules. They range in size from 0.2 to 2 cm and may become pedunculated[2]. These tumors grow slowly and the "buttonhole" sign is often present[2], i.e. the tumor is easily invaginated. Approximately 10% of patients develop multiple localized cutaneous neurofibromas, with some of these patients having one of the several types of neurofibromatosis (see Ch. 61). Additional clinicopathologic subtypes of neurofibroma include diffuse, intraneural, and plexiform variants. The diffuse subtype may present as indurated or soft nodules and plaques, while the intraneural variant presents as solitary fusiform masses. Except for plexiform neurofibromas, these subtypes rarely undergo malignant change.

Plexiform neurofibromas are especially important because they are considered pathognomonic of NF1 and carry a significant risk of transformation into malignant peripheral nerve sheath tumors (MPNSTs)[2]. These neurofibromas affect large segments of a nerve, distorting it into a "bag of worms", and present as baggy or pedunculated subcutaneous masses that can feel rope-like on palpation and are frequently hyperpigmented (Fig. 115.8). Involvement of an entire extremity leads to elephantiasis neuromatosa. Recognition and correct patient management is crucial in these cases, especially in subtle forms of NF1, where the other cutaneous stigmata may not be obvious. The exact incidence of malignant transformation is not known but it is estimated to occur in 2%–30% of NF1 patients, depending on disease severity in the population studied[2].

Pathology

Neurofibromas are poor- to well-circumscribed, nodular or oblong tumors that can be located anywhere within the dermis and subcutis[2,3]. Even when localized grossly, they lack a capsule and tend to infiltrate surrounding soft tissues. The common *localized cutaneous* variant usually has its center in the superficial dermis, creating a dome-shaped or polypoid elevation of its surface (Fig. 115.9). The tumor is composed of a fine fibrillary lattice of haphazardly arranged slender spindle cells[35], and the stroma can be variably vascular, fibrotic, edematous or myxomatous. In addition to Schwann cells and perineurial cells, plump fibroblasts and mast cells are present. Vague palisading of nuclei may occur, occasionally with true Verocay body formation, and can be regarded as hybrid neurofibroma/schwannoma tumors[2,35]. Mitotic figures are absent or rare. By utilizing special stains, rare scattered axons may be demonstrated, as in all other variants.

The *diffuse* variant lacks a well-defined growth pattern as it infiltrates the dermis and subcutis; characteristically, Meissner body-like structures may be observed in the deeper parts of these tumors. Intraneural neurofibromas are well-circumscribed masses along a peripheral nerve, being encapsulated by perineurium or epineurium[2]. *Plexiform* neurofibromas consist of a tortuous mass of neurofibromatous tissue with

an intraneural origin (Fig. 115.10). The neoplastic tissue progressively expands within the nerve branch then extends into the surrounding soft tissue, resulting in the frequent combination of intraneural and diffuse extraneural growth patterns.

MPNSTs may develop from pre-existing plexiform neurofibromas via deletions of the *CDKN2A/CDKN2B* locus. While cytological atypia alone in neurofibromas is not worrisome ("ancient neurofibromas"), malignant transformation is heralded by an intermediate histopathologic step (so-called "atypical neurofibromatous neoplasm of uncertain biologic potential" [ANNUBP]), which is defined by a variable combination of nuclear atypia, increased cellularity, and increased mitotic activity[36].

Differential Diagnosis

The clinical differential diagnosis of a solitary neurofibroma includes an intradermal melanocytic nevus, schwannoma, soft fibroma, and fibrolipoma (see Table 115.2). The majority of solitary or sporadic neurofibromas have similar clinical and histologic features to the multiple papular neurofibromas seen in patients with NF1. Plexiform neurofibromas with overlying hyperpigmentation and hypertrichosis can resemble congenital melanocytic nevi. As the latter can undergo neurotization and may be accompanied by satellite lesions, examination of the patient for Lisch nodules, axillary freckling, and café-au-lait macules is essential. Histologically, a plexiform neurofibroma must be differentiated from other plexiform tumors, including plexiform schwannoma, plexiform SCN, and desmoplastic melanoma.

Treatment

Neurofibromas are usually treated by simple excision. The evaluation and management of plexiform neurofibromas and neurofibromatosis is discussed in Chapter 61.

NERVE SHEATH MYXOMA AND CELLULAR NEUROTHEKEOMA

Synonyms: ■ Myxoma of the nerve sheath ■ Neurothekeoma

Key features

- Two distinct entities previously classified as morphologic variants within the same spectrum
- Nerve sheath myxoma is a true benign nerve sheath tumor with schwannian differentiation
- Cellular neurothekeoma is a non-neural neoplasm of presumptive fibrohistiocytic differentiation
- Both tumors present as nonspecific skin-colored to red–brown papulonodules
- Histologically, both tumors have a lobular or fascicular pattern with variable deposition of extracellular mucin
- Benign behavior, but local recurrences may occur

Introduction

Classic (myxoid) nerve sheath myxoma and cellular neurothekeoma were initially regarded as subtypes of the same neuromesenchymal entity ("nerve sheath myxoma"), characterized by the proliferation of nerve sheath cells in a variably myxomatous stroma[37]. There is now sufficient evidence to state that cellular neurothekeoma is not related to nerve sheath myxoma or to the neural crest, but rather represents a non-neural mesenchymal neoplasm, perhaps of fibrohistiocytic differentiation[38]. As such, the term "neurothekeoma" is a misnomer.

History

Nerve sheath myxoma was first described as a specific entity by Harkin and Reed in 1969. The term "cellular neurothekeoma" was coined by Rosati and colleagues in 1986[2].

Epidemiology

True nerve sheath myxomas are rare, affecting all ages and both sexes equally[39]. Cellular neurothekeoma has a predilection for adolescents and young adults (<40 years of age) and is nearly twice as common in women as men[40].

Pathogenesis

True *nerve sheath myxomas* are superficial peripheral nerve sheath tumors characterized by a benign proliferation of schwannian cells in a plexiform/multinodular growth pattern plus abundant myxoid degeneration. A thin, incomplete layer of perineurial cells may surround the nodules, as in SCN[39,41]. The extreme mucin production may explain the difficulty in detecting axons in these tumors.

Cellular neurothekeoma has a controversial histogenesis. Despite its morphologic similarities to nerve sheath myxoma, there is no expression of schwannian differentiation markers (e.g. S100 protein, SOX10)[40,42]. Based upon gene expression profile analyses, cellular neurothekeoma is more closely related to fibrohistiocytic neoplasms[38].

Fig. 115.11 Cellular neurothekeoma of the scalp, presenting as a small, firm, erythematous nodule.

Clinical Features

Nerve sheath myxoma is a soft, skin-colored papule or nodule, generally 5 to 10 mm in diameter and typically located on the distal extremities[39].

Cellular neurothekeomas favor the head and neck region as well as the upper extremities, although cases from a variety of anatomic sites have been reported. These tumors are described as firm papulonodules that are pink, red, or brown in color and range in size from 0.5 to 3 cm (Fig. 115.11). Symptoms are nonspecific and seem to relate to the size and firmness of the tumor[40].

Pathology

Nerve sheath myxoma is a well-defined, lobular or plexiform neoplasm that is usually located in the reticular dermis (Fig. 115.12). It often appears encapsulated by a compression of the surrounding fibrous tissue[39]. There is a hypocellular myxoid stroma with rare scattered spindled, stellate, or dendritic cells. The cells usually have scant pale cytoplasm with indistinct cytoplasmic contours and hyperchromatic, ovoid, or angulated nuclei[39,41]. Nucleoli are small and mitotic figures are rare or absent. On occasion, multinucleated giant cells with eosinophilic cytoplasm can be identified. Histochemically, the myxoid stroma stains strongly positive for acidic mucopolysaccharides (see Ch. 46)[39]. In a minority of cases, scattered neurofilament-positive axons may be detected[41]. The tumor cells are positive for S100 protein, SOX10, and collagen type IV and the capsule has a weak and discontinuous expression of epithelial membrane antigen (EMA) and other perineurial markers[2,41].

Cellular neurothekeomas are composed of ill-defined multilobular masses or fascicles in the reticular dermis[40] (Fig. 115.13). In some cases, the growth pattern can be frankly infiltrative or dissecting without any hint of a residual capsule, and there may be involvement of the superficial subcutis[42,43]. Cytologically, the predominant cell types are epithelioid or polygonal cells with ample eosinophilic cytoplasm and round nuclei with an open chromatin pattern[40,43]. Many cells have prominent nucleoli. Less often, the constituent cells are spindle-shaped with hyperchromatic nuclei, resembling those observed in nerve sheath myxomas. Mitotic figures are often present but are usually normal morphologically. Rare cases with increased mitotic figures and cytologic atypia have been reported[43]. The stroma can be markedly fibrotic or even hyalinized. There is no detectable connection with peripheral nerves.

The tumor does not have a consistent immunohistochemical profile, with the nonspecific marker NKI/C3 expressed in essentially all cases. Expression of PGP9.5 (neuron-specific peptide), microphthalmia transcription factor (MITF; see Ch. 65), and smooth muscle actin may be observed in individual cases. Importantly, expression of S100 protein, SOX10, and perineurial markers is consistently absent[40,44,45].

Differential Diagnosis

A nerve sheath myxoma is usually asymptomatic and clinically is often mistaken for an intradermal melanocytic nevus, neurofibroma, lipoma, or cyst (e.g. myxoid, ganglion) (see Table 115.2). Clinically, a cellular neurothekeoma usually resembles a dermatofibroma (including the sclerosing hemangioma variant), hypertrophic scar, keloid, or granular cell tumor.

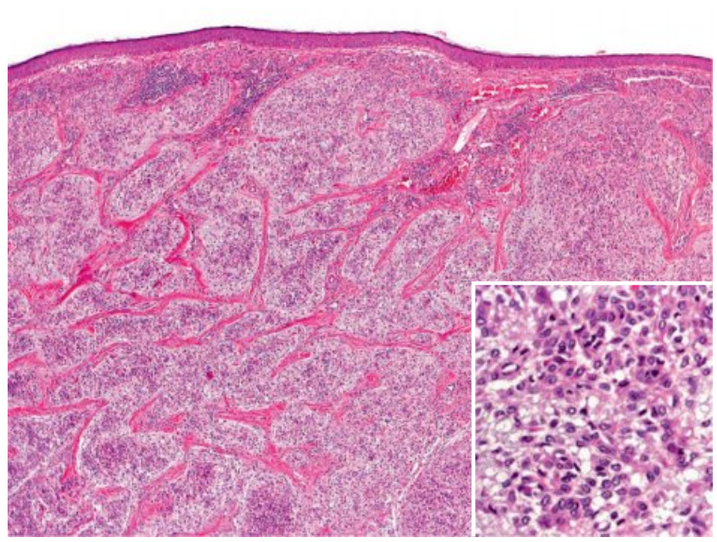

Fig. 115.13 Cellular neurothekeoma. Epithelioid nests are dispersed in a hyalinized stroma. Whorl-like arrangement of epithelioid cells with nuclear pleomorphism (inset). *Courtesy Lorenzo Cerroni, MD.*

Treatment

These lesions are usually treated by simple excision; however, if incompletely removed, a nerve sheath myxoma may recur. There have been a few case reports of atypical variants of cellular neurothekeoma with postulated uncertain behavior, in which case complete excision is recommended.

GRANULAR CELL TUMOR

Synonym: ■ Abrikossoff's tumor

Key features

- Seen more commonly in adults, women, and African-Americans
- Predilection for the head and neck, tongue, and breast, but may occur anywhere, including the viscera
- Malignant transformation is rare and usually occurs with deep-seated lesions
- Histologically, an ill-defined, infiltrative tumor, often with associated pseudoepitheliomatous (pseudocarcinomatous) hyperplasia
- Large polygonal cells with finely granular eosinophilic cytoplasm; the granules are PAS-positive, diastase-resistant

Introduction

Granular cell tumor is a neoplasm with neuroectodermal differentiation consisting of epithelioid to polygonal cells with granular change due to cytoplasmic accumulation of lysosomal granules. The exceedingly rare "cutaneous non-neural granular cell tumor" is a morphologically indistinguishable neoplasm that lacks expression of S100 protein or SOX10 and has frequent *ALK* (anaplastic lymphoma kinase gene) rearrangements[46]. Occasionally, granular cell change may occur in a variety of unrelated neoplasms as a secondary phenomenon (see below)[47].

History

This tumor was originally thought by Abrikossoff, who used the term "granular cell myoblastoma", to be derived from muscle[48]. Feyrter first suggested a neural origin.

Epidemiology

Granular cell tumor is a relatively rare tumor that occurs primarily in adults (age 30–50 years) and favors men and African-Americans. Up to 10% of patients have multiple lesions, and ~70% of tumors are located in the head and neck region, including 25% on the tongue[2]. Other common locations are the breast (5%–15%) and proximal extremities. Visceral lesions may develop in the gastrointestinal and upper respiratory tracts.

Pathogenesis

The neural origin of granular cell tumor has been a subject of debate, but immunohistochemical and ultrastructural studies have clearly proven its schwannian differentiation. Granular cells express S100 protein, SOX10, and CD57 (a neuronally expressed adhesion molecule), like Schwann cells[49–51]. Loss-of-function mutations in the V-ATPase accessory genes *ATP6AP1* (60%) and *ATP6AP2* (10%) have been detected in the majority of cutaneous and extracutaneous neural granular cell tumors, irrespective of anatomic site and biological behavior[52,53]. How inactivation of these membrane proton pumps leads to accumulation of lysosomes and tumorigenesis requires further investigation. Multiple cutaneous granular cell tumors can be seen in patients with RASopathies such as NF1, Noonan syndrome, and Noonan syndrome with multiple lentigines (LEOPARD syndrome), thus implying a role of the RAS/MAPK pathway in their pathogenesis[54] (see Fig. 55.4).

Clinical Features

A granular cell tumor presents as an asymptomatic or occasionally tender or pruritic, skin-colored to brownish-red, firm dermal or subcutaneous papulonodule, ranging in diameter from 0.5 to 3 cm. Occasionally, the surface will be ulcerated or verrucous. Granular cell tumors are slowly growing and in general have a benign behavior. Rarely, malignant behavior is observed (local infiltration or metastasis), more often when the tumor arises from a visceral or deep location. Malignant granular tumors may develop *de novo* or via malignant transformation of a pre-existing benign lesion[55].

Pathology

The dermis contains a poorly circumscribed nodule composed of polygonal, pale-staining cells that may infiltrate into the adjacent subcutis. The cells have abundant, granular, faintly eosinophilic cytoplasm with round, dark nuclei (Fig. 115.14)[56]. Characteristic larger cytoplasmic granules are called pustulo-ovoid bodies. With the PAS reaction, the granules are positive, but they are diastase-resistant. Occasionally, a perineurial growth pattern is present; however, the tumor is devoid of axons. Increased numbers of mast cells are present in some lesions, and the overlying epidermis is frequently hyperplastic. Rarely, a plexiform growth pattern has been described[56]. Histopathologic criteria predictive of aggressive behavior are not well established, but may include necrosis, increased mitotic rate, spindling of the cells, high nuclear:cytoplasmic ratio, vesicular nuclei, and nuclear pleomorphism[2,55,57].

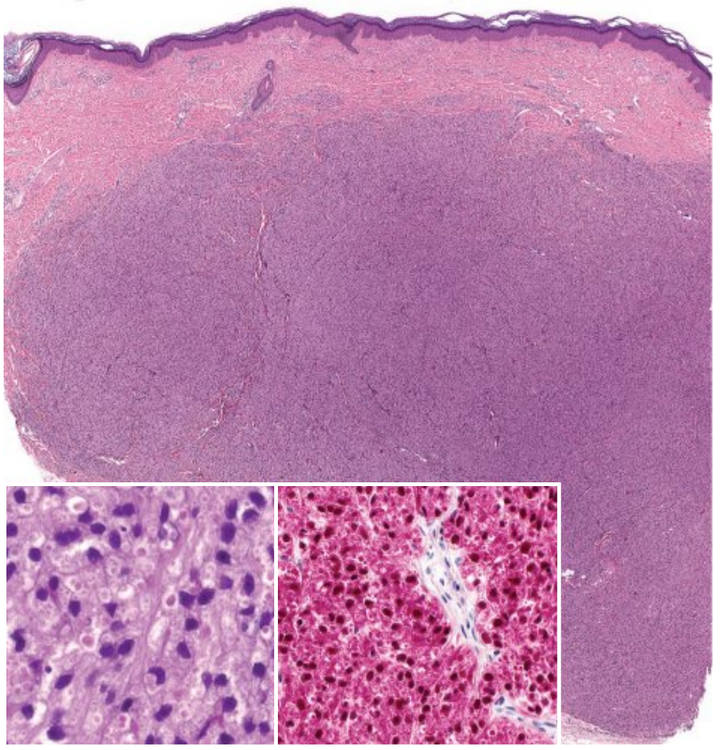

Fig. 115.14 Granular cell tumor. The tumor may show a nodular or infiltrative growth pattern. The large polygonal cells have finely granular cytoplasm, pustulo-ovoid bodies, and round nuclei (left inset) that stain positively for S100 (right inset). *Courtesy Lorenzo Cerroni, MD.*

True (neural) granular cell tumors express S100 protein, SOX10, PGP9.5 (neuron-specific peptide), and nerve growth factor receptor. The cells may stain positively for CD68 and NKI/C3, but are negative for the lineage-restricted histiocytic marker CD163 as well as melanocytic differentiation markers Melan-A and HMB-45. There may be diffuse nuclear reactivity for MITF and TFE3, posing a diagnostic challenge with *TFE3*-rearranged tumors and PEComas[58,59].

Differential Diagnosis

The clinical differential diagnosis of lingual lesions includes an irritation fibroma, verruca, and squamous cell carcinoma (SCC). Elsewhere, this tumor may resemble a dermatofibroma, regressing verruca, or adnexal neoplasm (see Table 115.2). Granular cell tumors can induce considerable pseudoepitheliomatous (pseudocarcinomatous) hyperplasia of the overlying epithelium, and superficial biopsy samples have been mistaken for SCC, especially on the tongue[60]. A variety of epithelial and mesenchymal neoplasms can show granular cell change, including BCCs, leiomyomas, dermatofibromas, and leiomyosarcomas[47].

Treatment

The treatment is complete excision. If incompletely excised, this tumor has a high local recurrence rate, due to the plexiform or perineurial growth pattern.

PERINEURIOMA

Synonyms: ■ Storiform perineurial fibroma ■ Fibrolamellar nerve sheath tumor ■ Localized hypertrophic neuropathy

Introduction

Perineuriomas represent a proliferation of perineurial cells, with both intraneural and extraneural growth patterns. These tumors are rare and Table 115.5 outlines their features.

KEY FEATURES OF SOFT TISSUE (EXTRANEURAL) PERINEURIOMAS OF INTEREST TO DERMATOLOGISTS
Clinical features
• Solitary, nondescript, skin-colored, soft tissue mass • Occurs primarily on the trunk and extremities of adults, with the sclerosing variant favoring the hands of young men
Histopathologic features
• Predominant cell type is the perineurial cell, which is a modified fibroblastic cell • In classic soft tissue perineurioma, there is a well-circumscribed (but non-encapsulated) proliferation of slender, elongated spindle cells within the dermis and/or subcutis; the latter form tightly woven fascicles, sometimes with a lamellar or storiform pattern (Fig. 115.15), and the intertwining stroma can be hyalinized or myxoid • In the sclerosing variant, there may be epithelioid cells alternating with spindle cells, intermixed with thick collagen bundles • Reticular perineurioma, another variant, is characterized by a lace-like arrangement of cells that leads to the formation of microscopic cysts • Hybrid benign peripheral nerve sheath tumors may show a perineurial neoplastic population closely intermingled with a schwannomatous (or more rarely neurofibromatous) population • Only very infrequent atypical cases have significant atypia and/or increased mitotic activity
Immunohistochemistry
• Cells stain positively for EMA, GLUT1, and claudin-1 • CD34 may be positive (60% of cases); S100 protein and SOX10 are invariably negative (with the exception of hybrid benign peripheral nerve sheath tumors)
Clinical differential diagnosis
• Benign soft tissue tumors (e.g. lipoma) and soft tissue sarcomas
Histologic differential diagnosis
• Neurofibromas with extensive fibrosis (S100-, SOX10-, and NF-positive), DFSP (EMA-, GLUT1-, and claudin-1-negative; CD34-positive), sclerosing fibroma (EMA-, GLUT1-, and claudin-1-negative)
Treatment
• Complete excision – biologic behavior usually benign, rarely malignant

Table 115.5 Perineuriomas – key features of extraneural variants of interest to dermatologists. DFSP, dermatofibrosarcoma protuberans; EMA, epithelial membrane antigen; NF, neurofilament. Claudin-1 is a tight junction-associated protein. Based upon references 122, 123, & 124.

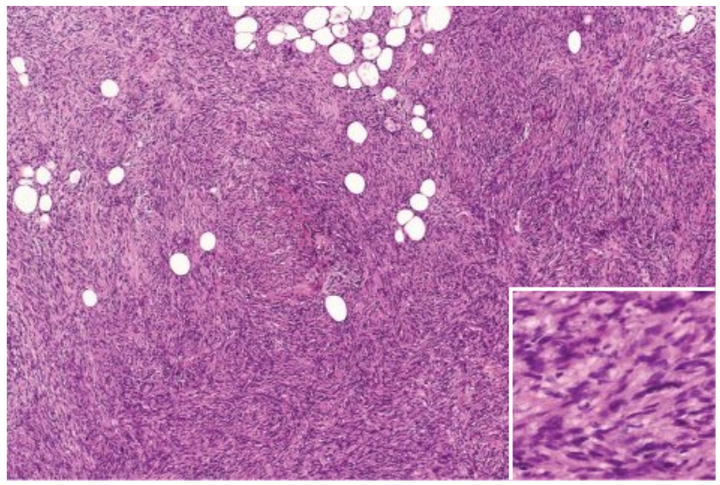

Fig. 115.16 Malignant peripheral nerve sheath tumor. Overall, the intersecting fascicles create a "herringbone" pattern. There is marked cellular pleomorphism with cytologic atypia and mitotic activity (inset). *Courtesy Lorenzo Cerroni, MD.*

MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

Synonyms: ■ Neurosarcoma ■ Malignant schwannoma

The term "malignant peripheral nerve sheath tumor" (MPNST) is preferable to the widely used but confusing synonyms above. This is because any cellular component of the peripheral nerve can give rise to these tumors, including perineurial or endoneurial fibroblasts (rather than Schwann cells)[61,62]. MPNST is primarily a tumor of deep soft tissues and rarely involves the skin. Despite its rarity, MPNST has clinical relevance for dermatologists because this malignancy develops within 2%–30% of plexiform neurofibromas, which are associated with NF1[63] (see Ch. 61).

A definitive diagnosis requires histologic examination, usually in conjunction with immunohistochemistry and molecular biologic analysis. Histologically, in the most common form, there is a proliferation of atypical spindle cells, often arranged in a "herringbone" pattern. There is variable cytologic atypia, numerous abnormal mitotic figures, and areas of necrosis and hemorrhage (Fig. 115.16)[61,62]. Staining for S100 protein and SOX10, if positive, is only patchy or focal[51]. Regardless of the clinical setting (sporadic, NF1-associated, or radiotherapy-associated), MPNSTs show frequent and concurrent loss-of-function mutations in *NF1*, *CDKN2A/CDKN2B*, and the polycomb repressive complex 2 (PRC2)-related genes *EED* or *SUZ12*[63]. Complete loss of PRC2 activity and an associated lack of immunohistochemical expression of the epigenetic marker H3K27me3 (trimethylation of lysine 27 on histone H3 which represses transcription) are observed in >80% of high-grade MPNSTs and may represent a useful tool for its differentiation from other soft tissue sarcomas[64].

MERKEL CELL CARCINOMA

Synonyms: ■ Primary neuroendocrine carcinoma of the skin ■ Trabecular carcinoma of the skin ■ Primary small cell carcinoma of the skin ■ Cutaneous apudoma

Key features

- Predilection for the head and neck region of older adults
- Solitary, rapidly growing nodule
- Histologically, tumor is composed of small, round blue cells, often with a nested or trabecular growth pattern
- High mitotic rate, frequent single-cell or zonal necrosis, often perinuclear dot-like CK20-positivity (pathognomonic)
- Approximately 40% of patients develop local, nodal, or distant metastasis

Introduction

Merkel cell carcinoma (MCC) is an aggressive cutaneous carcinoma that shares ultrastructural and immunohistochemical features with other neuroendocrine tumors. Although rare, the incidence of MCC is rapidly increasing along with the aging population. These tumors display nonspecific clinical features and highly aggressive behavior. Early recognition and adequate therapy are therefore critical.

History

This tumor was originally described by Toker and given the name "trabecular carcinoma" based on its lattice-like and infiltrative growth pattern[65]. Subsequently, the neuroendocrine nature of this tumor was recognized. Similarities to the normal Merkel cell of the skin led to its name[66].

Epidemiology

The male:female ratio is 1.5:1 and its incidence increases strikingly with age, e.g. MCC is 10 000 times more likely to arise in an 80-year-old individual than in a 20-year-old[67]. Other risk factors include lightly pigmented skin, extensive sun exposure, and chronic immunosuppression (e.g. organ transplantation recipients, hematologic malignancies)[68].

Pathogenesis

The cells of MCC and the normal Merkel cell, a touch-sensing cell located in the basal layer of the epidermis, share several features. However, the MCC's cell of origin is unclear and it appears unlikely that normal Merkel cells give rise to this carcinoma[66]. This tumor is also referred to as "primary neuroendocrine carcinoma of the skin", a term that is often used in pathology reports.

In 2008, a landmark discovery revealed the association of MCC with a novel polyomavirus, now referred to as Merkel cell polyomavirus (MCPyV)[69]. In humans, this polyomavirus is ubiquitous as it can be readily detected within the normal skin of most healthy people where it exists in an episomal form. Very rarely, a clonal integration event leads to critical portions of the virus being spliced into a human chromosome, ultimately resulting in MCC. Of note, the integration event must be accompanied by mutation(s) that lead to truncation of the large T antigen and inactivation of its helicase domain. If not inactivated, the helicase domain would initiate DNA replication at the integration site which would then lead to cell death. Inhibition of viral oncoproteins in polyomavirus-infected tumor cells results in a cessation of proliferation, suggesting that ongoing viral protein expression is required for MCCs[70].

In the US, ~80% of MCCs are driven by this polyomavirus[71], while the remaining 20% are virus-negative. The latter tumors arise in chronically sun-damaged skin and contain very high numbers of UV-signature mutations[72]. Interestingly, only about 40% of MCCs in Australia are virus-induced, with the majority related to ultraviolet exposure. In contrast, in Asian countries, where people have more pigmented skin, 90% of MCCs are virus-driven.

Clinical Features

This cutaneous carcinoma can develop at any site, but favors the head and neck region, followed by the extremities and the buttocks. It usually presents as a pink–red to violaceous, firm, dome-shaped, solitary nodule that has grown rapidly (Fig. 115.17)[67]. Ulceration can occur. Overall, the behavior is that of an aggressive tumor, with significant risk of local, regional, and/or distant recurrence and metastasis.

In an analysis of 9387 cases of MCC, 65% of patients presented with local disease whereas 26% and 8% presented with nodal or distant metastases, respectively[73]. Prior to the advent of immunotherapy,

Fig. 115.17 Merkel cell carcinoma (primary neuroendocrine carcinoma of the skin). A Exophytic violet tumor on the posterior thigh; the clinical differential diagnosis included lymphoma. **B** Minimally elevated violaceous plaque with peripheral blue color arising within the sun-protected skin of the buttocks; the clinical differential diagnosis included a vascular tumor. **C** Hemorrhagic purple nodule within sun-damaged skin on the scalp. **D–F** Large pink to red nodules arising in older adults within obvious photodamaged skin. The lesions can have a lobulated surface, central ulceration, or telangiectasias. *A–E, Courtesy Department of Dermatology, University Graz.*

five-year overall survival for these three groups was 50% (local disease), 35% (nodal disease), and 15% (distant disease). Tumor diameter at the time of diagnosis influences prognosis, with lesions >2 cm (but without invasion of fascia) having a 40% overall survival at five years (compared to 55% for tumors ≤2 cm; Table 115.6)[73].

Occasionally, paraneoplastic syndromes, similar to those seen with other neuroendocrine carcinomas, occur in patients with MCC. These include malignancy-associated hyponatremia and Lambert–Eaton myasthenic syndrome.

Pathology

The tumor appears as a poorly defined dermal mass, often infiltrating the subcutaneous fat, fascia, and even muscle. While it may show various growth patterns, a sheet-like growth pattern is seen most commonly, followed by nested and trabecular patterns (Fig. 115.18A)[74]. Characteristically, the edge of the tumor shows a trabecular infiltrating pattern[65]. The tumor is composed of monotonously uniform, small, round to oval cells that are about two to three times larger than mature lymphocytes[65,66]. Their cytoplasm is scant and faintly amphophilic. The nuclei of these cells are ovoid with a finely dispersed chromatin pattern and distinct nuclear membranes (Fig. 115.18B). Nucleoli are usually not prominent, but mitotic figures are abundant. Extensive areas of necrosis, individual cell necrosis, and characteristic crush or drying artifacts are common[74]. Intralymphatic involvement by tumor cells is not uncommon, sometimes distant from the main tumor mass. In some cases, single neoplastic cells or tiny aggregates are present at the edge of the biopsy specimen, rendering evaluation of the surgical margin difficult without the aid of immunohistochemistry (see below).

Various types of differentiation have been described in MCC, including rosette-like structures resembling Homer Wright rosettes of neuroblastoma, epidermotropic involvement with pagetoid spread, and eccrine and squamoid differentiation[75,76]. Immunohistochemically, there is a characteristic perinuclear globule upon staining for low-molecular-weight cytokeratins (CK) such as CK20, CK5/6, and CK7 (Fig. 115.18C). This corresponds to the ultrastructural distribution of paranuclear whorls of intermediate filaments[74,75]. In addition, there is positive staining for various neuroendocrine markers, including chromogranin, synaptophysin, somatostatin, calcitonin, and vasoactive intestinal peptide[75]. These peptides are associated with ultrastructurally demonstrable, membrane-bound, dense-core secretory granules.

The tumor also expresses neuron-specific enolase and occasionally neural filaments, CD56, and CD99; however, immunostaining for S100 protein is characteristically negative[75]. Likewise, a negative reaction for thyroid transcription factor 1 (TTF-1) helps to differentiate MCC from cutaneous metastases of other small cell carcinomas (pulmonary and extrapulmonary); the latter are characteristically positive for this marker[75]. Recognition of MCPyV, which can be detected by immunohistochemical (e.g. T antigen) and molecular biologic methods[77], provides an additional tool for diagnosis; however, false-positive PCR results are possible given the ubiquitous nature of the virus. For prognostication, increased p63 expression may portend clinically aggressive behavior, but to date has not altered prognosis based upon stage (Table 115.6)[78]. Negativity for MCPyV may associated with a somewhat poorer prognosis, whereas ALK-positive MCC (which is usually accompanied by MCPyV positivity) appears to have a less aggressive behavior[72,79]. A dataset for the reporting of MCCs has recently been proposed[79a].

Differential Diagnosis

The differential diagnosis of early-stage MCCs includes keratinocyte carcinomas, epidermoid cysts, adnexal tumors, and amelanotic melanoma. When tumors are violaceous or hemorrhagic, the differential

MERKEL CELL CARCINOMA – 8TH AJCC STAGING SYSTEM				
Stage		**Primary tumor**	**Lymph node**	**Distant metastasis**
0		*In situ* (only within the epidermis)	No regional lymph node metastasis	No
I	Clinical*	≤2 cm maximum tumor dimension	Nodes negative by clinical examination (no pathologic examination performed)	No
I	Pathologic†	≤2 cm maximum tumor dimension	Nodes negative by pathologic examination	No
IIA	Clinical	>2 cm tumor dimension	Nodes negative by clinical examination (no pathologic examination performed)	No
IIA	Pathologic	>2 cm tumor dimension	Nodes negative by pathologic examination	No
IIB	Clinical	Primary tumor invades bone, muscle, fascia, or cartilage	Nodes negative by clinical examination (no pathologic examination performed)	No
IIB	Pathologic	Primary tumor invades bone, muscle, fascia, or cartilage	Nodes negative by pathologic examination	No
III	Clinical	Any size/depth tumor	Nodes positive by clinical examination (no pathologic examination performed)	No
IIIA	Pathologic	Any size/depth tumor	Nodes positive by pathologic examination only (nodal disease not apparent by clinical examination)	No
		Not detected ("unknown primary")	Nodes positive by clinical examination; confirmed by pathologic examination	No
IIIB	Pathologic	Any size/depth tumor	Nodes positive by clinical examination and confirmed by pathologic examination – *or* – In-transit metastasis‡	No
IV	Clinical	Any	Regional nodal involvement +/–	Distant metastasis detected clinically
IV	Pathologic	Any	Regional nodal involvement +/–	Distant metastasis confirmed by pathologic examination

*Clinical detection of nodal or metastatic disease may be via inspection, palpation, and/or imaging.
†Pathologic detection/confirmation of nodal disease may be via sentinel lymph node biopsy and pathologic confirmation of metastatic disease may be via biopsy of the suspected metastasis.
‡In-transit metastasis: a tumor distinct from the primary lesion and located either: (1) between the primary lesion and the draining regional lymph nodes; or (2) distal to the primary lesion.

Table 115.6 Merkel cell carcinoma – 8th American Joint Committee on Cancer (AJCC) staging system. While more extensive lymph node involvement portends a poorer prognosis, the number of positive lymph nodes is not factored into the staging of MCC. *Adapted from www.merkelcell.org/staging and Harms KL, Healy MA, Nghiem P, et al. Analysis of prognostic factors from 9387 Merkel cell carcinoma cases forms the basis for the new 8th edition AJCC staging system. Ann Surg Oncol 2016;23:3564–71.*

diagnosis also includes pyogenic granuloma, hemangioma, angiosarcoma, and lymphoma (see Fig. 115.17A–C). Histologically, there is a broad spectrum of small, round, blue cell tumors of diverse histogenesis that can be confused with MCC[75]. These include metastatic neuroendocrine carcinoma of the lung (small cell or oat cell carcinoma), poorly differentiated eccrine carcinoma, lymphoma, metastatic neuroblastoma, primary peripheral primitive neuroectodermal tumor, Ewing sarcoma, melanoma, and poorly differentiated SCC[74,75].

Treatment

For newly diagnosed locoregional MCC, surgery remains the principal initial therapy. Excision of the primary tumor plus sentinel lymph node biopsy (SLNB) are recommended for most patients (Fig. 115.19), with these procedures also providing prognostic information[80–82]. SLNB positivity at the time of the initial MCC diagnosis is estimated to be 35%[83]. Age >65 years, immunosuppression, primary tumor on the trunk, and larger tumor size are associated with higher rates of SLN positivity[83,84]. However, even tumors ≤5 mm are associated with a positive SLNB in ~15% of patients[83]. Surgery is often followed by radiation therapy to the primary site and in some patients, the draining lymph node basin (see Fig. 115.19).

The management of MCC often requires a multidisciplinary approach with involvement of surgeons, medical and radiation oncologists, and dermatologists. Updated guidelines are readily available[85] and Fig. 115.19 provides a current algorithm for evaluation and treatment[86–93].

Prior to the advent of immunotherapy, cytotoxic chemotherapy was the primary option for advanced stage disease, but responses were not durable[94]. Several clinical trials, in which anti-PD-1 and anti-PD-L1 antibodies demonstrated significantly improved progression-free survival and overall survival compared to historical data for conventional chemotherapy[90–93,93a], led to FDA approval of avelumab, pembrolizumab, and retifanlimab. These antibodies are now considered first-line therapies for advanced MCC[85]. However, primary or acquired resistance to immunotherapy remains a major challenge, ultimately affecting >50% of treated patients[90–93,93b].

Careful surveillance is important because MCC recurs in up to 40% of patients[95] and effective treatments are now available. A baseline determination (within a few months of initial therapy) of the presence or absence of circulating antibodies against the Merkel virus oncoprotein is recommended[96]. In seropositive patients, antibody titers correlate with tumor burden and represent a sensitive and specific assay that can be followed longitudinally[96,97]. However, ~50% of patients do not produce these antibodies[96,97] and surveillance via imaging is required in these seronegative patients. The latter group may have an ~40% higher risk of recurrence compared to seropositive patients of the same stage.

Over 80% of recurrences of MCC arise within the first 3 years after diagnosis[95]. There is a web-based recurrence risk calculator (merkelcell.org/recur) that factors in stage as well as the disease-free interval since treatment, immune status, sex, age, and location of the primary site. This calculator provides an accurate assessment of a patient's ongoing risk of recurrence and assists in planning frequency of surveillance testing.

HETEROTOPIC NEURAL TISSUE OF THE SKIN

These rare lesions develop from embryologically misplaced neural tissue within the skin.

Nasal Glial Heterotopia

Synonyms: ■ Nasal glioma ■ Nasal neuroglial heterotopia ■ Nasal heterotopic brain tissue

Key features

- Rare, benign, congenital lesion
- Most common near the root of the nose, but can be intranasal
- Solitary, firm, smooth, skin-colored to red–purple papulonodule
- Microscopically, lobulated neuroglial tissue

History

The term "nasal glioma" was introduced by Schmidt in 1900.

Epidemiology

These extracranial rests of brain tissue are rare and usually manifest at the time of birth.

Pathogenesis

Nasal glial heterotopia (NGH) is the result of embryologic displacement of brain tissue, usually along the cranial closure lines and without apparent communication with underlying structures (see Figs. 64.1 & 64.8)[98]. It has

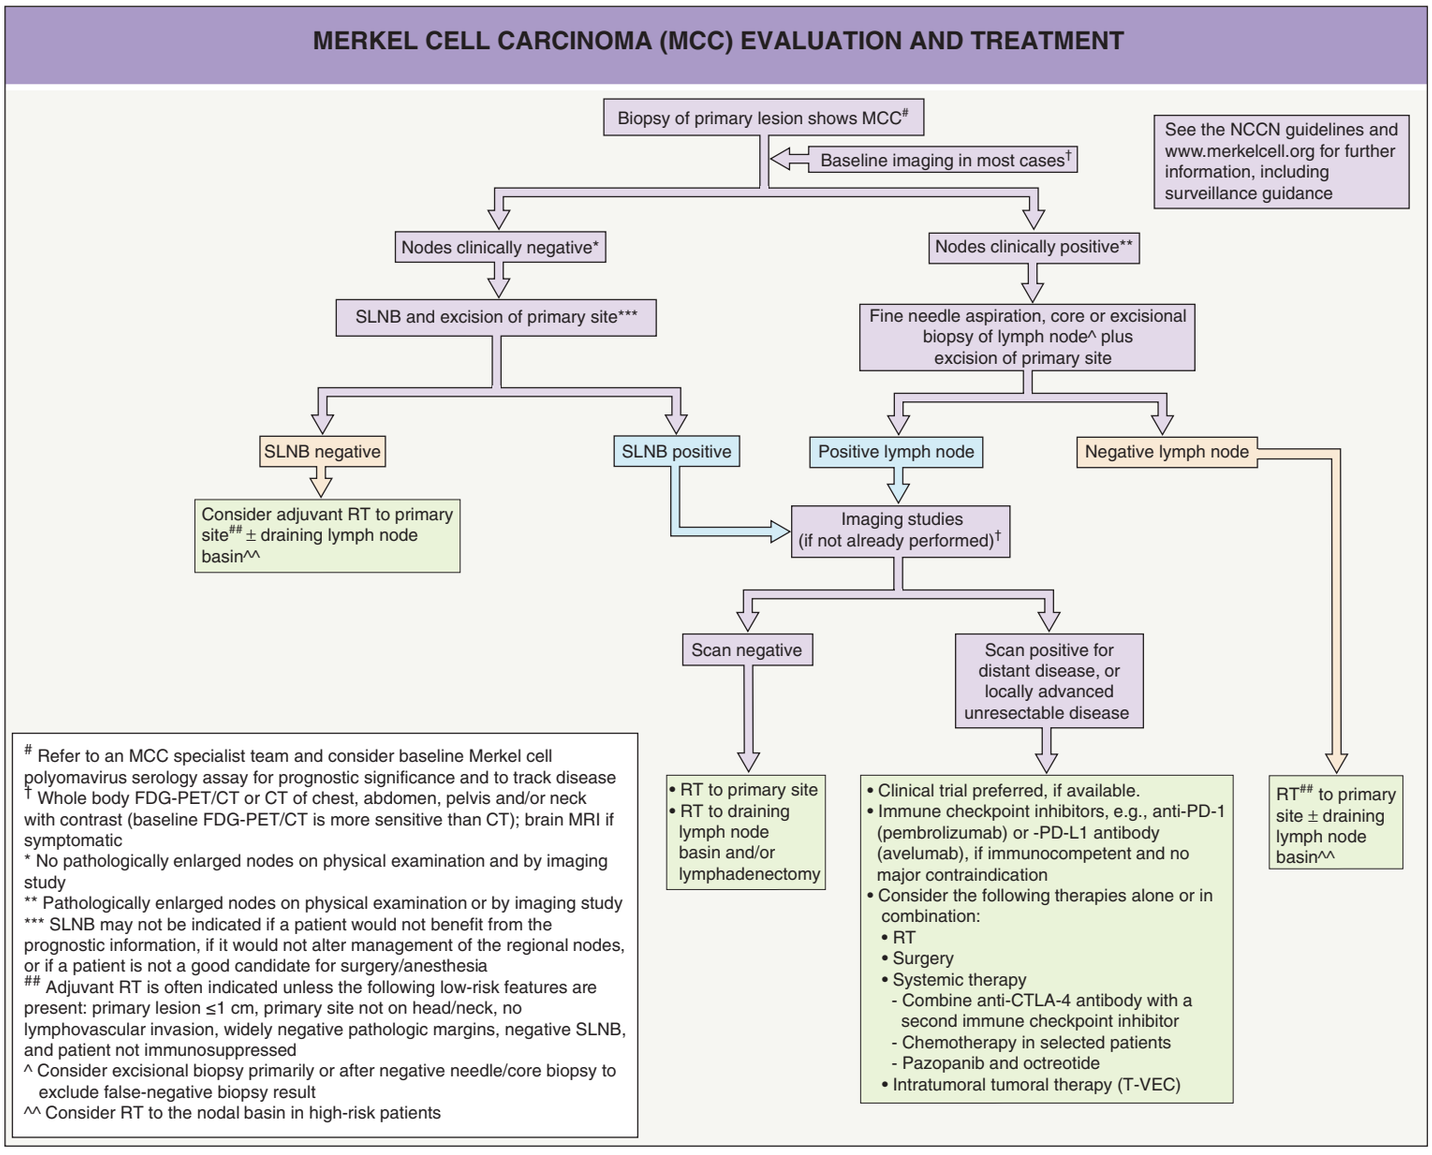

Fig. 115.19 Merkel cell carcinoma (MCC) evaluation and treatment algorithm. CT, computerized tomography; FDG-PET, fluorodeoxyglucose-positron emission tomography; NCCN, National Comprehensive Cancer Network; RT, radiotherapy; SLNB, sentinel lymph node biopsy.

a predilection for the perinasal area; therefore, it is commonly referred to as a nasal "glioma". As this is not a true neoplasm, the term is misleading[99].

Clinical features

NGHs are firm, smooth-surfaced, skin-colored to red–violet papulonodules that may have obvious telangiectasias and range in size from 1 to 3 cm. Approximately 60% are located on the bridge of the nose (Fig. 115.20), with the remainder usually located intranasally or in both locations[99,100].

Pathology

In a NGH, an ill-defined, non-encapsulated neuropil-like mass is seen within the dermis and subcutis. The neuropil-like tissue is composed of nests and strands of pale-staining, finely vacuolated or fibrillary matrix in which various types of astrocytes can be found[98]. Gemistocytic astrocytes, with polygonal, eosinophilic cytoplasm and eccentric nuclei, as well as multinucleated giant cells, are relatively common. Mature neurons are present in variable numbers[99]. Occasionally, residual meningoendothelial cells, ependymal cells, choroid plexus-like structures, and pigmented cells can be identified[100]. No mitotic activity or aggressive growth pattern has been described.

Differential diagnosis

Clinically, the lesion must be differentiated from other facial midline lesions (see Ch. 64)[99,101] as well as an infantile hemangioma, dermoid cyst, and nasal polyp (see Table 64.1).

Fig. 115.20 Nasal glial heterotopia ("nasal glioma") in a newborn. Pink to violet soft nodule.

Treatment

Most cutaneous neural malformations can be effectively treated by excision. Cranial imaging is recommended before these lesions are biopsied or removed[102], because NGHs can communicate with the

intracranial space, and therefore cerebrospinal fluid leakage and subsequent meningoencephalitis and other neurologic damage may occur after biopsy[99].

Heterotopic Meningeal Tissue

Synonym: ■ Rudimentary meningocele

Key features

- Rare disorder that usually presents in neonates and infants and favors the scalp, forehead, and dorsal midline
- Soft to firm, skin-colored nodule, often with partial alopecia and/or the "hair collar" sign when on the scalp
- Can be associated with other developmental anomalies
- Histologically, solid nests and strands, whorls of epithelioid or spindle cells, and psammoma bodies

History

The concept of rudimentary meningocele was introduced by Lopez et al.[103].

Epidemiology

Meningeal heterotopias are rare lesions, usually apparent at or shortly after birth[103].

Pathogenesis

Rudimentary meningoceles are thought to result from herniation of the meningeal lining into the skin and subcutaneous tissues during embryologic development, usually with no residual communication with the CNS (see Fig. 64.8)[104]. Although these lesions are sometimes classified as type I cutaneous meningiomas[103], considering their non-neoplastic nature, they are better classified as rudimentary meningoceles[104].

Clinical features

Rudimentary meningoceles most commonly present on the scalp of neonates and infants at the sites of cranial closure (see Fig. 64.1). Less often they occur on the forehead (midline) or overlie the spine. Skin-colored papules or nodules on the scalp are often associated with alopecia and/or the "hair collar" sign[105].

Pathology

A rudimentary meningocele is an ill-defined mass of cavernous, pseudovascular spaces embedded in a markedly collagenous stroma[104,106]. The spaces may be lined by elongated meningoendothelial cells characterized by eosinophilic cytoplasm, round or ovoid nuclei, and a fine chromatin pattern. Similar cells dissect or wrap around collagen fibers, producing "collagen bodies". No significant cytologic atypia or mitotic activity is present. Focal calcification and psammoma bodies (eosinophilic laminated and whorled structures with variable calcification) may occur. Meningothelial cells consistently express vimentin and EMA, whereas immunoexpression of S100 protein is variable.

Differential diagnosis

In neonates and infants, rudimentary meningoceles must be distinguished from "atretic" meningoceles (an intermediate form with an intracranial connection), membranous aplasia cutis congenita, heterotopic brain tissue, dermoid cysts, and infantile hemangiomas. Type II and type III meningiomas are in the histologic differential diagnosis. They usually develop on the scalp of adults, either along the course of a cranial nerve (type II) or as a cutaneous "metastasis" or direct extension of a primary meningioma of the arachnoid lining (type III)[103,105,107]. Within the deep dermis or subcutis, there is a multinodular mass, often with an infiltrative growth pattern[108–110]. The cells may show a variable degree of differentiation, and in the most common form, the spindle cells have a concentric, whorl-like arrangement[108]; psammoma bodies are often present[108–110]. Mitotic figures are rare in type II and variably increased in type III. Clinically, these nodular tumors may have associated alopecia and can resemble an epidermoid or pilar cyst, adnexal tumor, or cutaneous metastasis. They may occur in the setting of neurofibromatosis (types I and II)[111]. Lastly, the deeper portions of rudimentary meningoceles may have an infiltrative growth pattern with pseudovascular spaces, with a resemblance to angiosarcoma.

Treatment

As with nasal glial heterotopia, imaging studies are required prior to biopsy or excision. The latter is performed primarily by neurosurgeons.

PRIMITIVE NEUROECTODERMAL TUMORS

Synonyms: ■ Neuroblastoma (primary or metastatic) ■ Neuroepithelioma ■ Ganglioneuroma

Key features

- The third most common malignant neoplasm in children
- Cutaneous metastases (children) are seen more frequently than primary cutaneous tumors (adults)
- Cutaneous metastases present as multiple, blue to purple dermal nodules in association with elevated serum and urine catecholamines
- Histologically, small, round, blue cells in a nested or infiltrative growth pattern, with formation of Homer Wright rosettes
- Prognosis depends on the patient's age, clinical stage, and specific genetic abnormalities (e.g. *MYCN* oncogene amplification)

Introduction

Neuroblastic–ganglionic tumors are derived from the germinal neuroepithelium and/or from the neural crest. They display a wide spectrum of clinicopathologic features based on their relative degree of differentiation, ranging from very primitive neuroectodermal tumors to more mature forms such as neuroblastomas.

History

The concept of neuroectodermal tumors was introduced by Stout in 1918. Since then, different terms have been used for tumors with cytologically similar features, reflecting the controversy regarding this entity. Dehner performed a comprehensive review of the nosology of this diverse group of lesions, suggesting the term "primitive neuroectodermal tumors" (PNET)[112]. This concept was then further expanded following the recognition that PNET and extraosseous Ewing sarcoma can have similar immunohistochemical and chromosomal abnormalities (e.g. translocations involving *EWSR1*), and therefore nowadays they are considered within the same neoplastic spectrum[113].

Epidemiology

Neuroblastoma is the third most commonly observed childhood malignancy, and cutaneous metastases are frequent[3]. Most neuroblastomas develop as sporadic tumors, although familial cases have been reported. Primary cutaneous PNETs are tumors of adulthood (mean age, 40 years) and are exceedingly rare[3]. Cutaneous ganglioneuroma has a predilection for the trunk.

Pathogenesis

PNETs of the skin either represent metastases from a PNET of the adrenals and/or ganglionic chain (traditionally designated as neuroblastomas) or develop *de novo* from heterotopic neural crest cells[2]. In the latter case, they are referred to as peripheral PNETs or as peripheral neuroblastomas. *ALK* is implicated in the tumorigenesis of many familial and some sporadic cases of neuroblastoma. In addition, DNA ploidy and specific genetic abnormalities, such as *MYCN* oncogene amplification or aberrations of chromosomes 11q or 1p, influence prognosis[114]. Cutaneous ganglioneuroma is best regarded as resulting from abnormal migration and differentiation of neural crest cells.

Clinical Features

In children, the cutaneous metastases of neuroblastoma often manifest as multiple, blue to purple, dermal papules or nodules that resemble the "blueberry muffin" lesions seen with congenital infections or hematologic disorders[4] (see Ch. 121). These nodules may blanch upon stroking and develop an erythematous halo[115,116]. Serum and urine catecholamine levels are typically elevated. In children, complete spontaneous regression has been described in stage IV-S neuroblastoma, including cutaneous metastases[117].

In adults, PNETs are rapidly growing dermal or subcutaneous nodules that favor the trunk or head. Ulceration is common. These highly aggressive neoplasms have an almost invariably fatal outcome.

Pathology

In metastatic neuroblastoma, an ill-defined or infiltrative mass is present in the dermis and/or the subcutis. However, when smaller and more superficial, deposits are more defined. The tumor mass is composed of atypical, small, dark cells with scant cytoplasm[2,112]. The cells have larger nuclei than mature lymphocytes (with a coarse chromatin pattern) and they form irregular nests, cords, or poorly cohesive sheets. Rosette formation, by concentrically arranged tumor cells in double or multiple circles, is common. The center of the rosettes contains converging fine fibrillary material characteristic of Homer Wright-type rosettes[2] (Fig. 115.21). Mitotic activity is high, and abnormal mitoses are abundant. Extensive areas of necrosis and hemorrhage are common.

As the tumor differentiates, the relative proportion of neuroblastoma components decreases, and the ganglioneuromatous elements increase. Eventually, the tumor may show features indistinguishable from a ganglioneuroma[117]. Cutaneous ganglioneuromas are characterized by mature ganglion cells immersed in a Schwann cell-rich stroma. Lesions consisting of only ganglion cells may also occur and are referred to as "ganglion cell choristomas". Ganglion cells are round-to-polygonal with vesicular nuclei and abundant pale cytoplasm; the latter contains Nissl granules which may be highlighted by a toluidine blue stain. Immunohistochemically, the cells of neuroblastomas and ganglioneuromas react variably with neural and neuroendocrine markers, depending on their state of differentiation. These markers include neuron-specific enolase, S100 protein, neurofilaments, synaptophysin, chromogranin, and CD99 (see Ch. 0)[114].

Primary cutaneous PNETs have similar histopathologic features to those of the classic neuroblastoma, but ganglionic or neuromatous differentiation is not characteristic. These two tumors also share major immunohistochemical features. However, MIC-2(013) is commonly expressed by PNETs, but not by neuroblastomas, facilitating their distinction[114,117–120].

Differential Diagnosis

In children, the clinical differential diagnosis includes other types of cutaneous metastasis, extramedullary hematopoiesis, and mastocytosis, whereas in adults it includes adnexal tumors, lymphoma, and soft tissue sarcomas. Histologically, both metastatic neuroblastoma and primary cutaneous PNET must be differentiated from other small, round, blue cell tumors that form rosettes and may involve the skin[120,121] (see discussion in MCC section). Cutaneous ganglioneuroma must be distinguished from cutaneous metastases of neuroblastoma, with age of onset and other clinical history required for distinction.

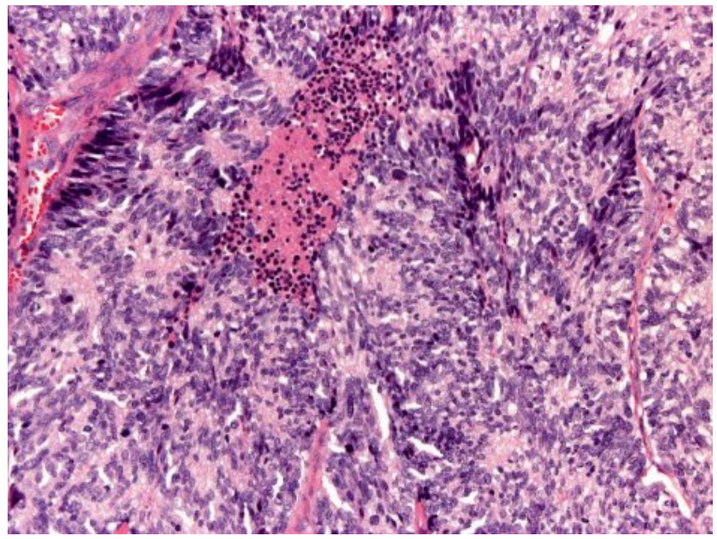

Fig. 115.21 Cutaneous neuroblastoma. The tumor is composed of small cells with small, round to ovoid nuclei that can be arranged in rosettes. The fibrillary material in the center of Homer Wright-type rosettes is characteristic. In the upper mid-portion of the figure there is a large area of necrosis. *Courtesy Lorenzo Cerroni, MD.*

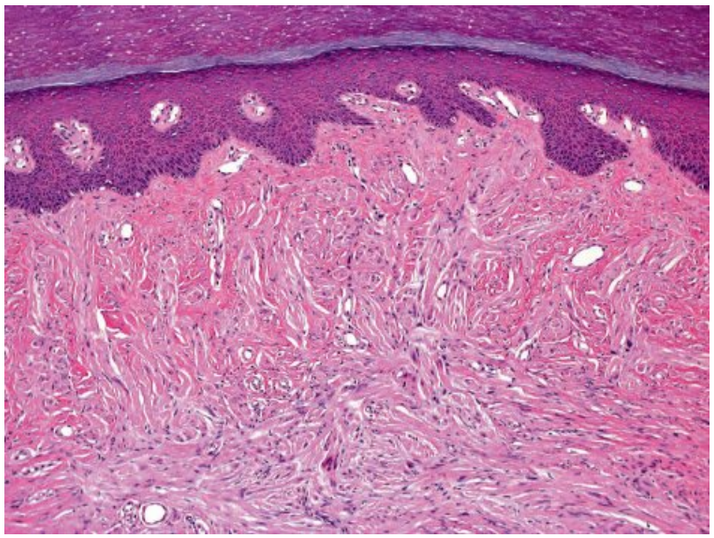
Treatment

The effective treatment of neuroblastoma requires an interdisciplinary team that includes oncologists, surgeons, and radiation therapists. The overall prognosis of localized tumor involvement has improved with combined surgical excision, multiagent chemotherapy, differentiating agents (e.g. 13-cis-retinoic acid), immunotherapy (e.g. dinutuximab), hematopoietic stem cell transplantation, and radiopharmaceuticals[114]. Important prognostic factors include the age, stage, histologic differentiation, specific genetic abnormalities (e.g. *MYCN* oncogene amplification, 11q aberration), and response to initial chemotherapy[2].



Additional figures and table on Tumors and tumor-like conditions of ectopic and heterotopic neural tissue involving the skin, available in our eBook (see inside front cover for access code).

TUMORS AND TUMOR-LIKE CONDITIONS OF ECTOPIC AND HETEROTOPIC NEURAL TISSUE INVOLVING THE SKIN				
	Nasal glial heterotopia ("nasal glioma")*	**Rudimentary meningocele**	**Cutaneous meningioma (types II and III)**	**Peripheral neuroblastoma**
Incidence	Rare	Rare	Extremely rare	Extremely rare
Age	Neonates	Neonates or infants	Usually adults	Late adulthood
Location	Most commonly near the root of the nose but can be intranasal	Scalp, forehead, paravertebral area	Scalp	Head and trunk
Size	1.0–3.0 cm	0.5–3.0 cm	0.5–4.0 cm	0.5–5.0 cm
Clinical appearance	Firm, smooth, skin-colored to red–purple nodule	Soft to firm nodule, often with alopecia or the "hair collar" sign; occasionally cystic; blue–red hue common	Soft to firm nodule, often with alopecia	Soft, skin-colored to red, often ulcerated nodule
Clinical differential diagnosis	Infantile hemangioma, nasal polyp, juvenile xanthogranuloma, dermoid cyst	Membranous aplasia cutis, heterotopic brain tissue, dermoid cyst, infantile hemangioma	Epidermoid or pilar cyst, adnexal tumors, cutaneous metastasis	Adnexal tumors, lymphoma, soft tissue sarcoma, cutaneous metastasis
Associations	Intracranial connection in ~20% ("atretic" encephalocele)	An intracranial connection may be present ("atretic" meningocele)	May be associated with neurofibromatosis (types I and II)	NA
Other	NA	NA	Metastasis of CNS meningioma must be excluded	Metastasis of ganglionic or adrenal neuroblastoma and extension of olfactory neuroblastoma must be excluded, especially in children
Histopathologic features	Lobulated neural tissue (glial cells, astrocytes, rarely true neurons)	Cystic or cavernous spaces, scattered meningothelial cells, pseudovascular pattern, psammoma bodies	Solid nests and strands, whorls of epithelioid or spindle cells, psammoma bodies	Rosette-like (Homer Wright-type) structures of small, round, blue cells, extensive infiltration and necrosis
Biologic course	Benign	Benign	Locally aggressive and destructive	Extremely malignant with widespread metastases

*Heterotopic brain tissue can also be located in the midline scalp, orbit, lip, and oropharynx.

eTable 115.1 Tumors and tumor-like conditions of ectopic and heterotopic neural tissue involving the skin.

116 Fibroblastic, Myofibroblastic, and "Fibrohistiocytic" Proliferations and Neoplasms of the Skin

Key features

- Proliferations and tumors categorized as fibroblastic, myofibroblastic, and "fibrohistiocytic" commonly develop in the skin
- These tumors are composed of fibroblasts, myofibroblasts, histiocytes, dermal dendritic cells, collagen fibers, elastic fibers, and connective tissue mucin, with each component present in variable proportions depending upon the particular neoplasm
- Benign proliferations of these cells, as in nodular fasciitis, can mimic malignant neoplasms
- Immunohistochemical staining for CD34, α-smooth muscle actin, factor XIIIa, and CD68 assists in confirming fibroblastic/myofibroblastic differentiation, with staining for keratins, S100, and SOX10 performed to exclude epithelial or melanocytic differentiation
- When differentiating the various tumors within this group, immunohistochemistry provides limited discrimination
- For some tumors (e.g. dermatofibrosarcoma protuberans, nodular fasciitis), RT-PCR, fluorescent *in situ* hybridization (FISH), and next generation sequencing (NGS) can detect translocations and fusion genes, allowing for more precise diagnoses
- While focusing primarily on proliferations and neoplasms commonly encountered by dermatologists, tumors of soft tissue are also reviewed

SKIN TAGS

Synonyms: ■ Acrochordons ■ Fibroepithelial polyps

Clinical Features

Skin tags are very common, presenting as soft, skin-colored to slightly hyperpigmented, pedunculated papules that favor the neck, axilla, and groin (Fig. 116.1). Skin tags are usually asymptomatic but can become painful secondary to irritation or infarction.

Epidemiology

Men and women are equally affected, and close to 50% of all individuals have at least one skin tag[1]. Although skin tags were once thought to be associated with colonic polyps, more recent studies have not confirmed this relationship[2]. Skin tags have also been reported as a cutaneous marker for diabetes mellitus[3].

Pathology

Histologically, skin tags are polypoid with loose to dense collagenous stroma and thin-walled blood vessels.

In Birt–Hogg–Dubé syndrome and Cowden syndrome, patients can have typical skin tags, but sometimes the "skin tags" represent fibrofolliculomas, trichodiscomas or perifollicular fibromas versus sclerotic fibromas, respectively[4].

Treatment

Unless irritated or infarcted, skin tags are more of a cosmetic issue than a clinical concern and can be removed by scissor excision.

CUTANEOUS ANGIOFIBROMA

Synonyms: ■ Fibrous papule ■ Pearly penile papule ■ Ungual fibroma (Koenen tumor) ■ Fibrous papule of the nose

Cutaneous angiofibroma is a descriptive term for a group of lesions with different clinical presentations and implications, but similar histologic findings.

Clinical Features

Fibrous papules are solitary, dome-shaped and shiny, skin-colored to reddish papules located on the face of adults, most commonly on the nose (Fig. 116.2)[5]. Clinically, they can mimic small intradermal melanocytic nevi, basal cell carcinomas (BCCs), or adnexal tumors. By dermoscopy, a white color is often seen.

Pearly penile papules are pearly, white, dome-shaped, closely aggregated small papules located on the glans penis, commonly in a multilayered and circumferential manner on the corona (Fig. 116.3). They are found in up to 30% of young postpubertal adults and are more common in uncircumcised men[6]. They can be mistaken for condylomata acuminata or hypertrophied sebaceous glands.

Multiple facial angiofibromas are seen in tuberous sclerosis (TS), multiple endocrine neoplasia type 1, Birt–Hogg–Dubé syndrome[7], and

Fig. 116.1 Multiple skin tags in the axilla. The lesions are skin-colored, soft and pedunculated.

Fig. 116.2 Fibrous papule of the nose. A smooth, dome-shaped, skin-colored papule.

Fig. 116.3 Pearly penile papules. Multiple small white papules along the corona of the glans penis. Note the multilayered distribution. *Courtesy Kalman Watsky, MD.*

rarely, neurofibromatosis type 2 or as an isolated finding. They are usually distributed bilaterally on the cheeks, nasolabial folds, nose and chin. In TS, facial angiofibromas usually appear during early to mid childhood and characteristically spare perioral skin. Patients with TS can also have multiple *ungual angiofibromas*. Both facial (≥3) and ungual (≥2) angiofibromas represent major diagnostic criteria for TS (see Table 61.7).

Pathology

All angiofibromas are dome-shaped lesions composed of a dermal proliferation of plump or stellate fibroblasts in a collagenous stroma with an increase in the number of thin-walled, dilated blood vessels (Fig. 116.4). The collagen fibers can be arranged in a concentric fashion around hair follicles and blood vessels (a variant known as perifollicular fibroma). Elastic fibers are decreased in number. Some fibroblasts can be multinucleated. Granular and clear-cell variants have been described.

DERMATOFIBROMA

Synonyms: ■ Benign fibrous histiocytoma (preferred terminology in soft tissue pathology) ■ Fibroma simplex ■ Sclerosing hemangioma ■ Nodular subepidermal fibrosis ■ Histiocytoma ■ Dermal dendrocytoma

Clinical Features

Dermatofibromas occur primarily in adults and often develop on the lower extremities. They are firm, minimally elevated to dome-shaped papules that are usually <1 cm in diameter, but occasionally are >2 cm. The lesions are commonly hyperpigmented (Fig. 116.5). On palpation, they may seem attached to the subcutaneous tissue; pinching the lesion gently usually results in apparent downward movement of the tumor, also known as the "dimple sign". By dermoscopy, a central white scar-like patch or white network surrounded by a delicate pigment network is most commonly observed (see Ch. 0).

Although some dermatofibromas are thought to arise at sites of trauma or arthropod bites, their precise etiology is unknown. Multiple eruptive dermatofibromas have been observed in patients with autoimmune disorders (e.g. lupus erythematosus) and atopic dermatitis and in the setting of immunosuppression (e.g. HIV infection)[8]. Clinically, dermatofibromas can be confused with cysts or melanocytic nevi, especially those with fibrosis. In the case of larger lesions, the possibility of dermatofibrosarcoma protuberans (DFSP), which is less well defined and multilobed, may be considered.

Pathology

Dermatofibromas are characterized by a nodular dermal proliferation, predominantly composed of spindle-shaped fibroblasts and myofibroblasts arranged as short intersecting fascicles (Fig. 116.6).

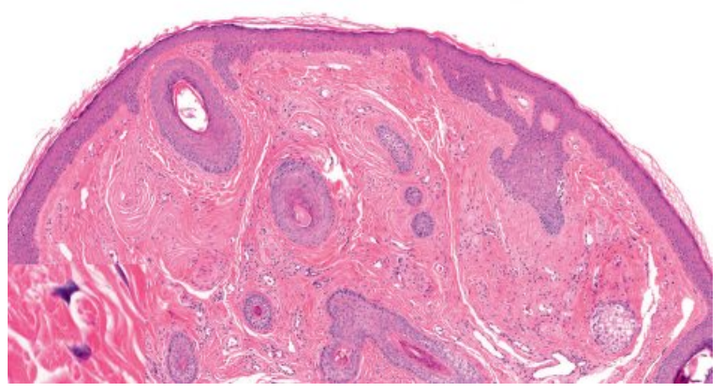

Fig. 116.4 Angiofibroma. A dome-shaped silhouette with a densely packed collagenous stroma and a diffuse array of fusiform and stellate fibroblasts is seen. These features plus dilated postcapillary venules are characteristic of an angiofibroma. *Courtesy Lorenzo Cerroni, MD.*

Fig. 116.5 Dermatofibroma. Firm papule on the lower extremity with peripheral hyperpigmentation. Accentuation of pigmentation at the periphery of the lesion is typical of dermatofibroma. *Courtesy Lorenzo Cerroni, MD.*

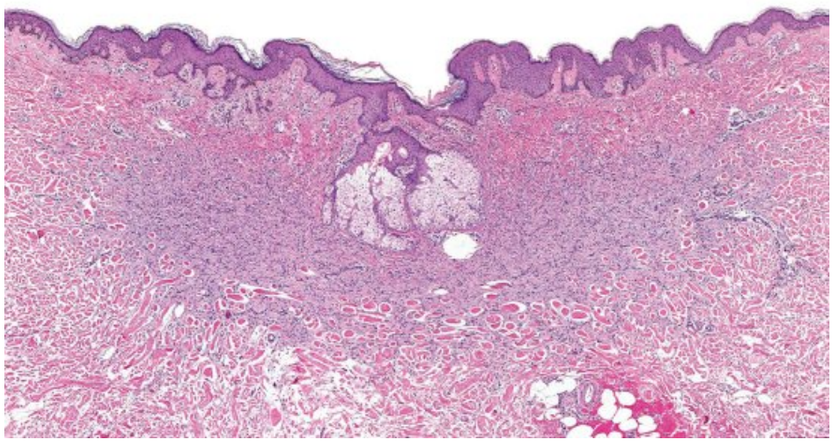

Fig. 116.6 Dermatofibroma. Symmetric, dermal proliferation of spindled fibroblasts in the dermis, with hyperplasia and hyperpigmentation of the overlying epidermis. Note a sebaceous gland "induced" by the fibroblastic proliferation. *Courtesy Lorenzo Cerroni, MD.*

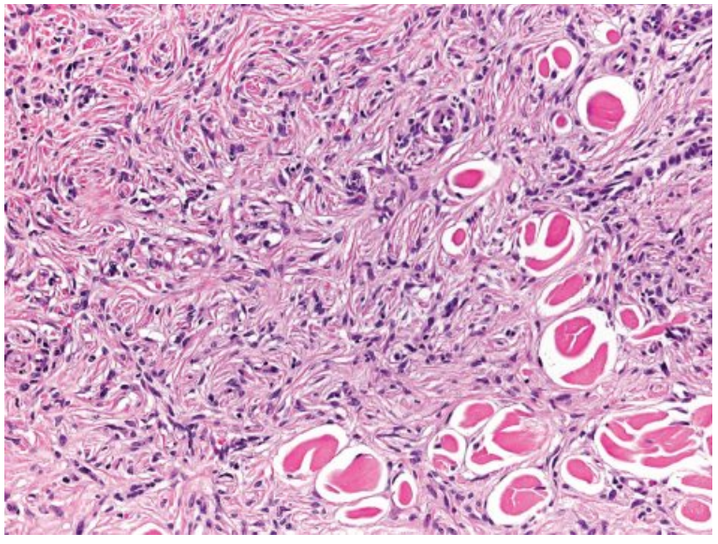

Fig. 116.7 Dermatofibroma. Thick "entrapped" collagen bundles at the outer margin of a cellular proliferation of small fusiform cells is typical of a dermatofibroma. *Courtesy Lorenzo Cerroni, MD.*

The fibroblasts and myofibroblasts have plump oval nuclei with small nucleoli and mitoses may be present. An admixture of these cells with mono- or multinucleated histiocytes with vacuolated (xanthomatous) cytoplasm can be seen, hence the synonym benign fibrous histiocytoma. "Keloidal" collagen bundles, which are refractile with polarized light, are seen at the periphery (Fig. 116.7); the presence of peripheral "entrapped" collagen bundles is considered a classic hallmark of dermatofibroma. Hemorrhage into a dermatofibroma explains the common finding of hemosiderin.

The overlying epidermis is usually hyperplastic. Sometimes there are aggregates of basaloid cells with follicular differentiation emanating from the epidermis (follicular and basaloid "induction"). This finding may be confused with a superficial BCC. There are, however, a few reported cases of true BCCs evolving within longstanding dermatofibromas[9]. Histologic variants of dermatofibroma are listed in Table 116.1.

Positive immunohistochemical reactions for vimentin, factor XIIIa[10–12], muscle-specific actin and CD68, as well as a negative reaction for CD34 (in the center of the lesion), support the diagnosis of dermatofibroma. Evolving cellular dermatofibromas may stain strongly for α-smooth muscle actin (SMA). The histologic differential diagnosis includes keloid, scar, connective tissue nevus, dermatomyofibroma, DFSP (CD34-positive), and nodular Kaposi sarcoma (HHV8-positive, ERG-positive). Of note, dermatofibromas may show CD34 positivity at the periphery while the center is usually CD34-negative, in contrast to DFSP which is homogeneously CD34-positive.

Whether dermatofibromas are reactive or neoplastic has been an area of controversy for a long time. The detection of clonality in a subset of fibrous histiocytomas in addition to a large size, mitotic activity, and/or high recurrence rate in some dermatofibromas and the very rare metastatic potential suggest that fibrous histiocytoma is a tumor rather than a reactive inflammatory process[13–17]. In addition, epithelioid fibrous histiocytomas, formerly classified as a variant of fibrous histiocytoma, have been shown to demonstrate recurrent *ALK* fusions[18]. Mutations in *F13A1*, which encodes coagulation factor XIII subunit A, have also been detected in families with autosomal

CLINICAL AND HISTOPATHOLOGIC VARIANTS OF DERMATOFIBROMA/FIBROUS HISTIOCYTOMA
Clinical variants
• Annular hemosiderotic dermatofibroma • *Deep dermatofibroma* • Delled ("atrophic") dermatofibroma • Dermatofibroma with satellitosis • Disseminated multiple dermatofibromas • Erosive and ulcerated dermatofibroma • Giant dermatofibroma • Hyperkeratotic dermatofibroma • Hyperpigmented nodular dermatofibroma • *Lipidized fibrous histiocytoma ("ankle-type" histiocytoma)* • Multinodular hemosiderotic dermatofibroma • Multiple grouped dermatofibromas • Nonpigmented dermatofibroma • Pedunculated or polypoid dermatofibroma • Unusual locations for dermatofibromas: *face*, finger, subungual, palmoplantar, scalp
Histopathologic variants
• Adenodermatofibroma • *Aneurysmal fibrous histiocytoma (hemorrhagic or hemosiderotic dermatofibroma)* • Balloon cell dermatofibroma • Cellular dermatofibroma (fibrous histiocytoma) • Cholesterotic dermatofibroma • Clear cell dermatofibroma • Combined dermatofibroma • *Deep dermatofibroma* • Delled ("atrophic") dermatofibroma • Dermatofibroma mimicking hemangiopericytoma • *Dermatofibroma with atypical cells (with "monster" cells or pseudosarcomatous dermatofibroma)* • Dermatofibroma with calcification or metaplastic ossification • Dermatofibroma with elastophagocytosis • Dermatofibroma with eosinophilic infiltrate • Dermatofibroma with follicular and/or sebaceous induction • Dermatofibroma with lymphoid follicles • Dermatofibroma with myofibroblastic differentiation • Dermatofibroma with osteoclast-like giant cells • Dermatofibroma with proliferation of nerve fibers • Dermatofibroma with prominent vascular component (sclerosing "hemangioma") • *Epithelioid fibrous histiocytoma* • Granular cell dermatofibroma • Lichenoid, erosive, and ulcerated dermatofibroma • *Metastasizing fibrous histiocytoma* • Myxoid dermatofibroma • Palisading dermatofibroma • Poorly cellular dermatofibroma (fibrous, hyalinizing, and keloidal dermatofibromas) • Signet-ring cell dermatofibroma • Xanthomatous dermatofibroma

Table 116.1 Clinical and histopathologic variants of dermatofibroma/fibrous histiocytoma. Entities in *italics* are reviewed in Table 116.2. *Adapted from Requena L, Kutzner H. Cutaneous soft tissue tumors. Philadelphia: Wolters Kluwer, 2014.*

dominantly inherited multiple dermatofibromas[19]. It has been hypothesized that a resultant conformational change in the subunit may lead to enhanced α4-integrin binding.

Treatment

Dermatofibromas may be biopsied or excised to exclude a melanocytic proliferation, a fibrosed cyst, or other mesenchymal neoplasm. Undisturbed, dermatofibromas usually persist, but with time may undergo partial regression, especially centrally.

Variants of Dermatofibroma

The many clinical and histologic variants of dermatofibroma are listed in Table 116.1 and key features of selected variants are outlined in Table 116.2.

ACRAL FIBROKERATOMA

Synonym: ■ Acquired digital fibrokeratoma

Clinical Features

This uncommon lesion presents as a solitary, skin-colored to pink, slightly keratotic, exophytic papulonodule with a collarette of elevated skin (Fig. 116.10). Acquired fibrokeratomas usually occur in middle-aged adults and the most common site is the finger[20]. Clinically, they can resemble a supernumerary digit (see Ch. 64), ungual fibroma, or verruca.

Pathology

Acral fibrokeratomas are composed of thick collagen bundles surrounded by blood vessels, oriented perpendicularly to the epidermis (Fig. 116.10, inset)[21]. The histopathologic differential diagnosis includes ungual fibroma and supernumerary digit[22].

ACRAL FIBROMYXOMA

Synonyms: ■ Superficial acral fibromyxoma ■ Digital fibromyxoma

Clinical Features

Acral fibromyxoma is a rare tumor of acral sites first described in 2001[23]. There is a 2:1 male:female ratio, with a broad range for age of onset[24–27]. The tumor presents as a slowly enlarging, often painful mass, with an average size of 1–2 cm. It usually develops on the toes or fingers, with two-thirds of tumors occurring close to or involving the nail bed[24–26]; 3% of tumors invade adjacent bone[24,27]. Less common sites include the palm or heel[28]. The clinical differential diagnosis includes primarily ungual fibroma and verruca.

Pathology

Acral fibromyxomas are located within the dermis with extension into the subcutis. There are non-encapsulated, poorly circumscribed masses composed of spindled to stellate cells arranged in a vague storiform or loosely fascicular growth pattern (Fig. 116.11). The stroma is myxoid to fibromyxoid with prominent blood vessels and frequent mast cells. Most tumors have alternating areas of fibrous and myxoid stroma[24]. Minimal cellular atypia is common, and occasionally scattered larger cells with so-called "degenerative change" are present[24]. Mitotic figures are rare. Significant pleomorphism, neural/perineural infiltration, and necrosis are not seen. In cases involving the nail bed, there is often papillary hyperplasia of the nail bed epithelium[28].

The majority of these tumors stain strongly for CD34 with occasional expression of epithelial membrane antigen (EMA) and SMA; expression of CD99, CD10[25], nestin, and desmin has also been reported (see Ch. 0)[24,28]. By immunohistochemistry, the majority of cases demonstrate loss of retinoblastoma 1 (RB1) expression due to deletion of *RB1*[29] (Table 116.3). The histologic differential diagnosis includes cellular digital fibroma, myxoid neurofibroma, superficial angiomyxoma, and DFSP.

Treatment

These tumors follow a benign course, with ~25% recurring after complete excision[24]. Neither malignant transformation nor metastasis has been reported[24].

SCLEROTIC FIBROMA OF THE SKIN

Synonym: ■ Storiform collagenoma

HISTOLOGIC VARIANTS OF DERMATOFIBROMA/FIBROUS HISTIOCYTOMA			
Variant	**Clinical features**	**Histopathologic features**	**DDx/Comments**
Aneurysmal fibrous histiocytoma (hemorrhagic or hemosiderotic dermatofibroma)[e1]	Large size and nodular or dome-shaped with a history of recent rapid growth	• Large blood-filled spaces rimmed by densely aggregated siderophages but without the typical endothelial lining of vascular structures (pseudovascular spaces; hemorrhagic pseudocysts; Fig. 116.8) • Extravasation of erythrocytes • Sheets of large histiocytes & brown, Prussian blue-positive siderophages interspersed with small capillaries without endothelial atypia • Siderophages may be multi-nucleated • Also conventional features of histiocyte-rich fibrous histiocytoma	• Clinically and histologically may be confused with malignant vascular tumors or angiomatoid fibrous histiocytoma • IHC staining with the endothelial marker CD31 may lead to confusion as also stains phagocytic histiocytes and siderophages
Deep dermatofibroma (extending into subcutaneous tissue)[88]	• Usually on the trunk and proximal extremities • 1–2 cm in diameter	• Similar features to common DF, but extension of dermal components into subcutis • Extension via two patterns: 1. ~70% of cases – vertical or horizontal fashion, predominantly along septa which become wedge-shaped 2. ~30% of cases – well-circumscribed base with smooth deep margin	• Clinically, may resemble lipoma or DFSP • Histologically, absence of the multilayered & "honeycomb" patterns characteristic of DFSP
Dermatofibroma with atypical cells (with "monster" cells or pseudosarcomatous dermatofibroma)[e2–e7,17]	• Middle-aged adults • Slightly >1 cm in diameter	• Architectural pattern & components of a common DF plus atypical mono- and multinucleated cells with large pleomorphic and hyperchromatic nuclei, some of which have prominent nucleoli (Fig. 116.9) • Cells have abundant vacuolated cytoplasm, often with hemosiderin deposits • Rare mitotic figures and no atypical mitoses	• Current recommendation is to treat with clinical caution • If in addition to features of a DF with atypical cells, there are numerous mitoses and many of the mitoses are atypical, then the tumor should be labeled as atypical fibrohistiocytic tumor with a genuine, but exceeding low, metastatic potential
Epithelioid fibrous histiocytoma (epithelioid cell histiocytoma)[e8,e9,19]	• Firm, sessile or polypoid papules or nodules • 0.5–1.5 cm in diameter	• Dome-shaped or polypoid dermal nodules with peripheral adnexal collarettes • Monomorphous population of large, stellate and triangular, epithelioid cells with eosinophilic cytoplasm & oval nuclei with small nucleoli; some cells have 2 or more nuclei; no nesting of cells • Rare mitotic figures • Cells separated by delicate collagen fibers & variable amounts of mucin • Proliferation of small blood vessels can be seen	• When vascular in appearance, pyogenic granuloma or sclerosing hemangioma • Spitz nevus/tumor • *ALK* rearrangement and overexpression • The major entity in the differential diagnosis is intradermal Spitz nevus
Fibrous histiocytoma of the face[e10]	Dermal/subcutaneous plaque	• Predominance of distinct cellular fascicles & bundles of spindle-shaped tumor cells plus classic features of a fibrous histiocytoma • Often extend into the subcutaneous fat and deeper soft tissues, including striated muscle	Compared to classic fibrous histiocytomas located elsewhere, excised with wider margins because of diffuse infiltration, involvement of deeper tissues, and increased rate of local recurrences
Lipidized fibrous histiocytoma ("ankle-type" fibrous histiocytoma, "ankle-type" dermatofibroma)[e11]	Striking predilection for the lower extremity, in particular the ankle	• Large foam cells and interspersed siderophages predominate • Focally, features of an ordinary fibrous histiocytoma (e.g. peripheral "entrapped" dermal collagen) can be seen	Prognosis excellent
Metastasizing fibrous histiocytoma[e2–e7,17,18]	Metastases are well-documented but exceedingly rare	• To date, no specific histologic feature predicts metastatic behavior • Warning signs – large primary tumor, extension into subcutis with infiltrative peripheral borders, high proliferation rate (Ki67) & mitotic activity, & multiple recurrences • Includes aneurysmal, cellular, and atypical fibrous histiocytomas	• Cytogenetic aberrations detected via aCGH may reflect a biologic continuum with 0 in common fibrous histiocytomas to some in atypical fibrous histiocytomas to many in malignant fibrous histocytomas/sarcomas • In metastasizing fibrous histiocytomas, genetic aberrations were seen in 2 to 3 chromosomes

Table 116.2 Histologic variants of dermatofibroma/fibrous histiocytoma. aCGH, array comparative genomic hybridization; ALK, anaplastic lymphoma kinase; DDx, differential diagnosis; DF, dermatofibroma; DFSP, dermatofibrosarcoma protuberans; IHC, immunohistochemical.

Clinical Features

This distinct, very collagenous variant of fibroma was originally reported as a component of Cowden syndrome (PTEN hamartoma tumor syndrome). However, a sporadic solitary form has also been described[30].

In Cowden syndrome, the sclerotic fibromas can be solitary or multiple. They appear on the skin and/or mucous membranes as pearly papules or nodules that measure from a few to up to 10 mm in diameter.

Pathology

Sclerotic fibromas are well-circumscribed, dome-shaped, dermal hypocellular nodules composed predominantly of sclerotic thick collagen bundles. The bundles are arranged as short intersecting stacks in a parallel arrangement and are separated by spaces containing connective tissue mucin (plywood-like or whorl-like pattern; Fig. 116.12). Between the collagen bundles, there are thin spindled cells.

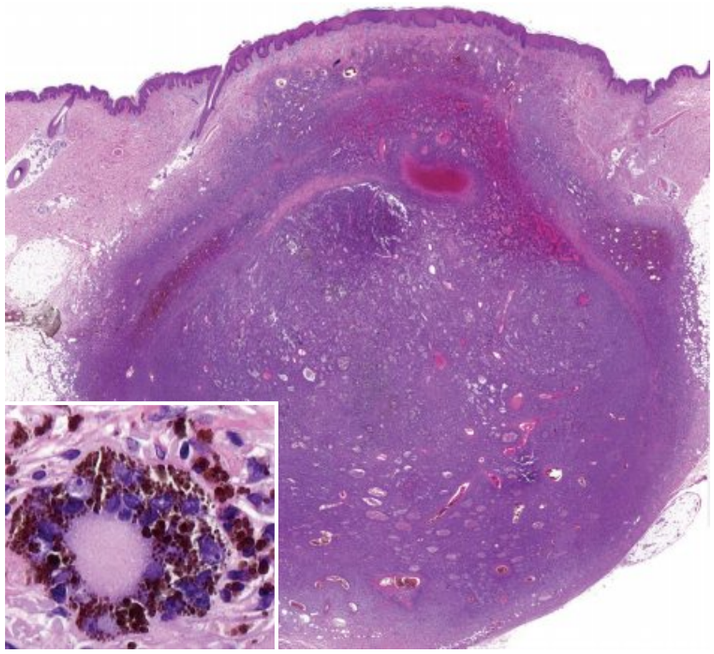

Fig. 116.8 "Aneurysmal" dermatofibroma. There are multiple blood-filled spaces and lacunae without an endothelial lining amidst a cellular proliferation replete with siderophages and foamy macrophages (inset).

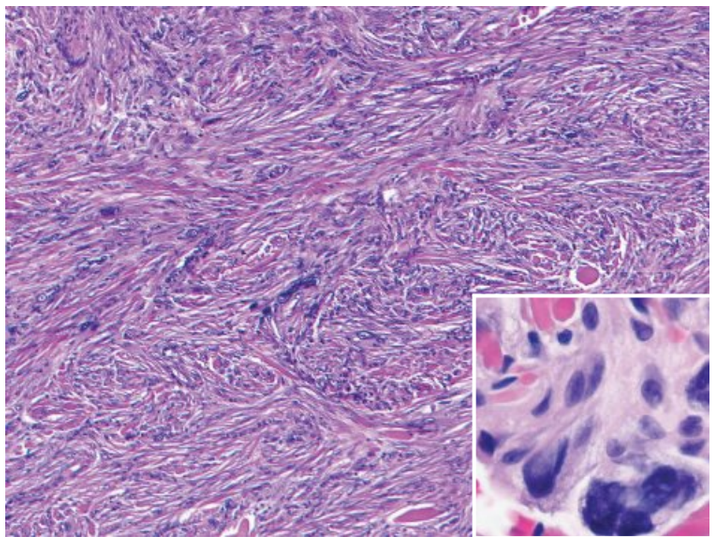

Fig. 116.9 Dermatofibroma with atypical cells ("monster" cells). There are histiocyte-like cells with large hyperchromatic (inset) and pleomorphic nuclei as well as scattered fibroblasts. Mitoses are not present.

The spindle cells react positively for vimentin, muscle-specific actin, and CD34[31]. Positivity for CD34 may result in the misdiagnosis of early DFSP.

PLEOMORPHIC FIBROMA OF THE SKIN

Clinical Features

This unusual variant of a fibroma was described by Kamino et al.[32] in 1989. Pleomorphic fibromas of the skin usually present in adults, with a slight preponderance in women. They favor the extremities and appear as asymptomatic, solitary, skin-colored, dome-shaped or polypoid papules which measure from a few millimeters to nearly 2 cm in diameter. Clinically, they resemble skin tags, neurofibromas,

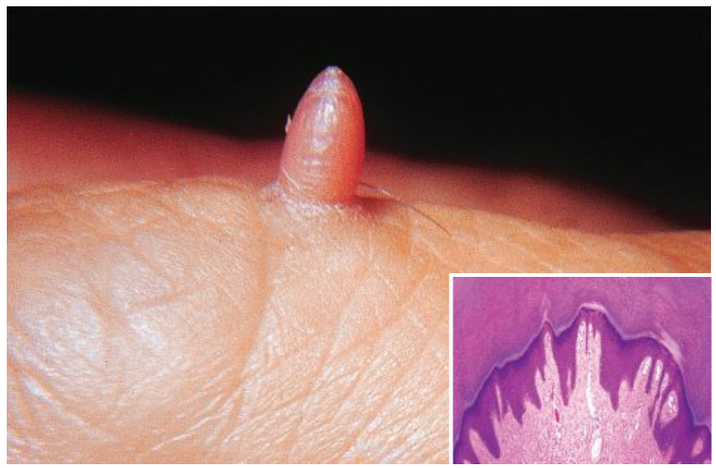

Fig. 116.10 Acral fibrokeratoma. A light pink exophytic papule arising from the dorsal surface of the finger. Histologically, there is a digitated fibrovascular core with vertically arranged collagen bundles lined by epidermal hyperplasia; note the thick stratum corneum (inset). *Courtesy Hideko Kamino, MD.*

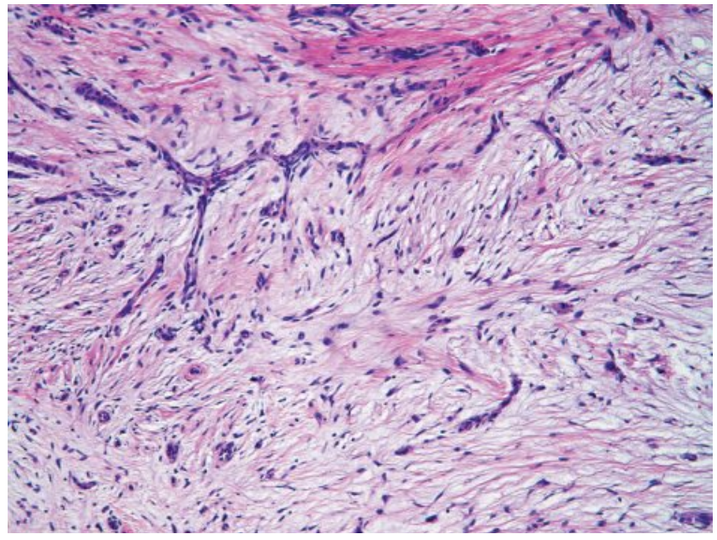

Fig. 116.11 Acral fibromyxoma. The lesion is composed of spindled and stellate cells arranged in a loose storiform pattern with a myxoid collagenous matrix. *Courtesy Shane Meehan, MD.*

or intradermal melanocytic nevi but are firmer to palpation. Treatment is simple excision, and to date there have been no reports of recurrence.

Pathology

Pleomorphic fibromas are polypoid or dome-shaped, well-circumscribed dermal lesions characterized by low cellularity with a predominance of thick collagen bundles in a haphazard array. There are scattered spindled cells and irregularly shaped multinucleated cells with scanty cytoplasm, indistinct cellular borders, and large pleomorphic and hyperchromatic nuclei (Fig. 116.13). Some of the multinucleated cells have multilobed nuclei. Mitotic figures are rare.

The spindle-shaped cells and the irregularly shaped, multinucleated cells are positive for vimentin and CD34[33], and the spindle-shaped cells react positively for muscle-specific actin. The differential diagnosis includes dermatofibroma with atypical cells, atypical fibroxanthoma, and neurofibroma with atypical cells. Superficial variants of pleomorphic lipoma or cutaneous atypical lipomatous tumor (ALT) have similar histologic features as pleomorphic fibroma albeit with larger numbers of entrapped adipocytes as well as occasional lipoblasts in ALT. In ALT, nuclear expression of MDM2 and CDK4 is seen.

FIBROBLASTIC, MYOFIBROBLASTIC AND "FIBROHISTIOCYTIC" PROLIFERATIONS AND NEOPLASMS – MUTATED GENES AND GENE FUSION PARTNERS			
Neoplasm/Proliferation	**Gene**	**Protein product**	**Protein function/dysfunction**
Epithelioid fibrous histiocytoma	*ALK*	Anaplastic lymphoma receptor tyrosine kinase	Rearrangements lead to overexpression of ALK
Acral fibromyxoma	*RB1*	Retinoblastoma 1	Loss of tumor suppressor function
Tenosynovial giant cell tumor (localized type)	*CSF1*	Colony-stimulating factor 1	Attracts macrophages
	COL6A3	Collagen type VI α-3 chain	Subunit of collagen
Nodular fasciitis	*MYH9*	Myosin heavy chain 9	Subunit of myosin
	USP6	Ubiquitin specific peptidase 6	Induces production of MMPs
Inherited infantile myofibromatosis	*PDGFRB*	Platelet-derived growth factor receptor-β	Ligand-independent receptor kinase activity
	NOTCH3	Notch receptor 3	Increased PDGFRB expression
Cellular/atypical myofibromas	*SRF*	Serum response factor	Vascular smooth muscle cell differentiation
	RELA	RELA proto-oncogene, NF-κB subunit	Pathologic activation of NF-κB pathway
Calcifying aponeurotic fibroma	*FN1*	Fibronectin 1	Allegedly drives inappropriate expression of EGF
	EGF	Epidermal growth factor (EGF)	Activation of signaling pathways via EGF receptor
Desmoid type fibromatosis (extra-abdominal fibromatosis)	*CTNNB1*	β-catenin	Nuclear accumulation stimulates target genes in WNT/β-catenin signaling pathway
DFSP, giant cell fibroblastoma	*COL1A1*	Collagen type I α-1 chain	Subunit of collagen
	PDGFB	Platelet derived growth factor subunit B	Continued expression leads to activation of PDGF receptor B
Fibrosarcomas	See Table 116.4		
Epithelioid sarcoma	*SMARCB1/ INI1*	SWI/SNF-related, matrix-associated, actin-dependent regulator of chromatin, subfamily B, member 1/integrase interactor 1	Regulates transcription as part of a complex that relieves repression of chromatin structures

Table 116.3 Fibroblastic, myofibroblastic and "fibrohistiocytic" proliferations and neoplasms – mutated genes and gene fusion partners. Tumors with gene fusion partners are shaded in peach; the protein that is overexpressed is shaded in blue. DFSP, dermatofibrosarcoma protuberans; MMPs, matrix metalloproteinases; SWI/SNF, SWItch Sucrose Non-Fermentable chromatic remodeling complex.

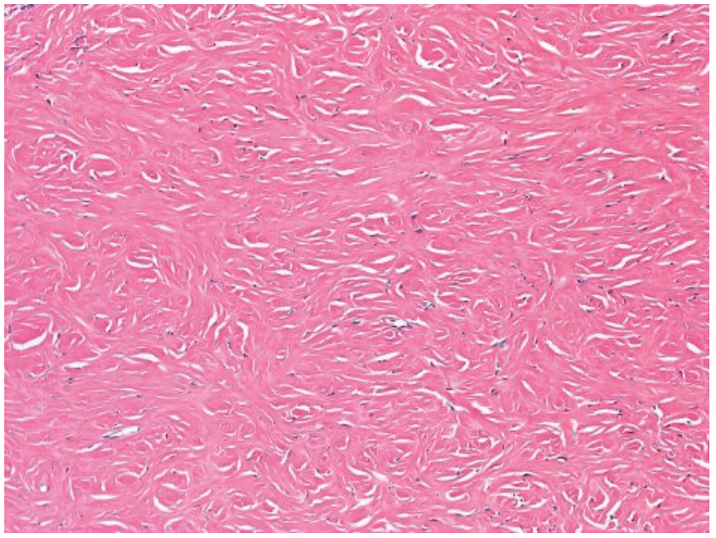

Fig. 116.12 Sclerotic fibroma. The collagen bundles in this hypocellular tumor are arranged in short parallel bundles, leading to a laminated or "plywood" appearance. *Courtesy Lorenzo Cerroni, MD.*

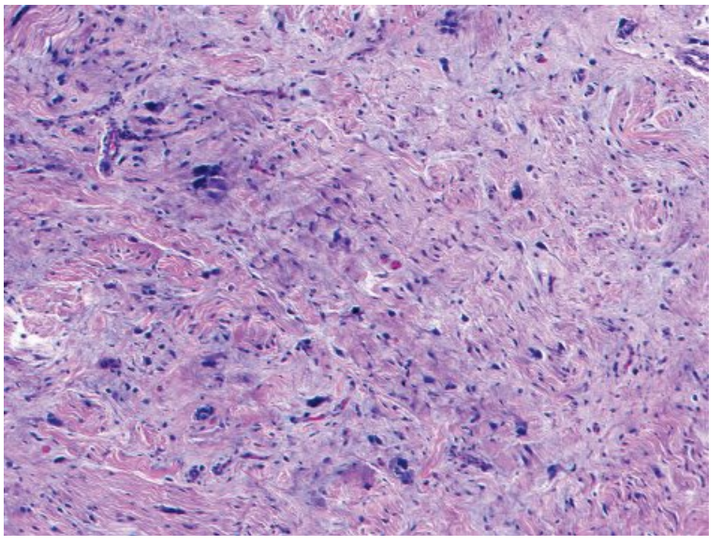

Fig. 116.13 Pleomorphic fibroma. There are delicate interwoven collagen bundles with a few interspersed large mononucleated and multinucleated atypical fibroblasts. The stroma is dominated by mesenchymal mucin.

MULTINUCLEATE CELL ANGIOHISTIOCYTOMA

Clinical Features

The typical clinical presentation of multinucleate cell angiohistiocytomas is that of slowly growing, multiple, discrete but grouped, red to violaceous papules, usually on the lower extremities or the dorsal aspect of the hands (Fig. 116.14). The lesions may be unilateral or bilateral, and typically affect women over 40 years of age[34]. A generalized form has also been described[35]. Clinically, lesions may resemble piloleiomyomas, Kaposi sarcoma, granuloma annulare, or sarcoidosis.

Pathology

These lesions are composed of a proliferation of dilated capillaries and small venules in the superficial to mid dermis within thickened collagen bundles (Fig. 116.15). The characteristic cell is a multinucleated giant cell, sometimes with peripheral palisading of the nuclei within eosinophilic cytoplasm (Fig. 116.15, inset). The histopathologic differential diagnosis includes dermatofibroma, angiofibroma, hemangioma, and interstitial granuloma annulare.

Fig. 116.14 Multinucleate cell angiohistiocytoma. Red–brown macules and papules on the dorsum of the hand.

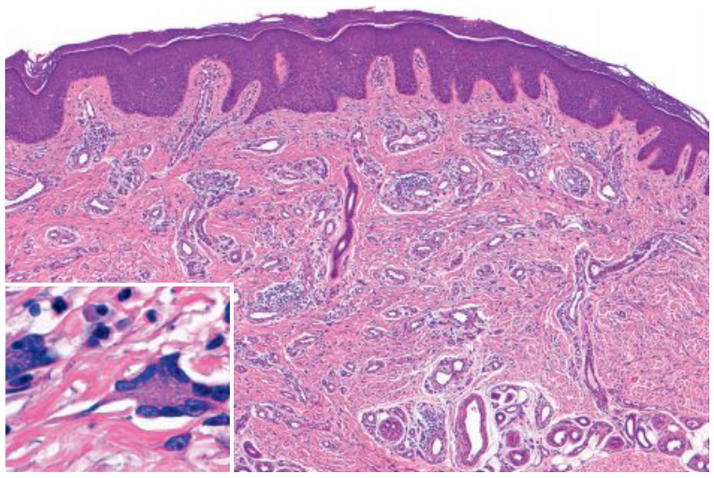

Fig. 116.15 Multinucleate cell angiohistiocytoma. There is a proliferation of dilated blood vessels with a sparse inflammatory infiltrate, an increase in fibroblasts, and the presence of stellate and angulated giant cells (inset). Resemblance to an incipient, richly vascularized dermatofibroma is striking.

Treatment

These lesions are benign. If left untreated, most cases progress slowly without evidence of spontaneous resolution.

DERMATOMYOFIBROMA

This tumor was described as plaque-like dermal fibromatosis in 1991 by Hügel[36] and as dermatomyofibroma by Kamino et al.[37]. It is a benign fibroblastic/myofibroblastic dermal neoplasm[38].

Clinical Features

Dermatomyofibromas most commonly occur in young women and favor the shoulder area, axilla, upper arm, and neck. Occasionally, these tumors arise during childhood. They are asymptomatic, well-circumscribed, oval or annular, skin-colored to red–brown plaques that have a smooth surface and measure 1–2 cm in diameter.

Pathology

Dermatomyofibromas are well-circumscribed plaques involving the reticular dermis and the upper portion of the subcutaneous septae; they are composed of well-defined, long fascicles of spindle-shaped cells parallel to the skin surface (Fig. 116.16). The cells have a very uniform appearance, with elongated nuclei having rounded or pointed ends and one or two small nucleoli. There is no evidence of nuclear atypia, and mitoses are rare. The cells are separated by thin collagen fibers and elastic fibers are preserved.

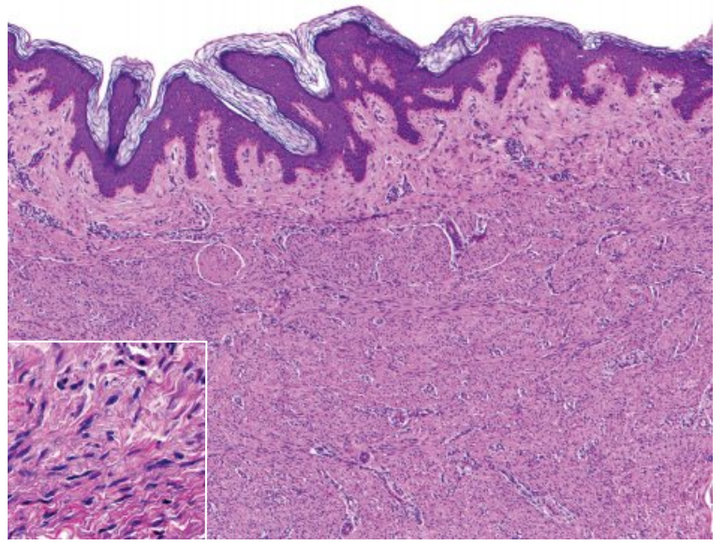

Fig. 116.16 Dermatomyofibroma. The myofibroblasts are arranged in long intersecting fascicles that are parallel to the skin surface. The cells have a uniform appearance, with elongated nuclei having rounded or pointed ends (inset). *Courtesy Luis Requena, MD.*

The fascicles, spindle-shaped cells, collagen fibers, and elastic fibers may have a wavy appearance. The adnexal structures are spared.

With Verhoeff–van Gieson stain, the elastic fibers appear slightly increased in number. The spindle-shaped cells react positively for vimentin and are variably positive for muscle-specific actin; staining for desmin, factor XIIIa, and CD34 is negative. These results support a fibroblastic/myofibroblastic differentiation rather than smooth muscle differentiation[36–38]. The histologic differential diagnosis includes dermatofibroma, DFSP, myofibroma, smooth muscle tumors, fibrous hamartoma of infancy, fibromatoses, and fibroblastic connective tissue nevus.

Treatment

The treatment is simple excision. Recurrence is uncommon even when marginally or incompletely excised[38].

TENOSYNOVIAL GIANT CELL TUMOR (LOCALIZED TYPE)

Synonyms: ■ Giant cell tumor of tendon sheath ■ Localized nodular tenosynovitis

Clinical Features

This tumor usually presents as a firm nodule on the hand or finger (Fig. 116.17), but can also occur on the toes and other periarticular sites. It is typically slowly growing and fixed to subcutaneous structures without attachment to the overlying skin, except on the distal fingers and toes. Although usually asymptomatic, there can be pain, numbness, or stiffness of the affected digit.

Localized tenosynovial giant cell tumor is the most common tumor of the hand and can present at any age, but usually appears in adults 30 to 50 years of age and is more common in women than in men[39].

Pathology

The localized type of tenosynovial giant cell tumor is lobulated and well circumscribed (Fig. 116.18). It is composed of mononuclear cells, multinucleated osteoclast-like giant cells, foamy histiocytes, and inflammatory cells set in a variably collagenized stroma. The characteristic multinucleated giant cells are typically scattered throughout the tumor

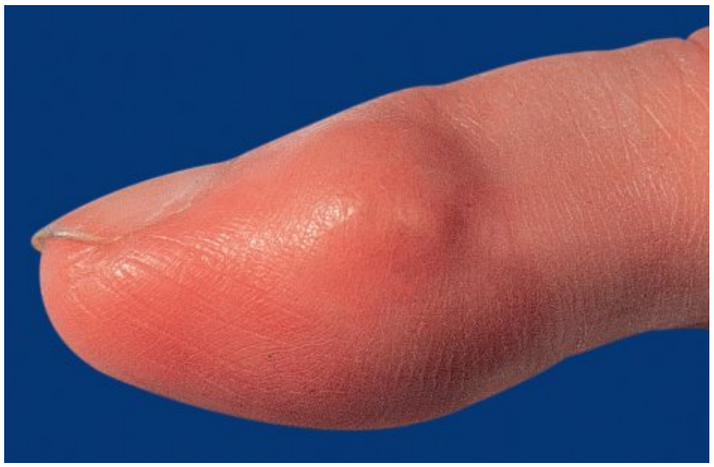

Fig. 116.17 Tenosynovial giant cell tumor (localized type). A skin-colored nodule on the lateral aspect of the index finger. This tumor was previously referred to as giant cell tumor of tendon sheath.

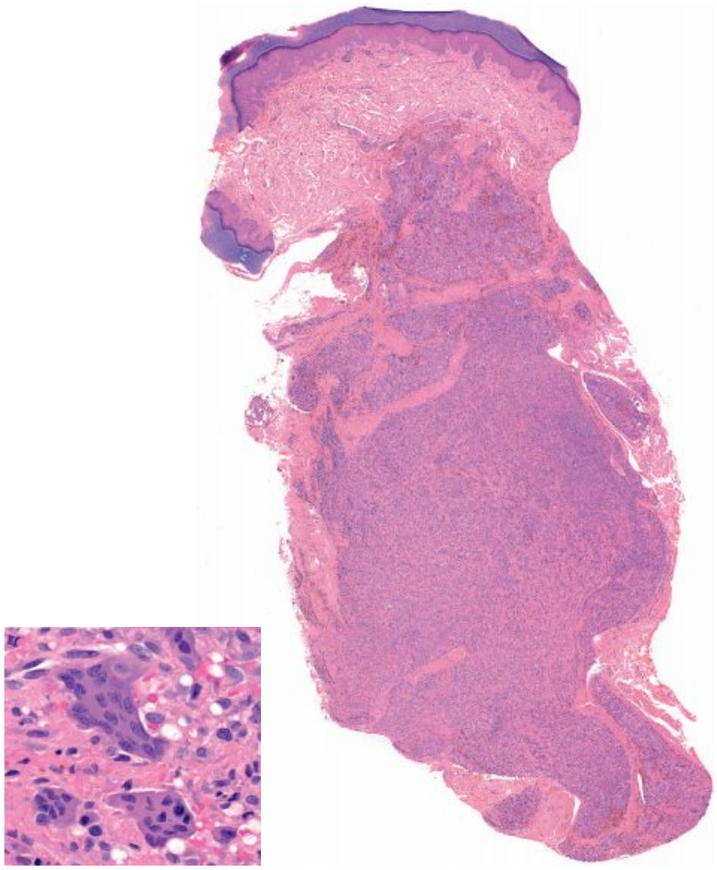

Fig. 116.18 Tenosynovial giant cell tumor (localized type). The tumor is composed of sheets of epithelioid histiocytes with a variable number of the characteristic multinucleated osteoclast-like giant cells (inset). Some of the histiocytes may have pale foamy cytoplasm. This tumor was previously referred to as giant cell tumor of tendon sheath. *Courtesy Lorenzo Cerroni, MD.*

in variable densities. These cells have eosinophilic cytoplasm and from a few to 50 nuclei (Fig. 116.18, inset). There are also both large and small mononucleated histiocytes with abundant vacuolated cytoplasm containing variable amounts of hemosiderin deposits. Stromal clefts, mitotic figures, and, rarely, vascular involvement may be observed.

By immunohistochemistry, the larger mononuclear cells express clusterin, which highlights their dendritic processes, and rarely stain positively for desmin. The smaller cells are positive for CD68, CD163, and CD45 (see Ch. 0). Remarkably, there is always a focal leukocyte common antigen (LCA)-positive lymphocytic infiltrate. Cytogenetically, this tumor has characteristic translocations, in particular t(1;2)(p13;q37) which fuses two genes – *CSF1* at 1p13 encoding colony-stimulating factor-1 and *COL6A3* at 2q37 encoding collagen type VI α-3[40–42]. This fusion leads to an overexpression of CSF1, which attracts large numbers of macrophages to the tumor site (see Table 116.3). The histologic differential diagnosis includes epithelioid sarcoma, synovial sarcoma, deep dermatofibroma, and tumors with myogenic differentiation.

Treatment

This tumor is benign, with a local recurrence rate of 30%. It can be treated by simple excision[39].

FIBROMA OF TENDON SHEATH

Synonym: ■ Tenosynovial fibroma

Clinical Features

This benign tumor presents as a small subcutaneous nodule. It is most frequently found on the hands and feet, with the most common site of involvement being the thumb. While usually asymptomatic, there can be limitation in the range of motion of involved joints[43].

This fibroma usually presents in those 20 to 50 years of age. Men develop these tumors three times more often than women. The clinical differential diagnosis includes localized type of tenosynovial giant cell tumor, neuroma, ganglion cyst, rheumatoid nodule, and subcutaneous granuloma annulare.

Pathology

The tumor has a well-circumscribed lobular appearance and is attached to a tendon sheath. It is composed of dense hyalinized collagen with scattered spindle-shaped fibroblasts/myofibroblasts and stromal clefts. There are characteristic elongated slit-like vessels as well as occasional giant cells and foci of myxoid change. Tumor cells stain focally for α-smooth muscle actin. In some cellular variants, *USP6* rearrangements similar to those in nodular fasciitis have been reported, raising the question if such variants represent tenosynovial nodular fasciitis[44].

Treatment

This tumor is benign, with a recurrence rate of ~25%. Some authors believe that this tumor may represent a sclerotic end-stage of the localized type of tenosynovial giant cell tumor[45].

NODULAR FASCIITIS

Synonyms: ■ Benign nodular (pseudosarcomatous) fasciitis
■ Subcutaneous pseudosarcomatous fibromatosis
■ Pseudosarcomatous fasciitis

Clinical Features

Nodular fasciitis is a benign transient tumor ("transient neoplasia")[46] that occurs in young to middle-aged adults. It presents as a rapidly growing (but self-limited) subcutaneous nodule measuring from 1 to 5 cm in diameter, and the upper extremity is the most common site. In children, the head and neck region is a frequent location[47]. Clinicopathologic variants include intradermal nodular fasciitis, intravascular fasciitis, and cranial fasciitis[48–50]. The latter variant develops predominantly in infants <2 years of age. It typically involves the outer table of the skull and contiguous soft tissue of the scalp but may extend through the inner table into the meninges.

Pathology

There is an unencapsulated, well-circumscribed or infiltrative, subcutaneous, fascial, or intramuscular nodule with a stellate appearance. A proliferation of plump spindle and stellate fibroblasts and myofibroblasts with oval nuclei is seen. In early lesions, the cells are loosely arranged in an edematous, myxomatous stroma imparting a "feathered" appearance (Fig. 116.19A,B), with a proliferation of small blood vessels, scattered lymphocytes, and extravasated erythrocytes ("tissue culture pattern"). Mitoses are frequent, but atypical mitoses are not seen. Intradermal fasciitis, intravascular fasciitis, and cranial fasciitis are similar histologically to nodular fasciitis.

The fibroblasts and myofibroblasts react positively for vimentin and muscle-specific actin and, to a lesser degree, for α-smooth muscle actin; rarely, desmin expression is seen. The interstitial monocytic round cells are positive for CD68[51]. An immunophenotypic pattern consisting of a loosely arranged α-smooth muscle actin-positive myofibroblastic proliferation sprinkled with $CD68^+$ macrophages and histiocytes is highly characteristic of nodular fasciitis (Fig. 116.19C,D). Cytogenetically, *USP6* rearrangements with formation of the fusion gene *MYH9-USP6* occur in most examples of nodular fasciitis (see Table 116.3)[42,46]. Mapping of *USP6* via FISH or next generation sequencing is a useful adjunct in the diagnosis of nodular fasciitis[42,52].

Treatment

Nodular fasciitis is treated with a conservative excision. The recurrence rate is ~1%[53].

CONNECTIVE TISSUE NEVUS

Variants/synonyms: ■ Collagen nevus: collagenoma, shagreen patch ■ Elastic tissue nevus: elastoma, dermatofibrosis lenticularis disseminata (Buschke–Ollendorf syndrome) ■ Mucin nevus: mucinous connective tissue nevus ■ Fibroblastic nevus: fibroblastic connective tissue nevus

Clinical Features

Connective tissue nevi are firm, solitary or multiple, skin-colored papules, nodules, or plaques that usually present at birth or arise during childhood (Fig. 116.20). A linear arrangement occasionally occurs. These nevi may represent hamartomas rather than neoplasms. Clinically and histologically, they may be subtle and even resemble normal skin. Several variants have been described, based upon the dominant tissue component present, and they are listed above, along with their synonyms.

The shagreen patch of tuberous sclerosis most commonly presents as a pebbly plaque with a "pigskin" appearance on the lower back (see Ch. 61). In the Buschke–Ollendorf syndrome, multiple skin-colored or slightly yellowish papules are seen and are referred to as dermatofibrosis lenticularis disseminata. This syndrome is due to loss-of-function mutations in *LEMD3* which then lead to loss of antagonism of the TGF-β and bone morphogenic protein signaling pathways[54]. The disorder is inherited in an autosomal dominant pattern and the papules begin at an early age. In radiograms, a characteristic stippled appearance to the bone is seen, called osteopoikilosis (Fig. 116.21). This abnormality is asymptomatic.

Connective tissue nevus is the sole category A criterion for Proteus syndrome. The nevi occur most commonly on the plantar surface and acquire a cerebriform appearance, but can be seen elsewhere (e.g. hands, abdomen; see Fig. 104.10).

Fig. 116.20 Connective tissue nevus. Coalescence of multiple tan papules and plaques on the lower back. The lesion was firm to palpation and histologically had increased collagen.

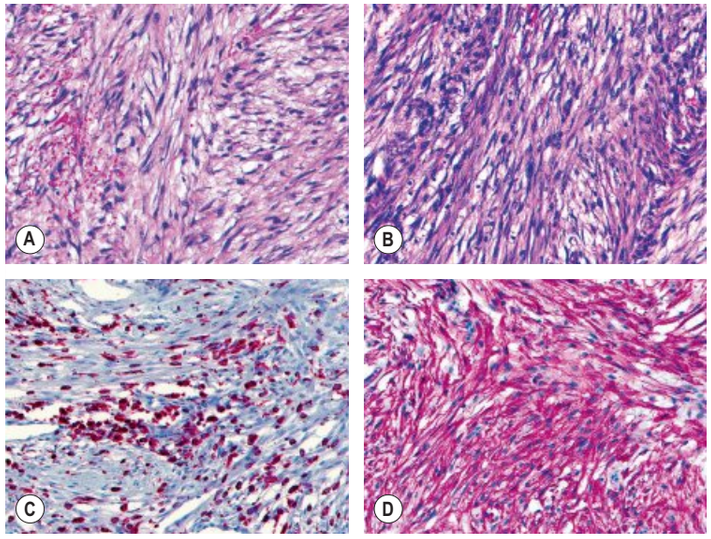

Fig. 116.19 Nodular fasciitis. A,B Proliferation of spindle-shaped and plump fibroblasts arranged in a haphazard array with focally myxoid stroma. The plump and spindle-shaped fibroblasts within the myxoid stroma have a vague "tissue culture-like" appearance. **C** Typical clusters of $CD68^+$ macrophages that are amidst a dense proliferation of α-smooth muscle actin-positive myofibroblasts (**D**).

Fig. 116.21 Osteopoikilosis. In this radiograph, multiple asymptomatic round to oval areas ("islands") of increased bone density are seen in the tibia. *Courtesy Jean L. Bolognia, MD.*

Pathology

There is usually a poorly demarcated area of increased dermal collagen bundles without an apparent increase in fibroblasts. Those lesions with a prominent collagen component are designated as *collagenomas*. A variant with increased elastic fibers has been called *elastoma*. Many of the cutaneous lesions in Buschke–Ollendorf syndrome tend to have increased elastic fibers, but some appear to be primarily collagenous. *Mucinous connective tissue nevi* are characterized by increased mucin deposition within the dermis. *Fibroblastic connective tissue nevus* is a recently delineated variant that presents as a solitary, slowly growing, asymptomatic, firm plaque or nodule. It has a smooth surface and is tan–white to light brown in color. These nevi most commonly occur on the trunk and in the head and neck region of children, with involvement of the deep dermis and superficial subcutis[55]. There is an intradermal proliferation of bland $CD34^+$ fibroblastic/myofibroblastic cells arranged in short-intersecting fascicles. It must be distinguished from $CD34^+$ plaque-like dermal fibroma (medallion-like dermal dendrocyte hamartoma; see eTable 116.1), DFSP, and dermatomyofibroma.

Differential Diagnosis

Although the differential diagnosis includes fibromatoses, fibrous hamartoma of infancy, infantile myofibromatosis, and dermatofibromas, clinicopathologic correlation usually establishes the diagnosis fairly easily.

INCLUSION BODY FIBROMATOSIS

Synonyms: ■ Infantile digital fibroma ■ Recurring digital fibrous tumor of childhood

Clinical Features

Inclusion body fibromatosis commonly presents as multiple, firm, smooth, skin-colored, dome-shaped nodules on the dorsolateral aspects of the fingers and toes (Fig. 116.22). They can be up to several centimeters in diameter and tend to spare the thumb and great toe.

Almost all cases occur in infants under 1 year of age. Rare adult cases of a histologically similar tumor have been reported at extradigital sites[56]. Multiple lesions may be seen in patients with terminal osseous dysplasia with pigmentary defects.

Fig. 116.22 Inclusion body fibromatosis. Firm skin-colored nodule on the dorsolateral aspect of the second toe in a young child. This entity was previously referred to as infantile digital fibroma.

Pathology

These fibromas are poorly circumscribed proliferations of spindle-shaped myofibroblasts, arranged as interwoven fascicles with a collagenous stroma within the dermis or subcutaneous tissue. The cells have uniform, spindle-shaped, wavy nuclei without nuclear atypia or mitoses. The pathognomic feature is the presence of eosinophilic intracytoplasmic inclusions (Fig. 116.23), which are often perinuclear and are red-purple in color with Masson's trichrome stain.

Treatment

In general, the clinical course is benign, although functional impairment is possible. Spontaneous regression within 2–3 years is the usual natural history[57]. Contractures can be problematic. Recommended treatment options include conservative excision or observation (after histologic confirmation), with additional surgery as necessary for recurrences[58].

INFANTILE MYOFIBROMATOSIS

Synonyms: ■ Infantile fibromatosis ■ Congenital multicentric fibromatosis ■ Congenital generalized fibromatosis ■ Infantile myofibroma/myofibromatosis

Clinical Features

Clinically, *infantile myofibromatosis* presents as one or more, firm to rubbery, skin-colored to purple, dermal or subcutaneous nodules, commonly located in the head and neck region or on the trunk (Fig. 116.24). Some patients have a multicentric form *without visceral involvement* where multiple lesions develop in the skin, subcutaneous tissue, bone, and/or muscles. The multicentric (generalized) form *with visceral involvement* represents the most severe expression of the disease and is characterized by multiple lesions in the skin, subcutaneous tissue, muscles, and/or bones as well as involvement of one or more internal organs, in particular the lungs, heart, and gastrointestinal tract. Skeletal involvement, which occurs in approximately half of patients with multicentric disease, typically presents as lytic metaphyseal lesions.

Approximately 50% of patients have lesions present at birth, with more appearing during the first two years of life. Familial cases have been

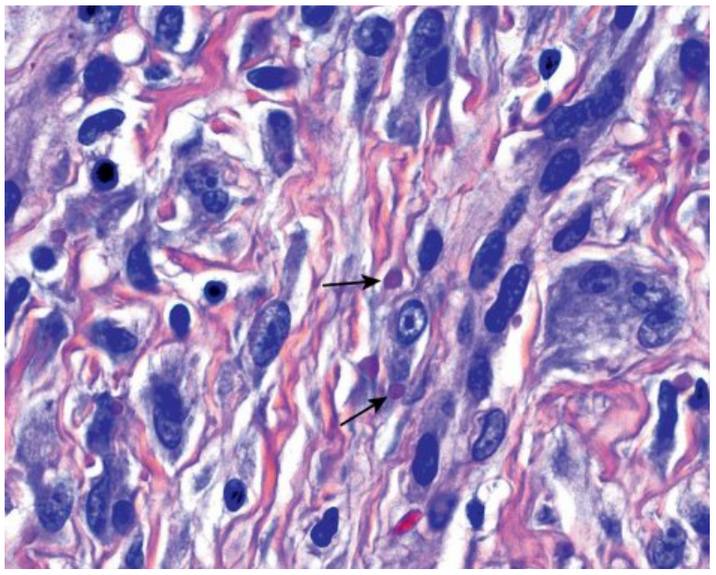

Fig. 116.23 Inclusion body fibromatosis. Myofibroblasts have pathognomonic cytoplasmic eosinophilic hyalin globules (arrows). This entity was previously referred to as infantile digital fibroma. *Courtesy Hideko Kamino, MD.*

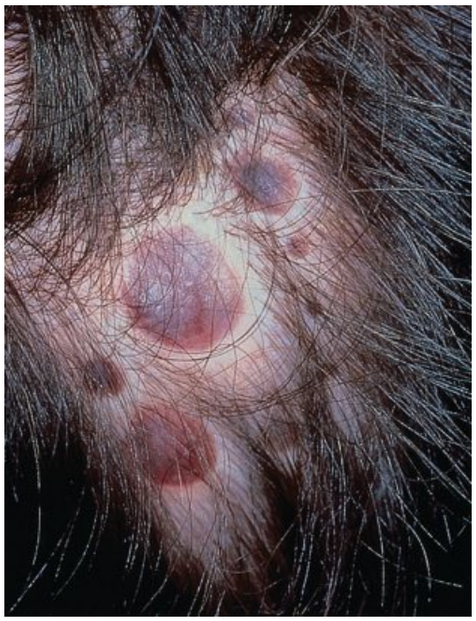

Fig. 116.24 Infantile myofibromatosis. Multiple firm violaceous papulonodules on the scalp.

reported, with an autosomal dominant inheritance pattern (see below), and female infants have a greater tendency for visceral involvement[59]. Evaluation for internal involvement includes skeletal radiographs, electrocardiogram, and CT scan of the chest and abdomen or whole-body MRI. The multicentric form without visceral involvement (and the solitary form) typically undergo spontaneous regression but can recur, whereas the visceral form is associated with a mortality rate of up to 75%.

Solitary myofibromas represent the third and the most common form of infantile myofibromatosis (~75% of cases). They exist on a spectrum with *myopericytomas*, may also develop in older children or adults, and have a good prognosis (see below)[60].

Pathology

In the 5th edition of the WHO classification of soft tissue and bone tumors, myofibromas are categorized within the group of pericytic/perivascular tumors. These tumors are composed of circumscribed nodules with a biphasic appearance. Areas of plump spindle-shaped myofibroblasts with abundant cytoplasm, arranged in fascicles within a collagenous stroma, blend with more cellular areas composed of smaller, rounder cells having less cytoplasm and an associated stag-horn pattern of dilated branching blood vessels. Mitotic figures, necrosis, intravascular growth, and stromal hyalinization can be present.

Immunohistochemically, the spindle and rounded cells are positive for vimentin and SMA, with negative staining for desmin, as is seen in myofibroblasts. The histologic differential diagnosis includes infantile hemangiopericytoma, which some authors suggest exists on a continuum with myofibromatosis (see Ch. 114).

PDGFRB plays a role in tumor pathogenesis, with germline mutations in this gene detected in the autosomal dominant form of infantile myofibromatosis[61]. A *NOTCH3* mutation that leads to increased PDGFRB expression has also been reported in familial infantile myofibromatosis[62], and *SRF-RELA* gene fusions have been noted in cellular/atypical myofibromas (see Table 116.3)[63]. Lastly, gain-of-function mutations in *PDGFRB* have been detected in solitary pediatric myofibromas[64].

Treatment

Patients with only soft tissue and bony involvement have a good prognosis, as the tumors regress spontaneously within months via massive apoptosis[65]. Those with visceral involvement have a high mortality rate within the first 4 months owing to the compromise of vital organ function (e.g. cardiopulmonary failure). However, if patients survive beyond this period to when the tumors begin to regress, the prognosis is much improved. Because the tumors tend to regress, debulking surgery is recommended only for symptomatic lesions. Targeted tyrosine kinase inhibitors (e.g. imatinib) and combination chemotherapy have been used in severe cases[59].

MYOPERICYTOMA

Synonyms: ■ Cutaneous adult myofibroma ■ Perivascular myoma ■ Glomangiopericytoma

Clinical Features

This tumor is the adult counterpart of infantile myofibromatosis, but as noted previously can be seen in older children[60,66–69]. It presents as a solitary, firm, deep dermal nodule and is often diagnosed clinically as a dermatofibroma, cyst, or angioleiomyoma. Multicentric variants are rare.

Pathology

These perivascular tumors possess a broad morphologic spectrum: at one end is a myoid nodular proliferation resembling an angioleiomyoma and at the other end is a hemangiopericytoma-like, richly vascularized, biphasic tumor with both myoid basophilic spindle cell nodules and richly vascularized myopericytic sheets. A highly characteristic finding is the "spinning off" of the outer vessel wall of small myopericytic cells. Myopericytomas may have degenerative changes including symplastic nuclear atypia, hyalinization, and cystic changes.

The term myopericytomatosis has been introduced for an apparently benign variant of myopericytoma characterized by innumerable, discrete microscopic myopericytomatous nodules that typically diffusely involve superficial soft tissue in adults. *PDGFRB* alterations are present in a subset of myopericytomas/myopericytomatosis and infantile myofibromatosis/myofibromas. Therefore these entities appear to lie within a histogenetic continuum. When *PDGFRB* alterations are present, tyrosine kinase inhibitors represent a potential therapeutic strategy, if needed[61,70].

Treatment

Myopericytoma can be interpreted as infantile myofibromatosis "en miniature". Lesions are benign, with malignant variants being exceedingly rare. Treatment consists primarily of local excision.

CALCIFYING APONEUROTIC FIBROMA

Synonyms: ■ Juvenile aponeurotic fibroma ■ Calcifying fibroma ■ Cartilage analogue of fibromatosis

Clinical Features

This is a very rare entity that presents as a solitary, slowly growing, asymptomatic, firm subcutaneous nodule that is usually fixed to underlying structures. It occurs primarily on the hands, and sometimes on the feet. A characteristic radiologic finding is the presence of stippled calcifications. Most cases occur in young children and adolescents, and boys are affected more frequently than girls[71].

Pathology

The tumor is poorly circumscribed with an infiltrating border. It is composed of sheets of spindled and epithelioid fibroblasts with parallel nuclei in a collagenous stroma. The biphasic pattern of plump epithelioid cells in conjunction with slender spindle cells can be striking. Most cases have a myofibroblastic immunophenotype with expression of α-smooth muscle actin.

In addition, there are characteristic islands of calcifications surrounded by palisaded epithelioid fibroblasts (Fig. 116.25). In older lesions, these areas of calcification can undergo chondroid and osseous metaplasia. *FN1-EGF* gene fusions have been reported in these tumors and can facilitate diagnosis in unusual cases[72].

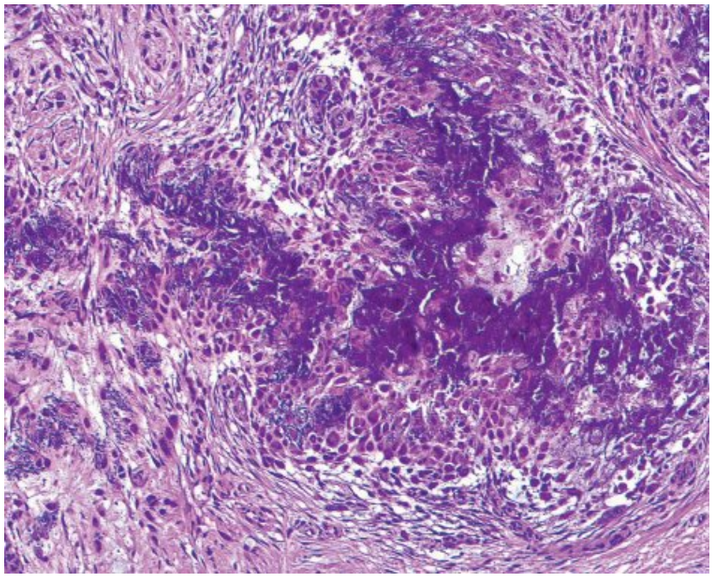

Fig. 116.25 Calcifying aponeurotic fibroma. Islands of calcification are surrounded by palisaded and osteoclast-like fibroblasts. In between these areas are sheets of spindled and epithelioid fibroblasts in a collagenous stroma.

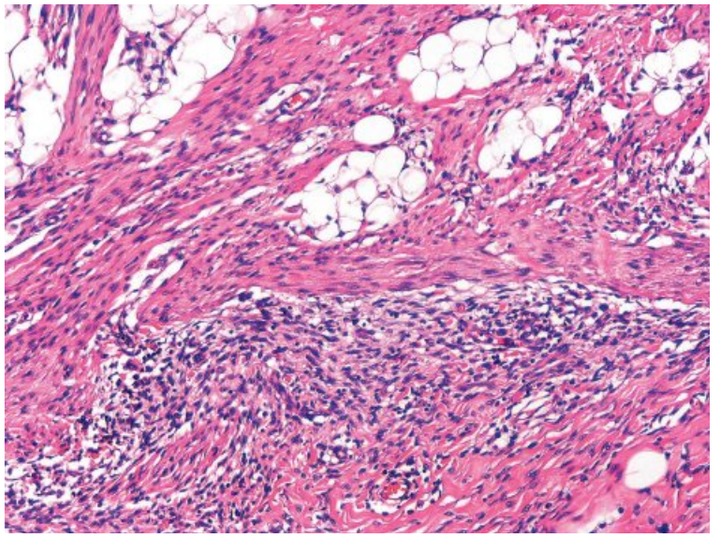

Fig. 116.26 Fibrous hamartoma of infancy. It is composed of a mixture of elongated bundles of spindle-shaped myofibroblasts, clusters of smaller immature mesenchymal cells in a myxoid stroma, and mature adipocytes.

Treatment

These tumors are benign, with a local recurrence rate of ~50%[71]. Treatment consists of local excision, with re-excision for recurrences.

FIBROUS HAMARTOMA OF INFANCY

Synonym: ■ Subdermal fibromatous tumor of infancy

Clinical Features

This tumor typically presents as a solitary, painless, skin-colored subcutaneous nodule. It favors the axilla, shoulder, and upper arm, although it can appear in other sites such as the groin[73,74]. There is a variable rate of growth, and a fibrous hamartoma can become quite large. Fixation to underlying structures may be observed. Occasionally, hyperhidrosis and hypertrichosis are present[75].

Most of these tumors appear within the first year of life, but some are congenital. Boys are affected three times as often as girls[73,76]. Fibrous hamartomas may mimic other subcutaneous malignancies of infancy such as rhabdomyosarcoma and cutaneous metastases (e.g. neuroblastoma, leukemia) as well as other fibromatoses and subcutaneous fat necrosis.

Pathology

This tumor is not well circumscribed, and it is composed of three distinctive elements in variable proportions: (1) a proliferation of spindle-shaped, α-smooth muscle actin-positive myofibroblasts arranged as broad fascicles within a collagenous stroma; (2) nests and aggregates of smaller, round to plump, spindle-shaped, immature mesenchymal cells within a myxoid matrix (primitive-appearing cells can express CD34); and (3) mature adipocytes (Fig. 116.26). Hyalinized zones with cracking artifact, mimicking giant cell fibroblastoma, are frequently observed[77].

Treatment

Fibrous hamartoma of infancy is benign and the usual treatment is local excision, with recurrence being fairly uncommon[76]. If left untreated, the tumor continues to grow and stabilizes in size by mid-childhood. In rare cases, the presence of "sarcomatous" areas provides evidence that these are complex neoplasms rather than hamartomas[77].

FIBROMATOSES

Synonyms/subtypes:

- Superficial fascial fibromatosis:
  - palmar fibromatosis (Dupuytren disease)
  - plantar fibromatosis (Ledderhose disease)
  - penile fibromatosis (Peyronie disease)
  - knuckle pads (holoderma)
  - pachydermodactyly
- Deep musculoaponeurotic fibromatosis:
  - desmoid type fibromatosis (extra-abdominal fibromatosis) [synonym: aggressive fibromatosis]

Clinical Features

Fibromatoses are slowly growing tumors. The superficial variants may reach up to several centimeters in greatest diameter[78]. They appear as firm nodules, plaques, or cord-like tumors along the flexor tendons.

Palmar and plantar fibromatoses usually appear during adulthood and the incidence increases with age. Flexion contractures, especially

Fig. 116.28 Pachydermodactyly. A form of digital fibromatosis characterized by soft tissue swelling of the lateral aspects of the fingers, usually in the area of the proximal interphalangeal joints of the second to fourth fingers. *Courtesy Julie V. Schaffer, MD.*

of the fourth and fifth fingers, can result (see Ch. 98). Although nuclear β-catenin expression is observed in a subset of tumors, neither *CTNNB1* nor *ABC* mutations have been detected.

Penile fibromatosis is more common in middle-aged to elderly men; pain and erectile dysfunction are common.

Knuckle pads affect the extensor surfaces of the interphalangeal and metacarpophalangeal joints (Fig. 116.27) and may be associated with palmar and plantar fibromatosis. While often idiopathic, they may also be a reflection of trauma. In Bart–Pumphrey syndrome, knuckle pads are seen in association with palmoplantar keratoderma, hearing loss, and leukonychia (see Ch. 58).

Pachydermodactyly is an uncommon form of digital fibromatosis. It typically presents in adolescent boys as soft tissue swelling of the lateral aspects of the proximal interphalangeal joints of the second to fourth fingers (Fig. 116.28). This disorder may be related to mechanical trauma[79].

Deep musculoaponeurotic fibromatoses or *desmoid tumors* are usually rather large – up to 25 cm in diameter. There are abdominal and extra-abdominal variants. They may present in postsurgical scars, within the abdominal wall following trauma or pregnancy, and as mesenteric fibromatosis in Gardner syndrome (due to *APC* mutations; see Ch. 63). Up to 95% of sporadic desmoid tumors harbor mutations in *CTNNB1* which encodes β-catenin[80].

Pathology

Fibromatoses consist of large, poorly circumscribed, dermal and subcutaneous plaques and nodules composed of long sweeping fascicles of monotonous fibroblasts and myofibroblasts, along with compressed and elongated vessels (Fig. 116.29). The neoplastic cells usually infiltrate the adjacent aponeurosis, fascia, and skeletal muscle.

In general, tumor cells in all types of fibromatoses stain variably for muscle-specific actin and α-smooth muscle actin, depending upon the extent of myofibroblastic differentiation. In palmar and plantar fibromatoses, at least 50% of tumor cells may show nuclear immunopositivity for β-catenin[81], but in the absence of a mutation; in desmoid tumors (desmoid-type fibromatosis), ~70%–75% of cell nuclei stain positively for β-catenin[81]. As noted previously, the vast majority of sporadic desmoid tumors have mutations in *CTNNB1*[80].

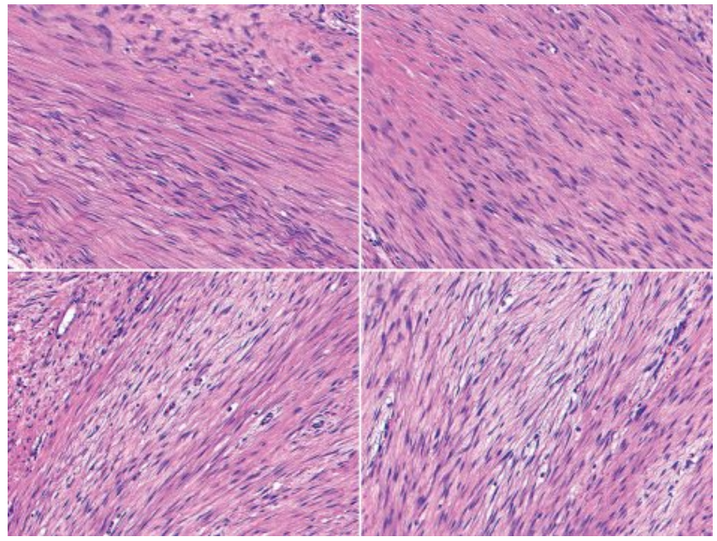

Fig. 116.29 Extra-abdominal desmoid tumor (fibromatosis). There is a distinct cellular proliferation of bland spindled cells arranged in ill-defined long fascicles. These cells have bland nuclear features.

Cytogenetic abnormalities have been identified less frequently in superficial fibromatoses as compared to their deep counterparts, and in the former, usually exhibit simple numerical changes, especially gains of chromosome 8[82].

Treatment

Surgical excision with fasciectomy is standard therapy for palmar and plantar fibromatosis, with the goal of reducing functional impairment rather than complete disease removal. Injection of collagenase (from *Clostridium histolyticum*) represents a nonsurgical option for Dupuytren contractures, with response rates of 45%–65%[83]. Penile fibromatoses may resolve spontaneously in approximately a third of patients[84]. Therefore, a waiting period is recommended before injections of collagenase, surgical excision, or laser therapy. The deep musculoaponeurotic fibromatoses have a higher recurrence rate and appropriate treatment of these is beyond the scope of this book[85].

PLEXIFORM FIBROHISTIOCYTIC TUMOR

Clinical Features

A plexiform fibrohistiocytic tumor typically presents as a slowly growing, firm, painless mass in a child or young adult[86]. It is usually <3 cm in diameter and usually occurs on an extremity. This tumor is regarded as having intermediate biologic behavior with a tendency to recur locally but only rarely metastasizing.

Pathology

The tumor develops at the dermal/subcutaneous junction and appears as an infiltrative mass that may invade muscle. It is composed of small nodules of histiocytes and multinucleated giant cells surrounded by fascicles of spindled cells in variable proportions. These spindle cells express SMA. Mitotic figures and mild nuclear pleomorphism may be seen as well as lymphovascular invasion. Based on shared morphologic and phenotypic features, there is growing evidence to suggest that cellular neurothekeoma and plexiform fibrohistiocytic tumor exist on a continuum[87].

Treatment

These tumors are locally aggressive with high rates of recurrence, requiring excision with wider margins and long-term evaluation[88].

ATYPICAL FIBROXANTHOMA

Clinical Features

This tumor usually presents as a rapidly growing, exophytic, dome-shaped nodule that measures from 1 to 2 cm in diameter (Fig. 116.30). Secondary changes include serosanguineous crusts and ulceration[89]. In the 5th edition of the WHO classification of soft tissue and bone tumors, atypical fibroxanthoma (AFX) is defined as a dermal-based mesenchymal neoplasm of uncertain differentiation that develops within photodamaged skin. It is viewed as existing on a disease spectrum with pleomorphic dermal sarcoma. However, when strict diagnostic criteria are applied, AFX generally behaves in a benign fashion[90–92].

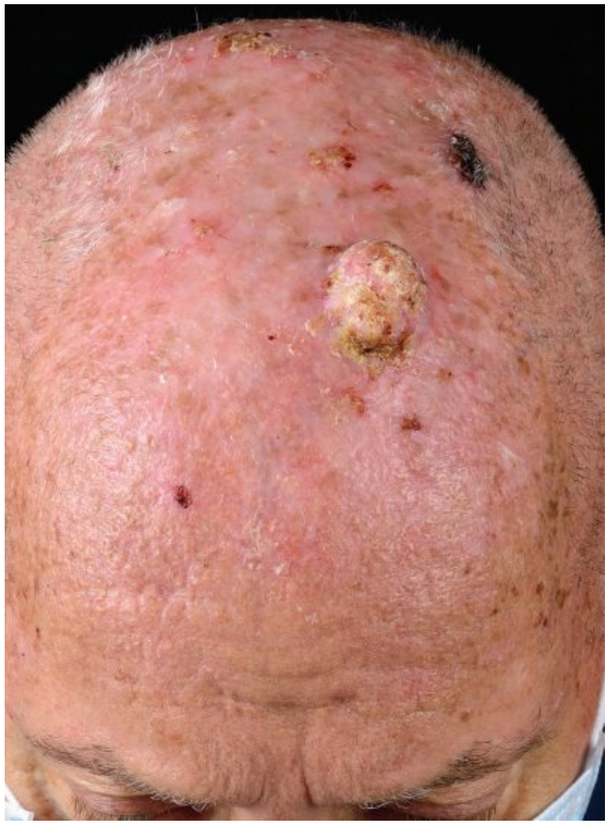

Fig. 116.30 Atypical fibroxanthoma. A crusted nodule on the scalp arising within a background of chronic photodamage with multiple actinic keratoses and diffuse scarring. *Courtesy Lorenzo Cerroni, MD.*

Pathology

This dermal-based tumor is well circumscribed and commonly ulcerated, and it usually has a collarette of hyperplastic epithelium. The neoplasm is confined to the dermis, with minimal to no infiltration of the subcutaneous fat; extensive infiltration of fatty tissue actually excludes the diagnosis of AFX. The tumor can push both adnexal structures and abnormal elastic fibers (solar elastosis) to the bottom of the lesion.

AFX is composed of atypical spindle-shaped cells with moderate amounts of cytoplasm and large atypical cells with abundant pale-staining vacuolated cytoplasm. The cells have large pleomorphic and hyperchromatic nuclei and some of them are multinucleated (Fig. 116.31A). Several morphologic variants of AFX exist – spindle-cell non-pleomorphic, clear cell, pigmented, myxoid, osteoclast-like giant cell-rich, keloidal, and granular cell (Fig. 116.31B–D)[93–98].

Tumor cells can express muscle-specific actin, CD68, and CD10[99]. However, these markers are considered to be nonspecific in the context of an AFX. As a rule, the diagnosis of AFX must be established by exclusion, in particular of squamous cell carcinoma and its variants, cutaneous melanoma, angiosarcoma, myxofibrosarcoma, variants of fibrous histiocytoma, pleomorphic fibroma, non-neural granular cell tumor, and superficial leiomyosarcoma[91]. An AFX is characteristically negative for all types of cytokeratins, melanocytic markers, the endothelial marker ERG, and desmin.

Tumors whose pathologic features are similar to AFX but demonstrate subcutaneous invasion, necrosis, and/or lymphovascular or perineural invasion are thought to be associated with an adverse outcome and are better regarded as *pleomorphic dermal sarcoma* or *undifferentiated pleomorphic sarcoma of skin*[92].

Treatment

The behavior of AFX is benign in the vast majority of patients, provided that strict diagnostic criteria are applied[91]. Because the incidence of local recurrences is very low and metastases are rare[99], AFX is usually cured by complete excision, including via Mohs micrographic surgery. In contrast, pleomorphic dermal sarcoma/undifferentiated pleomorphic sarcoma should be excised with wide tumor-free margins, and patients should be followed closely as these sarcomas have a local recurrence

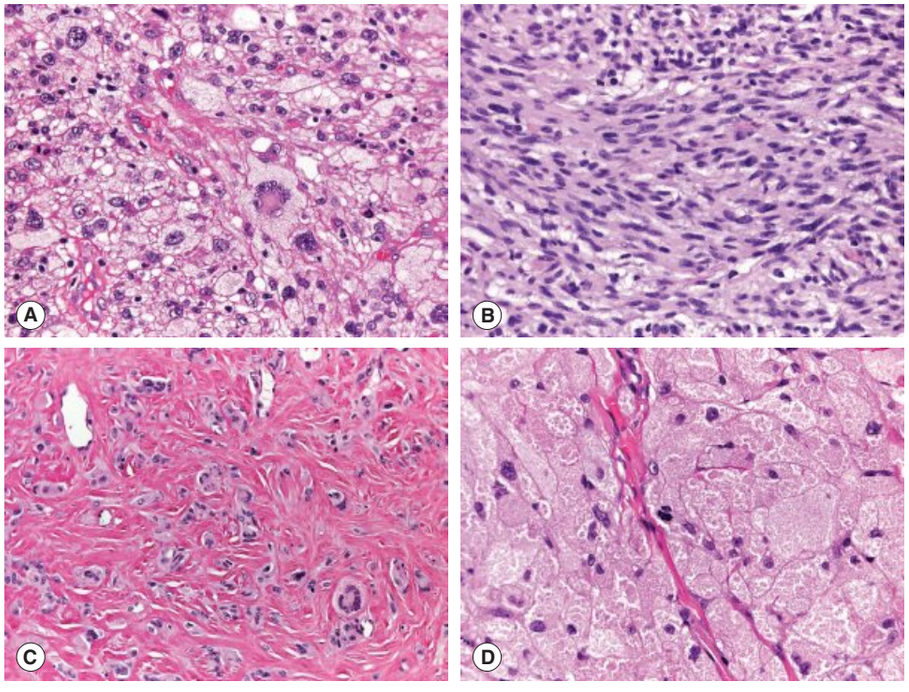

Fig. 116.31 Atypical fibroxanthoma (AFX) – four different histopathologic variants. A "Conventional" AFX with multiple "Touton-like" giant cells and marked pleomorphism. **B** Spindle cell variant characterized by a proliferation of spindle cells with only minimal pleomorphism. **C** Keloidal variant characterized by pleomorphic tumor cells embedded in a desmoplastic stroma. **D** Granular cell variant characterized by granular cytoplasm of the neoplastic cells, resembling a granular cell tumor. *Courtesy Lorenzo Cerroni, MD.*

rate of 25%–30% and a metastatic rate of 10%[92]. Progressive metastatic disease may occur[92].

DERMATOFIBROSARCOMA PROTUBERANS

Clinical Features

Dermatofibrosarcoma protuberans (DFSP) is a locally aggressive sarcoma of intermediate malignancy that favors young to middle-aged adults. Lesions that are present at birth or with an onset during childhood have also been reported. DFSP occurs on the trunk in 50%–60% of patients, the proximal extremities in 20%–30%, and the head and neck in 10%–15%. There is a predilection for the shoulder or pelvic region. Initially, a slowly growing, asymptomatic, skin-colored, indurated plaque is seen that eventually develops violaceous to red–brown nodules measuring from one to several centimeters in diameter (Fig. 116.32)[100]. On palpation, the lesion is firm and attached to the subcutaneous tissue. There are reports of accelerated growth during pregnancy[101].

The early plaque stage may be misdiagnosed as a benign tumor and incompletely excised. Moreover, superficial samples may not yield diagnostic material. Congenital and childhood-onset DFSP may have an atrophic appearance and/or hypopigmented to blue–red color, with the latter potentially leading to misdiagnosis as a vascular malformation or tumor. Multiple DFSPs have been observed in children with adenosine deaminase-deficient severe combined immunodeficiency[102].

Fig. 116.32 Dermatofibrosarcoma protuberans. A broad, pink–brown, multinodular, firm plaque on the back.

Pathology

Early plaque lesions are characterized by a flat surface and low cellularity and are comprised of slender spindle-shaped cells arranged as long fascicles parallel to the skin surface. The cells are scattered between thin collagen fibers and infiltrate thick collagen bundles which appear cellular and wavy. Nuclear atypia is minimal and mitotic figures are rare. Adnexal structures are infiltrated and obliterated. The spindle cells infiltrate into the subcutaneous tissue, very often in a multilayered pattern (Fig. 116.33A)[103].

In the nodular stage, the tumor becomes more cellular, with the cells arranged as short fascicles in a "storiform" arrangement (Fig. 116.33B). The cells infiltrate the subcutaneous tissue in a "honeycomb" pattern. Nuclei are hyperchromatic, and mitotic figures are easily identified. The nodules may develop myxomatous areas, characterized by more rounded to stellate cells in a highly vascular myxomatous stroma. Fibrosarcomatous areas are highly cellular, with intersecting fascicles in a "herringbone" pattern, with increased cytologic atypia and frequent mitoses.

Less than 5% of DFSPs contain melanin-producing cells with melanocyte or melanocyte-schwannian differentiation, and they are referred to as Bednar tumors[104].

In plaque-stage tumors, the spindle-shaped cells are strongly positive for CD34 (Fig. 116.33C)[10,105,106]. The reaction is stronger within the plaque areas than in the nodular foci[107]. The general immunostaining pattern of DFSP – CD34-positive, factor XIIIa-negative – serves to distinguish it from large and/or highly cellular dermatofibromas.

Unique cytogenetic abnormalities have been reported, such as reciprocal t(17;22) translocations (see below) and supernumerary ring chromosomes containing sequences from chromosomes 17 and 22[108]. Overexpression of *p53* has been found within the fibrosarcomatous areas of DFSP that have higher proliferative activity and aneuploidy[109].

The pathologic differential diagnosis of the plaque stage of DFSP includes atrophic dermatofibroma, dermatomyofibroma, fibroblastic connective tissue nevus, and neurofibroma. For the nodular stage, it includes deep dermatofibroma extending to the subcutaneous tissue, fibrosarcoma, and malignant peripheral nerve sheath tumor. The clinicopathologic criteria for CD34$^+$ plaque-like dermal fibroma (medallion-like dermal dendrocyte hamartoma) and superficial, mostly dermal DFSP overlap. However, the former does *not* have an unbalanced reciprocal

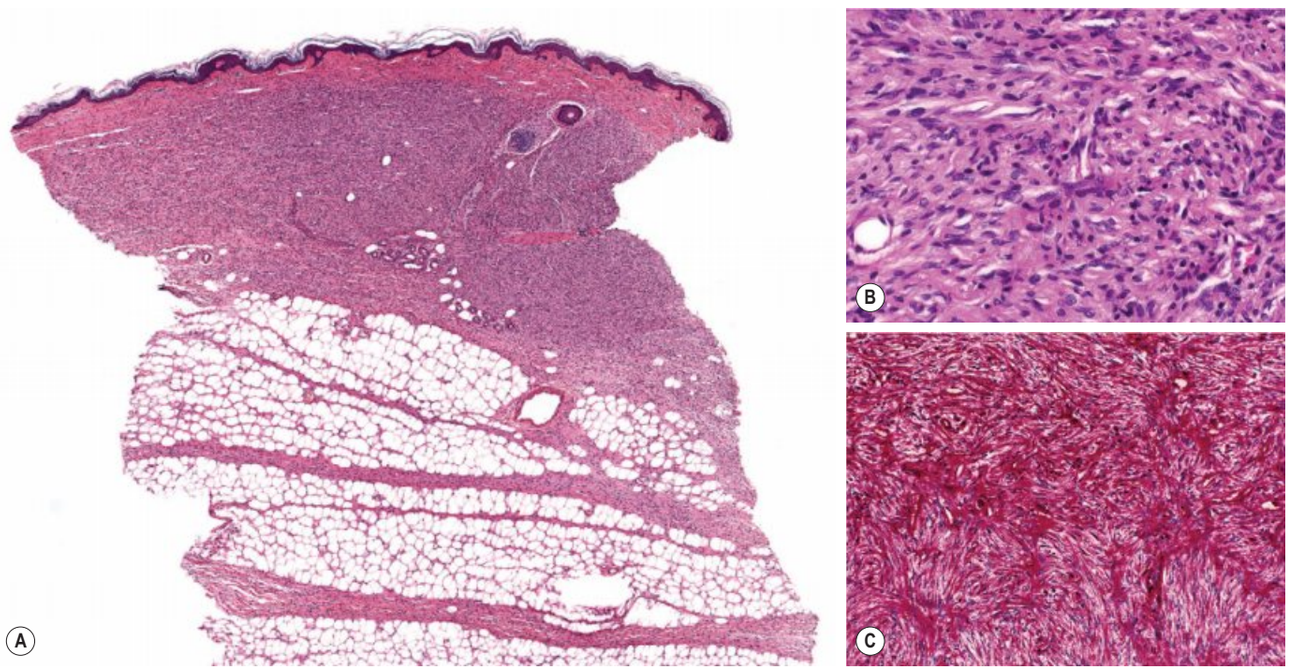

Fig. 116.33 Dermatofibrosarcoma protuberans. A Characteristic multilayered pattern of infiltration into the subcutaneous tissue. Note storiform pattern (**B**) and positivity for CD34 (**C**). *Courtesy Lorenzo Cerroni, MD.*

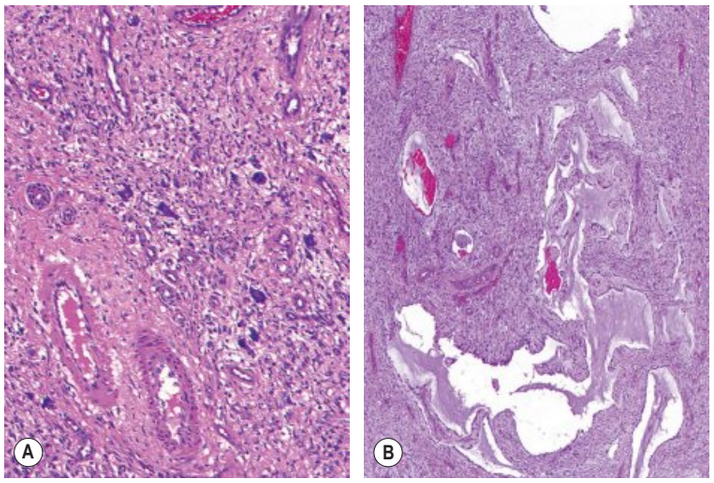

Fig. 116.34 Giant cell fibroblastoma. This variant of DFSP has a biphasic architecture consisting of: (**A**) foci of giant tumor cells with atypical nuclei; and (**B**) areas with pseudovascular or "angiectoid" spaces. Often the areas with atypical tumor cells and lacunar spaces are situated close to one another.

t(17;22) translocation[110] and it usually has a cellular, band-like, CD34$^+$ fibroblastic proliferation within the papillary and adjacent upper reticular dermis. For DFSP and its simulators, incisional biopsy specimens, including ample subcutaneous tissue, are optimal for diagnosis.

Molecular diagnostics utilizing FISH, RT-PCR or NGS can facilitate precise diagnosis via detection of the *COL1A1-PDGFB* gene fusion found in the majority of DFSPs (see Table 116.3). Rarely, alternative fusions involving *PDGFD* (*COL6A3-PDGFD*; *EMILIN2-PDGFD*) are identified[111,112]. In fibrosarcomatous DFSP, alterations in the PDGFRB/AKT/mTOR pathway have been reported[113].

Treatment

Complete surgical excision, including Mohs micrographic surgery, is the standard treatment for DFSP[114]. This tumor is characterized by its local invasion and tendency to recur. In rare cases, recurrent tumors with fibrosarcomatous areas have metastasized to the lungs[115]. Because the translocation (17;22) places the platelet-derived growth factor (PDGF) subunit B gene under the control of the collagen 1A1 promoter, imatinib (which targets the PDGF receptor [as well as other proteins with tyrosine kinase activity, e.g. KIT and BCR-ABL]) was tried in patients with DFSP. It is currently FDA-approved for adults with unresectable, recurrent, and/or metastatic DFSP. In a recent systematic review of relevant studies (2002–2017) in which imatinib was administered for metastatic or locally advanced DFSP, there was a complete response, partial response, or stable disease in 5%, 55%, and 28% of patients, respectively[116]. Either dosage (400 or 800 mg/day) led to similar results. Tumor progression occurred in 9% of patients, with severe adverse side effects in 15%[116].

GIANT CELL FIBROBLASTOMA

Clinical Features

Giant cell fibroblastoma is a rare, locally aggressive, histologic variant of DFSP[90]. It presents as a solitary, slow-growing, asymptomatic, skin-colored nodule involving the neck, trunk, or groin. In approximately half of patients, a protuberant or polypoid configuration is seen. Giant cell fibroblastoma usually appears during early childhood, with a strong predilection for boys[117].

Pathology

This lesion is composed of diffusely infiltrating sheets of spindle-shaped fibroblasts and multinucleated cells with hyperchromatic nuclei within a slightly myxoid matrix (Fig. 116.34A). Irregular "angiectoid" or pseudovascular spaces lined by multinucleated giant cells are present throughout the tumor (Fig. 116.34B). These giant cells do not react with markers for endothelial differentiation but do react with anti-CD34 antibodies[118]. Molecular studies have shown that giant cell fibroblastoma and DFSP share the same t(17;22) chromosomal translocation which places the PDGF subunit B gene under the control of the promoter of the collagen 1A1 gene[119]. Accordingly, in the most recent WHO classification of tumors of soft tissue and bone, giant cell fibroblastoma is considered to be closely related to DFSP[90,120].

MALIGNANT TUMORS WITH FIBROBLASTIC AND MYOFIBROBLASTIC DIFFERENTIATION		
Type of sarcoma	**Genetic abnormalities**	**Comments**
Adult-type fibrosarcoma	*STRN3-NTRK3* fusion	Often diagnosed after excluding synovial sarcoma, solitary fibrous tumor, MPNST
Congenital or infantile fibrosarcoma*	*ETV6-NTRK3* fusion; other *NTRK*-related fusions	
Low-grade fibromyxoid sarcoma (hyalinizing spindle cell tumor with giant rosettes)	*FUS-CREB3L2*; *FUS-CREB3L1*; *EWSR1-CREB3L1* fusions	IHC: expression of MUC4
Myxofibrosarcoma	Complex karyotype	Diagnosis based upon morphology
Myxoinflammatory fibroblastic sarcoma	Reciprocal t(1;10) (p22;q24) translocations; *BRAF*-related fusions; *VGLL3* gene amplification	
Sclerosing epithelioid fibrosarcoma	*FUS-CREB3L2*; *FUS-CREB3L1*; *EWSR1-CREB3L1* fusions	IHC: expression of MUC4
*Locally aggressive but overall favorable outcome[122].		

Table 116.4 Malignant tumors with fibroblastic and myofibroblastic differentiation. *CREB3L1*, cAMP responsive element binding protein 3 like 1; *CREB3L2*, CREB3 like 2; *ETV6*, ETS variant transcription factor 6; *EWSR1*, EWS RNA binding protein 1; *FUS*, FUS RNA binding protein; IHC, immunohistochemistry; MPNST, malignant peripheral nerve sheath tumor; MUC4, mucin 4, cell surface associated; *NTRK3*, neurotrophic receptor tyrosine kinase 3; *VGLL3*, vestigial like family member 3.

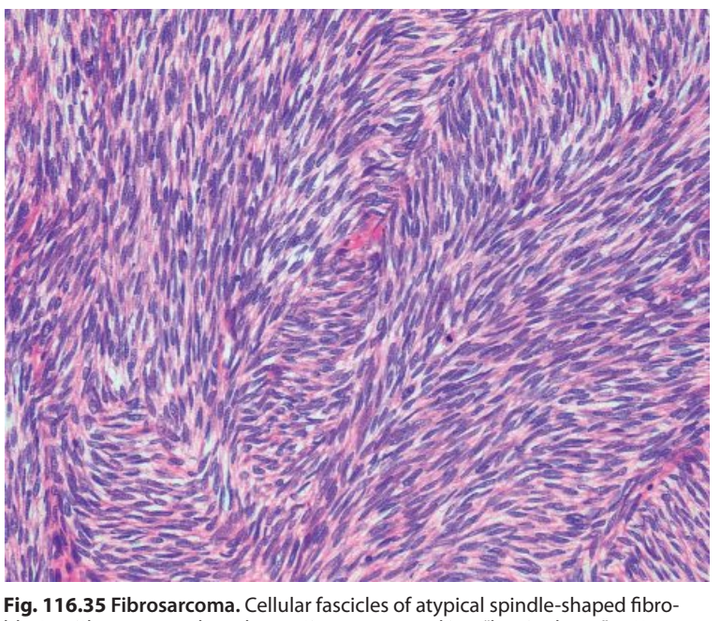

Fig. 116.35 Fibrosarcoma. Cellular fascicles of atypical spindle-shaped fibroblasts with coarse nuclear chromatin are arranged in a "herringbone" pattern.

Treatment

This tumor is regarded as being of intermediate biologic behavior, with a significant risk of local recurrence if incompletely excised[117]. Metastases have not been reported[90].

FIBROSARCOMA

Clinical Features

Previously, the term "fibrosarcoma" encompassed a heterogeneous group of high-grade and low-grade soft tissue tumors. Nowadays, specific tumor entities within the group of fibroblastic and myofibroblastic soft tissue sarcomas can be identified via molecular diagnostics (Table 116.4)[121].

Classic fibrosarcomas usually affect middle-aged adults. The most common location is the lower extremities, followed by the upper extremities, trunk, and head and neck region. This is a neoplasm predominantly of the deep soft tissues, with secondary involvement of the overlying subcutis and skin. Fibrosarcoma is a slowly growing tumor that measures from 1 to 10 cm in diameter and is usually diagnosed when it becomes a palpable painful nodule or plaque[123]. They may appear in old burn scars and in areas of prior irradiation[124].

Pathology

The tumor is composed of a proliferation of atypical spindle-shaped cells arranged as intersecting fascicles in a "herringbone" pattern (Fig. 116.35). There are thin collagen bundles between the cells which have scanty cytoplasm and elongated hyperchromatic nuclei. Mitotic figures are easily identified and myxomatous foci may be present. A sclerosing epithelioid variant that simulates an infiltrating carcinoma has been described[125]. High-grade fibrosarcomas are characterized by increased cellularity with more atypical nuclei, a higher mitotic rate, foci of necrosis, and a less distinct "herringbone" pattern.

Treatment

The traditional treatment for fibrosarcoma is wide excision. When wide free margins cannot be achieved, adjuvant radiation therapy and amputation are additional options. In high-grade fibrosarcomas, neoadjuvant or adjuvant systemic chemotherapy is given. Hematogenous metastases to the lung, and less often to the bones, develop in patients with high-grade or poorly differentiated fibrosarcomas. The overall 5-year survival rate is ~40%[123]. In tumors with *NTRK* fusions, targeted therapy with pan-tropomyosin receptor kinase (TRK) inhibitors (e.g. larotrectinib, entrectinib) has shown encouraging results[126,127].

EPITHELIOID SARCOMA

Synonyms/variants: ■ Classic or conventional – distal type
■ Proximal – large-cell type

Clinical Features

In the 5th edition of the WHO classification of soft tissue and bone tumors, epithelioid sarcomas are classified within the tumor group with uncertain differentiation. Two clinicopathologic subtypes of epithelioid sarcoma are recognized: (1) the *conventional or classic ("distal") form*, characterized by its proclivity for acral sites and a pseudogranulomatous growth pattern; and (2) the *proximal-type ("large-cell") variant* that usually arises more proximally or on the trunk and is composed of nests and sheets of large epithelioid cells[90,128]. Classic epithelioid sarcomas present as a slow-growing, firm, subcutaneous nodule of the distal extremities, usually the hands and fingers. There may be associated ulceration if the tumor involves the dermis. Advanced metastatic disease can present as a linear arrangement of widely spaced, ulcerated nodules extending from distal to proximal sites on affected extremities, with intervening tumor-free skin. If there is involvement of a large nerve, associated pain, paresthesias, and muscle wasting can occur[129].

The majority of patients are between 20 and 40 years of age, and men are affected twice as often as women. Hand and finger lesions may resemble the localized type of tenosynovial giant cell tumor (giant cell tumor of tendon sheath), fibroma of tendon sheath, nodular fasciitis, subcutaneous granuloma annulare, rheumatoid nodule, or ganglion cyst. Penile lesions can mimic Peyronie disease[129].

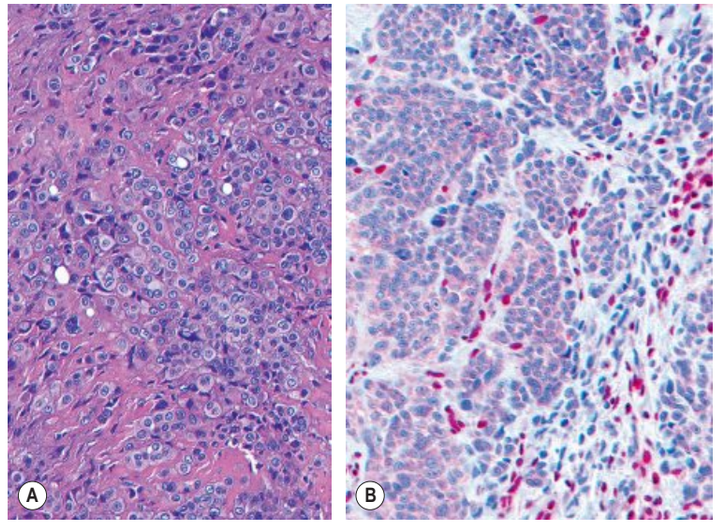

Fig. 116.36 Epithelioid sarcoma. A Large epithelioid tumor cells with ample cytoplasm may imitate a granulomatous or epithelial growth pattern. **B** The nuclei of these tumor cells are INI1-negative, which is an important diagnostic feature. Note the adjacent INI1-positive lymphocyte nuclei.

Pathology

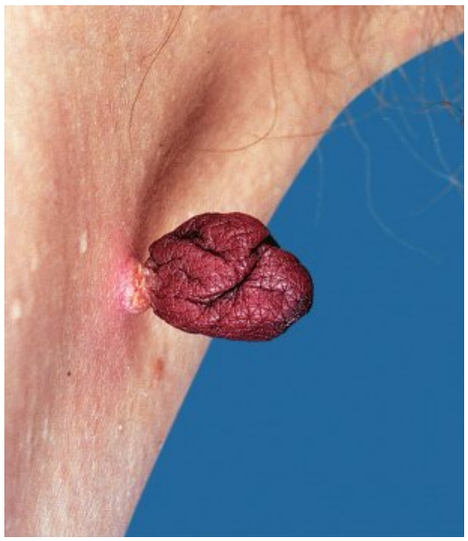
In *classic "distal" epithelioid sarcoma*, there is a nodular proliferation of spindle-shaped to round or epithelioid/polygonal cells with abundant eosinophilic cytoplasm and small uniform nuclei without prominent nucleoli (Fig. 116.36A). Epithelioid tumor cells are usually seen centrally, with a gradual transition to a spindle cell morphology towards the periphery[128]. When present, cytoplasmic vacuoles may mimic vascular tumors. Within larger tumor nodules, zones of central necrosis surrounded by palisaded tumor cells can be seen as well as a mixed chronic inflammatory cell infiltrate.

Proximal-type epithelioid sarcoma has a multinodular, sheet-like growth pattern and is composed of large epithelioid (carcinoma-like) cells that have enlarged vesicular nuclei with prominent nucleoli and abundant eosinophilic cytoplasm. A rhabdoid morphology is more commonly observed in this variant. While necrosis can be seen, a pseudogranulomatous morphology is more typical of the classic form (see above).

Both subtypes of epithelioid sarcoma demonstrate an infiltrative growth pattern and these tumors are frequently associated with fascia, periosteum, tendons, and nerves. The tumor cells are typically positive for keratins, EMA, and CD34 while negative for S100, HMB45, and CD31. ERG expression has been reported in up to two-thirds of tumors.

Epithelioid sarcomas have distinct genetic alterations of 22q11–12, including mutations, deletions, and other alterations of the tumor suppressor gene *SMARCB1/INI1* (see Table 116.3)[90]. Therefore, loss of INI1 expression by immunohistochemistry is characteristic of both conventional and proximal-type epithelioid sarcoma[130] (Fig. 116.36B).

Treatment



Both subtypes typically demonstrate an infiltrating growth pattern along tendons, nerves and fascia, with skip lesions commonly observed in classic "distal" epithelioid sarcomas. Although earlier therapeutic approaches involved radical surgery, including amputation, there has been a movement toward more conservative surgery with adjuvant radiation therapy[131]. Epithelioid sarcoma, especially the proximal ("large-cell") type, is an aggressive tumor with a high local recurrence rate. For all epithelioid sarcoma variants, 5- and 10-year overall survival rates are 60%–80% and 40%–60%, respectively[90,129,132]. Metastases develop in 40%–50% of patients, usually after repeated recurrences, and frequently involve the lung and regional lymph nodes. For metastatic or locally advanced epithelioid sarcoma with INI1 loss, tazemetostat, an oral inhibitor of the methyltransferase enzyme EZH2, improved disease outcome[133].

INTRODUCTION

Smooth muscle, adipose, and cartilage neoplasms arising in the skin and subcutis comprise a wide spectrum of benign and malignant neoplasms that show myocyte, adipocyte, and chondrocyte differentiation, respectively. Tumors of fat, especially lipomas, occur most commonly. These neoplasms often present as solitary lesions with significant overlap in clinical appearance. In addition, the clinical differential diagnosis can be rather broad (Fig. 117.1). As with other cutaneous tumors, multiple lesions raise the possibility of an inherited disease (e.g. hereditary leiomyomatosis and renal cell cancer).

In this group of neoplasms, the histopathologic diagnosis is established primarily on the basis of characteristic morphologic features, including architecture and cytomorphology, as well as identification of the predominant direction and level of differentiation (Fig. 117.2). Determination of whether a tumor is benign or malignant also requires assessment of features such as circumscription and if atypia and increased mitotic activity are present. Great care is necessary when applying traditional morphologic criteria for malignancy to cutaneous mesenchymal neoplasms because some clinically less aggressive tumors may exhibit prominent atypical features. In other words, aggressive behavior is not always predictable based solely on morphologic findings. For several of these neoplasms, immunohistochemical studies provide helpful diagnostic information (Table 117.1). Cytogenetic analysis and molecular studies are increasingly being used for diagnosis and classification of many soft tissue tumors as there can be relatively histiotype-specific molecular features (see below).

A number of tumor-related and patient-related factors may influence the choice of treatment, including tumor type and size, anatomic location, patient's life expectancy, presence of comorbidities, and cosmetic concerns. For the majority of solitary, benign, or relatively non-aggressive malignant neoplasms, excisional surgery with clear margins is the treatment of choice. However, removal of a benign tumor is often done at the patient's request rather than for medical reasons. Other modalities, e.g. cryotherapy, laser ablation (multiple leiomyomas), liposuction (large lipomas), may be preferable in certain patients. For more aggressive malignant tumors, the therapeutic goal is complete eradication, via either wide local excision or Mohs micrographic surgery, while trying to preserve normal function and avoiding mutilating surgery. As expected, the most significant predictor of recurrences is surgical margin status. In some dermal sarcomas, extension into the subcutis represents a negative prognostic factor.

TUMORS OF SMOOTH MUSCLE

Leiomyoma

Synonyms: ■ Superficial leiomyoma ■ Leiomyoma cutis ■ Superficial benign smooth muscle tumor

Key features

- Three distinct variants: piloleiomyoma, genital leiomyoma, and angioleiomyoma
- A solitary or multiple clustered (piloleiomyomas) papules or nodules in an adult
- Piloleiomyomas and angioleiomyomas may be painful
- Multiple piloleiomyomas may be a manifestation of hereditary leiomyomatosis and renal cell cancer (Reed syndrome)
- Smooth muscle cells (myocytes) are fusiform cells with centrally located, cigar-shaped nuclei

Introduction

Superficial (cutaneous) leiomyomas represent benign smooth muscle tumors that can arise from: (1) arrector pili muscles; (2) the dartoic, vulvar, or mammary smooth muscles; or (3) the muscles enveloping dermal blood vessels. Thus, they are subclassified into piloleiomyomas (solitary or multiple), leiomyomas of the external genitalia, and angioleiomyomas. Some authors categorize vulvar and scrotal leiomyomas separately, based upon distinctive clinical and histologic features[1].

History

In an early review article, Arthur Purdy Stout[2] cites an 1854 publication of Rudolf Virchow as the first case report of multiple leiomyomas involving the skin near the areola in a 32-year-old man.

Epidemiology

Cutaneous leiomyomas are relatively uncommon neoplasms, but their exact incidence is not known[3]. Angioleiomyomas appear to be more common than piloleiomyomas[4], with genital leiomyomas being the least common variant.

Pathogenesis

The exact pathogenesis of superficial leiomyomas has yet to be determined. Piloleiomyomas are thought to arise from the smooth muscle cells within the arrector pili muscle of the folliculosebaceous unit. Leiomyomas of the external genitalia are probably derived from the network of smooth muscles in the external genitalia (e.g. scrotum, vulva) and areolae. Angioleiomyomas are believed to originate from the smooth muscle within the walls of arteries and veins. However, there is a morphologic spectrum that encompasses angioleiomyoma and myopericytoma. Angioleiomyomas may exhibit cytogenetic abnormalities including monosomy of chromosome 13 and loss of 6p, 21q, and 13q, as well as *NOTCH2* rearrangement.

Multiple piloleiomyomas may occur sporadically or they may be inherited in an autosomal dominant manner (with variable penetrance) as a component of hereditary leiomyomatosis and renal cell cancer (HLRCC), also referred to as Reed syndrome, in which patients have multiple cutaneous leiomyomas and uterine leiomyomatosis as well as renal cell cancer[5,6] (Table 117.2). Affected individuals are heterozygous for germline loss-of-function mutations in the fumarate hydratase gene

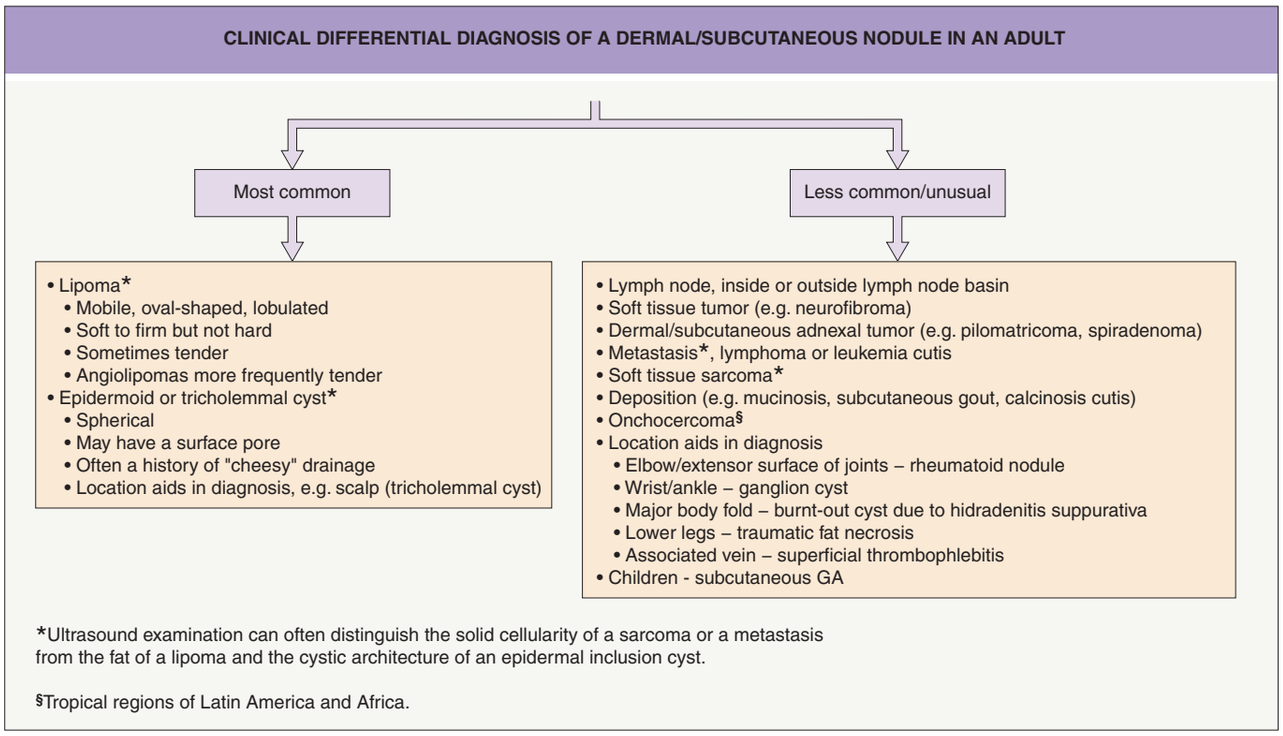

Fig. 117.1 Clinical differential diagnosis of a dermal/subcutaneous nodule in an adult. GA, granuloma annulare.

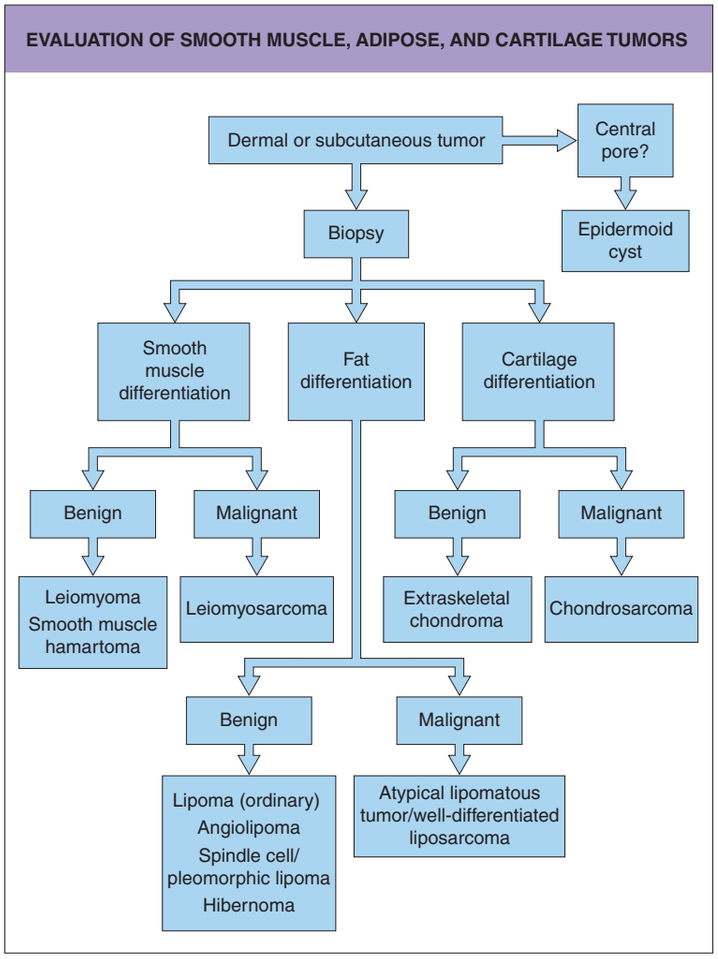

Fig. 117.2 Evaluation of smooth muscle, adipose, and cartilage tumors.

(*FH*). Although the molecular basis of HLRCC is known, how this translates into smooth muscle tumors is not understood.

Multifocal subcutaneous leiomyomas arising in the setting of immunodeficiency, including HIV infection, may be associated with Epstein–Barr virus infection.

Clinical features

Piloleiomyomas can be solitary or multiple, and in an occasional patient may even number in the hundreds. They present as firm, reddish-brown to skin-colored papules or nodules. Solitary piloleiomyomas develop primarily during adulthood and there is an approximately equal sex distribution[7]; rare congenital or pediatric cases have been reported. When multiple, the distribution pattern is most often clustered (Fig. 117.3), linear, or along the lines of Blaschko, but widespread lesions are observed occasionally. Most piloleiomyomas measure 1–2 cm in diameter, and they usually develop on the extremities and trunk (especially the shoulder), with solitary lesions favoring the limbs and multiple lesions the trunk[7]. Piloleiomyomas are often associated with spontaneous or induced pain, e.g. following cold exposure, but the explanation is still unclear[7].

Genital leiomyomas are most often solitary and painless. They can develop on the vulva, penis, scrotum, nipple, or areola and usually measure less than 2 cm in diameter. Occasionally, lesions are pedunculated.

Angioleiomyomas most commonly present as a solitary, firm subcutaneous nodule on the lower extremity. They often develop in women during the fourth to sixth decades of life[4]. Approximately 50% of angioleiomyomas are painful.

Pathology

Piloleiomyomas are typically centered within the reticular dermis, with focal extension into the subcutaneous fat in some cases. They are composed of interlacing fascicles of relatively bland smooth muscle cells (myocytes), which peripherally tend to ramify between surrounding dermal collagen bundles (Fig. 117.4); often there is a close relationship to hair follicles[4]. Occasionally, the overlying epidermis is hyperplastic. Smooth muscle cells have abundant brightly eosinophilic cytoplasm and blunt-ended, cigar-shaped nuclei.

Mitotic figures are rare. In the presence of bland cytology, one or two morphologically normal mitotic figures per 10 high-power fields may be seen, which does not signify aggressive behavior. Cases with

IMMUNOHISTOCHEMISTRY OF SELECTED SMOOTH MUSCLE, ADIPOSE, AND CARTILAGE NEOPLASMS		
Neoplasm	**Cell type(s)**	**Stain(s)**
Leiomyoma	Myocytes	• Smooth muscle actin (SMA) + [more sensitive], desmin + [more specific] • If diagnostic dilemma, h-caldesmon +, calponin +, muscle actin (HHF35) +, smooth muscle myosin (SMM) +
Leiomyosarcoma	Myocytes	• SMA +, desmin + (may be –) • If diagnostic dilemma, h-caldesmon +, calponin +, muscle actin (HHF35) +, SMM + • Pitfall: cytokeratin + (some cases)
Lipoma	Adipocytes	• S100 + • Adipophilin –
Angiolipoma	Adipocytes, endothelial cells	• S100 + (adipocytes) • CD34 +, CD31 + (vascular component)
Spindle cell/pleomorphic lipoma	Spindle and multinucleated giant cells, adipocytes	• CD34 + (spindle and multinucleated giant cells) • S100 + (adipocytes)
Hibernoma	Adipocytes, spindle cells	• S100 +, CD31 + (adipocytes) • CD34 + (spindle cells)
Lipoblastoma/ lipoblastomatosis	Adipocytes	• S100 +
Atypical lipomatous tumor/liposarcoma	Adipocytes, adipoblasts	• MDM2, CDK4 and p16 staining depends upon histologic subtype (see Table 117.4 & Fig. 117.19) • CD10 + in ~20%
Extraskeletal chondroma	Chondrocytes	• S100 +

Table 117.1 Immunohistochemistry of selected smooth muscle, adipose, and cartilage neoplasms. When the neoplasm is easily recognizable, e.g. lipoma, immunohistochemical staining is not routinely done. Myofibroblasts can be SMA +, SMM +, and calponin +; fibroblasts can be SMA +. CDK4, cyclin-dependent kinase 4 (cell cycle regulation); h, high molecular weight; MDM2 (binds p53).

CLINICAL FEATURES OF HEREDITARY LEIOMYOMATOSIS AND RENAL CELL CANCER (REED SYNDROME)	
Genetic aspects	• Autosomal dominant • Mutations in the gene on chromosome 1q42.3-43 that encodes fumarate hydratase, an enzyme in the mitochondrial Krebs cycle
Clinical features	• Cutaneous leiomyomas: multiple painful, grouped, skin-colored to red–brown papules appear during the second to fourth decades • Uterine leiomyomas: >90% of affected women; menorrhagia and pelvic pressure or pain • Renal cell carcinoma: 10%–15% of patients with syndrome; most commonly type 2 papillary renal cell carcinomas that are often early-onset and aggressive (metastases in >50% of patients); less often tubulo-papillary or collecting duct carcinomas
Screening of individuals with multiple cutaneous leiomyomas	• Abdominal and pelvic ultrasound (or CT scan) • Complete history and physical examination, including pelvic examination in women • Immunohistochemistry of cutaneous leiomyomas: (1) negative staining for fumarate hydratase (in one series, 83% sensitivity and 75% specificity was found[9]); and (2) intracellular accumulation of S-(2-succino)-cysteine • Genetic testing for heterozygous pathogenic variant in the fumarate hydratase gene (*FH*; 70%–90% detected by sequence analysis) • If pathogenic *FH* variant not detected, can measure fumarate hydratase activity (will be ≤60%)
Patients with confirmed syndrome	• Complete history and physical examination yearly, including pelvic examination in women • Yearly abdominal MRI (if baseline or follow-up scan normal) • If renal lesion detected, then CT scan and renal ultrasound performed; PET-CT scan can be done • Complete physical examination (including pelvic examination in women) of first-degree family members and other family members as indicated; abdominal and pelvic ultrasound as indicated
Establishing diagnosis: heterozygous pathogenic variant in *FH* (rarely not detected). Clinical criteria: major criterion is multiple cutaneous leiomyomas (at least 1 confirmed histologically); minor criteria are: (1) severely symptomatic uterine leiomyomas before age 40; (2) type 2 papillary renal cell carcinoma before age 40; and (3) first-degree relative who meets one of these aforementioned criteria. Diagnosis is strongly suspected if major criterion met or ≥2 minor criteria present.	

Table 117.2 Clinical features of hereditary leiomyomatosis and renal cell cancer (Reed syndrome). CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

nuclear pleomorphism and atypical nuclei, but without mitotic activity (symplastic leiomyomas), have also been described[8].

In leiomyomas, smooth muscle differentiation is usually obvious in H&E-stained sections, but sometimes special stains for smooth muscle cells are utilized. Tumor cells consistently stain positively for both smooth muscle actin (SMA) and desmin, with other useful markers listed in Table 117.1. In HLRCC, there is often negative immunohistochemical staining for fumarate hydratase in the cutaneous leiomyomas (in one series, 83% sensitivity/75% specificity[9]). Intracellular accumulation of S-(2-succino)-cysteine in uterine leiomyomas may suggest fumarate hydratase aberration but this is not specific for HLRCC[10]. In contrast to uterine leiomyomas, cutaneous leiomyomas do not express receptors for estrogen or progesterone[11].

Genital leiomyomas of the scrotum or vulva tend to be larger and better circumscribed than piloleiomyomas. Scrotal leiomyomas are usually homogeneous spindle cell tumors, while vulvar lesions may demonstrate an epithelioid cytology, myxoid changes, and/or hyalinization[1]. Leiomyomas of the nipple closely resemble piloleiomyomas.

Angioleiomyomas are usually well-circumscribed tumors centered within the superficial subcutis (Fig. 117.5). They are composed of bland smooth muscle cells compactly arranged into bundles and whorls around thick-walled vascular channels[4]. Degenerative changes including hyalinization, focal thrombosis, myxoid changes, dystrophic calcification, pyknotic nuclear atypia, and fat foci may be present. Tumors composed of a proliferation of blood vessels, smooth muscle cells, and adipose tissue are termed angiomyolipomas or angiolipoleiomyomas.

Differential diagnosis

For single lesions, the clinical appearance is nonspecific and the differential diagnosis includes a wide range of entities that can present as solitary dermal nodules, including dermatofibromas. When a lesion is painful or there is a clustering of multiple red–brown papulonodules, the diagnosis may be strongly suspected prior to biopsy.

Histopathologically, leiomyomas need to be distinguished from other spindle cell tumors with fibrohistiocytic or peripheral nerve sheath differentiation.

Fig. 117.3 Clustered piloleiomyomas on the back. The trunk is a common location for multiple piloleiomyomas. Patients with this clinical presentation need to be evaluated for the possibility of hereditary leiomyomatosis and renal cell cancer (Reed syndrome; see Table 117.2). *Courtesy Julie V. Schaffer, MD.*

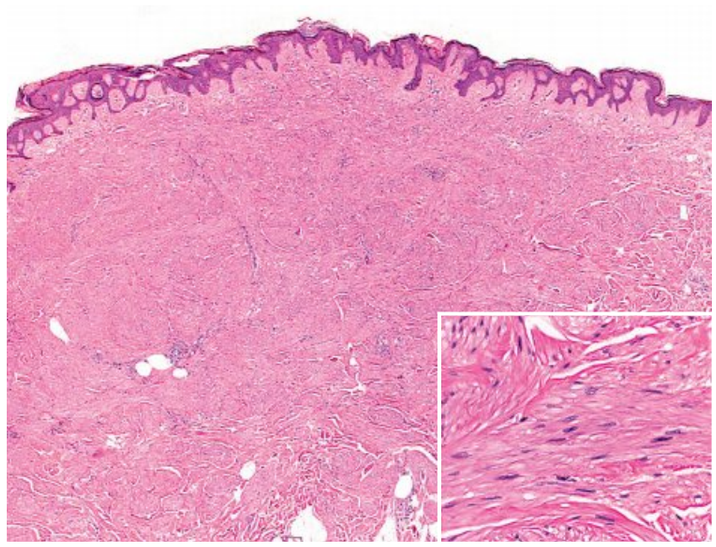

Fig. 117.4 Piloleiomyoma. Bundles of myocytes within the dermis are arranged in interdigitating fascicles. Inset, the myocytes have eosinophilic cytoplasm and elongated or cigar-shaped nuclei.

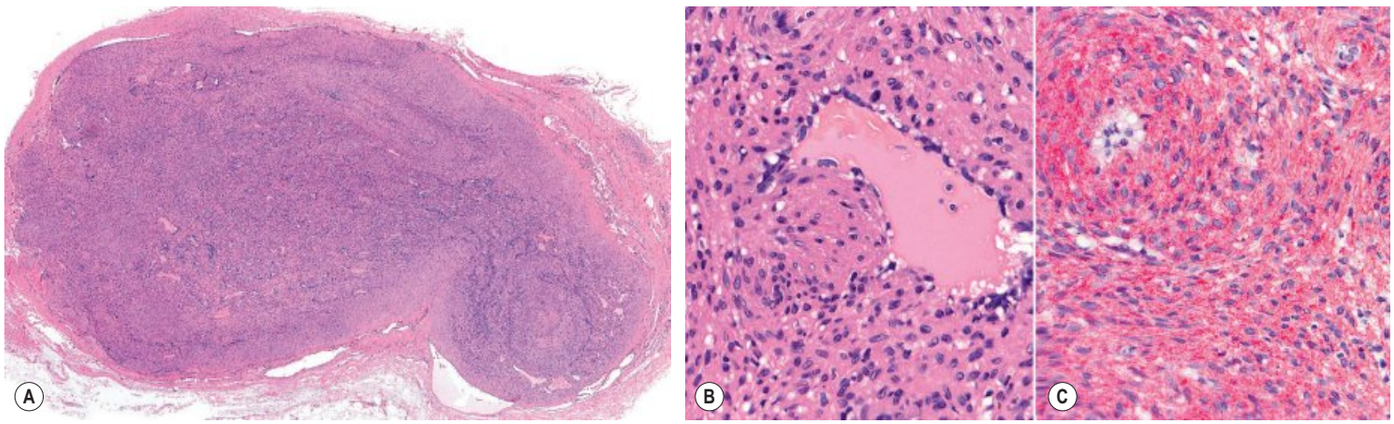

Fig. 117.5 Angioleiomyoma. A Angioleiomyomas are well circumscribed and often located in the deep dermis, extending into the subcutis. **B** At higher magnification, thick-walled vessels are surrounded by aggregates of smooth muscle cells and stain positively for smooth muscle actin (**C**).

Treatment

Simple excision is usually curative for solitary or limited tumors. For those tumors that are not amenable to surgery because of their number or location, treatment with gabapentin, medications that reduce smooth muscle contraction (e.g. nifedipine, nitroglycerin, doxazosin), cryotherapy, or CO_2 laser ablation may provide relief from pain[12,13].

Leiomyosarcoma

Synonyms: ■ Atypical intradermal smooth muscle neoplasm ■ Piloleiomyosarcoma ■ Superficial leiomyosarcoma ■ Superficial malignant smooth muscle tumor

Key features

- Malignant smooth muscle neoplasm
- Occurs primarily in adults >50 years of age
- Most commonly located on the extremities, in particular the lower leg
- *Dermal* leiomyosarcomas are typically cured by simple excision and rarely metastasize; *subcutaneous* leiomyosarcomas require wide excision and have a 25%–40% risk of metastasis

Introduction

For management and prognostic reasons, it is important to differentiate between "superficial leiomyosarcomas" that are limited to the dermis and lesions that primarily arise in or extensively involve the subcutis. The former have a favorable prognosis and can recur, but very rarely metastasize. Subcutaneous leiomyosarcomas, in contrast, metastasize in ~25%–40% of cases[14,15]. To emphasize this distinction, the term *atypical intradermal smooth muscle neoplasm* has been suggested for dermal lesions (rather than leiomyosarcoma).

Epidemiology

Cutaneous and subcutaneous leiomyosarcomas are rare neoplasms, comprising only 4%–6.5% of soft tissue sarcomas[16,17].

Pathogenesis

Dermal leiomyosarcomas are thought to arise from either arrector pili or genital smooth muscles. Subcutaneous leiomyosarcomas probably originate from vascular smooth muscle. Predispositions include Li–Fraumeni syndrome due to *TP53* mutations, retinoblastoma (RB) inactivation due to *RB1* or *CDKN2A* ($p14^{ARF}$) mutations or deletions (see Fig. 107.4), and Epstein–Barr viral infection in the setting of immunosuppression. Anecdotal reports describe a rare association with trauma and radiation[17,18].

Clinical features

Cutaneous and subcutaneous leiomyosarcomas classically present as a solitary, firm, skin-colored to red–brown nodule or plaque. Dermal

Fig. 117.6 Leiomyosarcoma. Two red–brown tumor nodules on the lower extremity. *Courtesy Lorenzo Cerroni, MD.*

tumors range from 0.5 to 4 cm in diameter[19], while subcutaneous lesions tend to be larger. Sometimes the tumors are painful or become ulcerated. Leiomyosarcomas favor the extremities, in particular the lower leg of older adults (Fig. 117.6)[4,19,20]. There is a slight male preponderance[4]. Patients with multiple tumors should be evaluated to exclude the possibility of metastases due to a primary retroperitoneal or visceral leiomyosarcoma.

Pathology

The histopathologic features of leiomyosarcomas span a morphologic continuum that, at the well-differentiated end, demonstrates an overlap with leiomyomas, while poorly differentiated lesions closely resemble atypical fibroxanthomas or "malignant fibrous histiocytomas"[21]. Leiomyosarcomas of moderate differentiation are comprised of cells that cytologically resemble normal smooth muscle cells. However, compared to leiomyomas, malignant smooth muscle tumors are more cellular, exhibit cytologic atypia, and contain easily identifiable mitotic figures (Fig. 117.7). At least focally, the spindle cells are arranged in fascicles. Cytologically, poorly differentiated leiomyosarcomas may resemble myofibroblastic or fibrohistiocytic tumors. Notably, the degree of differentiation may vary within a single tumor. Rarely, the cells have an epithelioid appearance[22].

A definitive diagnosis of leiomyosarcoma often requires adjuvant special stains and/or immunohistochemical studies to support the cell lineage. Leiomyosarcomas consistently stain positive for SMA and desmin. Of the two markers, SMA is more sensitive and desmin is somewhat more specific; additional useful markers are listed in Table 117.1. By definition, dermal leiomyosarcomas (atypical intradermal smooth muscle neoplasms) are superficial malignant neoplasms with at least 90% of the tumor confined to the dermis[23]. They are usually poorly circumscribed and are composed of spindle cells; the latter are focally arranged in fascicles that infiltrate between adjacent collagen bundles. In comparison, subcutaneous leiomyosarcomas tend to be better circumscribed and may be surrounded by a pseudocapsule of compressed tissue.

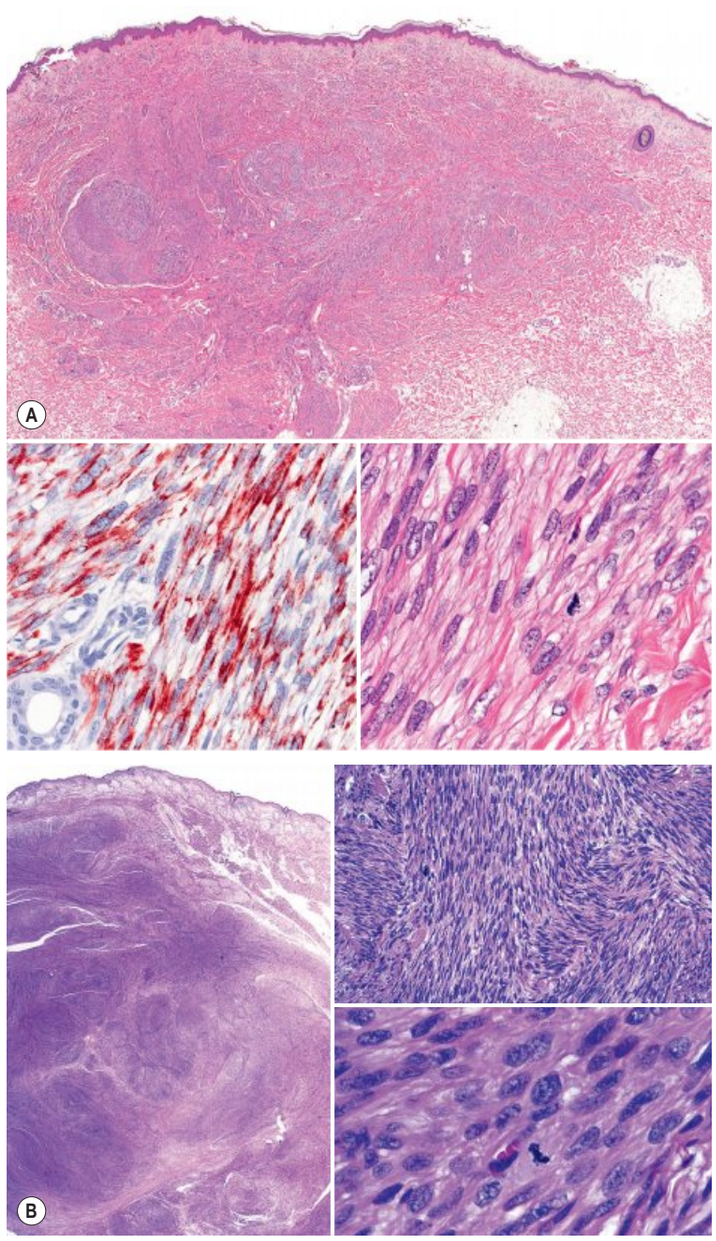

Fig. 117.7 Leiomyosarcoma – dermal versus subcutaneous. A In the superficial leiomyosarcoma, the tumor bundles are confined to the dermis, with the spindled cells staining positively for desmin and exhibiting slight nuclear pleomorphism; a mitotic figure is also seen. **B** A large tumor, composed of interdigitating fascicles, extends from the upper reticular dermis deep into the subcutis; at higher magnification, nuclei are pleomorphic and hyperchromatic. Mitotic figures are numerous and easily identified.

Differential diagnosis

Because the clinical features are not unique, the differential diagnosis includes a number of tumors that can present as solitary plaques, e.g. dermatofibrosarcoma protuberans, or firm nodules (see Fig. 117.1).

The histopathologic differential diagnosis usually raises two problems: the differentiation of leiomyosarcoma from leiomyoma and its delineation from other spindle cell neoplasms. Traditionally, the number of mitotic figures is used as the most reliable diagnostic criterion when trying to predict clinical behavior. In the presence of cytologic atypia, a mitotic rate of one or more mitotic figures per high-power field is generally considered to be indicative of malignancy[16]. It is important to remember, however, that the prognosis of leiomyosarcomas appears to depend more on the depth of involvement (dermal vs subcutaneous), and the extent of mitotic activity is probably more important in subcutaneous lesions. Necrosis and angiolymphatic invasion are generally not useful in predicting prognosis for patients with dermal and subcutaneous leiomyosarcomas.

The distinction of leiomyosarcoma from other dermal spindle cell neoplasms nearly always requires immunophenotyping. This is best approached by using a panel of antibodies that examine the neoplasm for its line of differentiation (Table 117.3). A standard panel consists of antibodies to SMA, desmin, cytokeratin, S100 protein, and CD68. Leiomyosarcoma will usually be SMA-positive and desmin-positive, but negative for keratin, S100 protein, and CD68.

Treatment

Wide excision with meticulous examination of all surgical margins is crucial in order to prevent recurrence. Recurrent tumors tend to infiltrate more deeply, and they are often less well differentiated. In addition, they are more difficult to treat and carry a higher risk of metastasis. Several authors have reported successful treatment with Mohs micrographic surgery[17], allowing for complete margin control.

Complete surgical excision of a primary dermal leiomyosarcoma can be curative. Local recurrences, due to incompletely excised tumors, are

CD10 is also known as CALLA, common acute lymphocytic leukemia antigen; CD68 is a glycoprotein expressed by monocytes and macrophages; h-caldesmon is a calmodulin binding protein that inhibits ATPase activity of myosin.

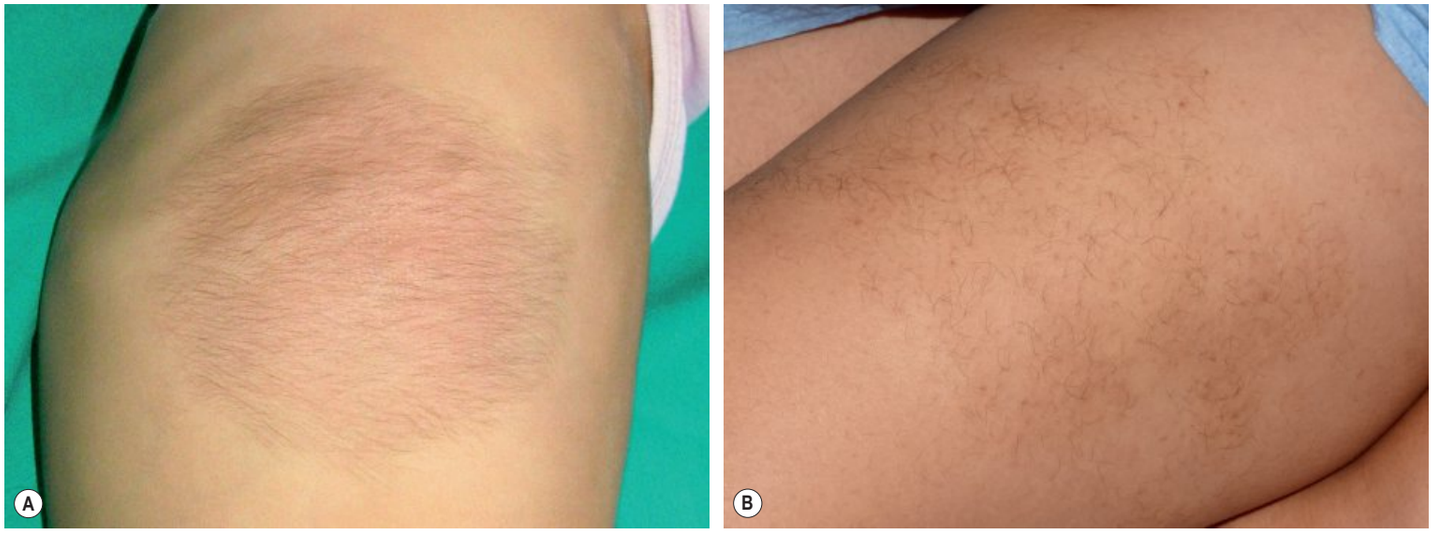

Fig. 117.8 Smooth muscle hamartoma. A A hyperpigmented plaque with hypertrichosis that can be misdiagnosed clinically as a congenital melanocytic nevus or less often a neurofibroma. **B** Sometimes the hamartoma has a broken-up appearance and there is overlap with Becker melanosis (nevus) both clinically and histologically. *A, Courtesy Antonio Torello, MD; B, Courtesy Julie V. Schaffer, MD.*

unusual and metastases rarely, if ever, develop. As noted previously, some authors have even suggested using the term "atypical intradermal smooth muscle neoplasm" rather than leiomyosarcoma[24].

Subcutaneous leiomyosarcomas metastasize in 25%–40% of patients. The risk of metastasis appears to be related to size, as metastasis is unlikely in tumors <5 cm in diameter. Metastatic spread occurs hematogenously to the lung and, less often, other visceral organs, or via the lymphatics to regional lymph nodes[18,23].

Smooth Muscle Hamartoma

Key features

- Congenital or acquired skin-colored to hyperpigmented plaque on the trunk or proximal extremities
- Commonly exhibit follicular prominence and/or hypertrichosis
- Clinical and histopathologic overlap with Becker melanosis (nevus)

Introduction

Hamartoma is derived from the Greek word *hamartia*, which means "fault", "defect", or "flaw", and *oma* (tumor). Hamartomas are defined as lesions that are: (1) most commonly present at birth, but can also be acquired; and (2) are composed of aberrant mature or nearly mature structures. The term hamartoma is synonymous with "nevus", for example, nevus sebaceus, apocrine nevus, eccrine nevus. A smooth muscle hamartoma may be congenital or acquired and may be associated with Becker melanosis (nevus).

History

The first description of a smooth muscle hamartoma is attributed to Stokes in 1923[25].

Epidemiology

The estimated incidence ranges from 1 : 1000 to 1 : 27 000 live births.

Clinical features

Smooth muscle hamartomas not associated with Becker melanosis (nevus) present as firm, skin-colored or hyperpigmented plaques, most commonly located on the trunk, buttocks, or proximal extremities (Fig. 117.8). Surface changes may be present in the form of small follicular papules or hypertrichosis. Lesions with hypertrichosis and hyperpigmentation overlap with Becker melanosis (see Ch. 112). These hamartomas are most often solitary, but may be multiple. Extensive lesions can present as large areas of hypertrichotic skin with dimpling (accentuated upon exposure to cold) and/or folding, and generalized involvement may produce a "Michelin tire baby" phenotype (see Table 97.7)[26]. Rubbing of the plaque may result in a pseudo-Darier sign, consisting of transient induration of the affected area.

Pathology

Well-defined and thickened bundles of smooth muscle are haphazardly distributed throughout the dermis. Connections with hair follicles may

be present. The epidermis is often acanthotic and has hyperpigmentation of the basal layer.

Differential diagnosis

Clinically and histologically, smooth muscle hamartomas demonstrate overlap with Becker melanosis, and the two lesions possibly represent a spectrum of phenotypic expression of the same process. Leiomyomas usually present as papulonodules rather than plaques. Histologically, the smooth muscle fibers in a piloleiomyoma aggregate to form dermal tumors with irregular margins, but they are not haphazardly scattered throughout the dermis as in a smooth muscle hamartoma.

Treatment

Therapy may be indicated for cosmetic reasons. A small lesion may be amenable to excision. Treatment of Becker melanosis with lasers that target melanin (e.g. Q-switched ruby laser) lead to modest, if any, improvement[27]. Photoepilation of pigmented hairs via laser therapy is usually more successful (see Ch. 137).

TUMORS OF FAT

Lipoma

Key features

- Common benign tumor of mature fat
- Asymptomatic, soft to rubbery, subcutaneous nodule arising at any site but rare on the hands and feet
- Multiple lipomas are seen in familial multiple lipomatosis, Madelung disease, adiposis dolorosa, Gardner syndrome, PTEN hamartoma tumor syndrome, and Proteus syndrome

Introduction

(Ordinary) lipomas are benign tumors composed of mature adipocytes. They are among the most common neoplasms in humans, and they represent the most common mesenchymal neoplasm[28]. Lipomas are often solitary, but 5%–10% of patients have multiple lipomas, usually in the setting of a lipomatosis or less often a multisystem syndrome.

Epidemiology

Lipomas develop at any age, but they usually become clinically apparent between the fourth and sixth decades of life. Most studies report the incidence of lipomas to be slightly higher in men than in women[28].

Pathogenesis

Little is known about the pathogenesis of lipomas. Of note, the incidence of lipomas is increased in overweight individuals, diabetics, and patients with elevated serum cholesterol[28]. In familial multiple lipomatosis, there is clearly a genetic component. In approximately two-thirds of patients, clonal chromosomal aberrations are present (Table 117.4).

Clinical features

Classically, lipomas present as solitary, painless, soft (to rubbery), mobile, subcutaneous nodules, with a normal overlying epidermis[4]. They are often oval in shape and may feel multilobular. Most lipomas measure a few centimeters in diameter, but occasionally reach over 10 cm in size. Although lipomas may develop within any fatty tissue, sites of predilection are the neck, proximal extremities, forearms, and buttocks; lipomas also occur on the trunk, but are very rarely seen on the hands and feet. They present primarily in adults over the age of 30 years.

Lipomas usually exhibit an initial slow growth phase, then remain stable in size with no tendency to involute. The rate of growth may accelerate during periods of weight gain, but weight loss, even when extreme, does not seem to affect their size. Weight loss, however, may result in lipomas becoming more clinically apparent.

Multiple lipomas may be observed in patients with a lipomatosis or in the setting of a multisystem syndrome, such as Proteus syndrome.

Infiltrating or diffuse lipomatosis is characterized by non-encapsulated mature fat infiltrating subcutaneous tissue, muscle, skin, and, at times, even fascia and bone. This entity usually occurs before 30 years of age and is rarely congenital. Diffuse lipomatosis has been described

Fig. 117.9 Familial multiple lipomatosis. Several discrete lipomas are present on the forearm.

Fig. 117.10 Benign symmetric lipomatosis (Madelung disease). Large symmetric fatty deposits in the supraclavicular region, lateral chest, and abdomen.

in association with tuberous sclerosis (see Ch. 61) and paralytic poliomyelitis[29–31]. The lower extremities are most commonly affected, but involvement of the head, neck, face, and upper extremities have all been reported. Pelvic involvement may lead to urinary tract, intestinal, and even vena caval obstruction[32].

Familial multiple lipomatosis is also known as familial multiple lipomas, multiple circumscribed lipomas, hereditary multiple lipomas, and discrete lipomatosis. This disorder is characterized by multiple lipomas occurring in several members of one kindred. The tumors are discrete, mobile, and surrounded by a capsule, as opposed to the diffuse and infiltrative tumor growth observed in benign symmetric lipomatosis (Madelung disease)[33]. Favored sites include, but are not limited to, forearms and thighs (Fig. 117.9). The neck and shoulders are generally spared.

Proteus syndrome is a complex sporadic disorder due to mosaicism for an activating mutation in the *AKT1* oncogene. It is characterized by asymmetric, disproportionate (i.e. progressive and distorting) overgrowth of multiple tissues and multiple hamartomatous malformations (see Ch. 62)[34]. The tissue overgrowth tends to plateau after adolescence.

Lipomatosis arising in the setting of Proteus syndrome is associated with overgrowth of multiple tissues in a mosaic pattern, and this can lead to partial gigantism of the head or limbs, vascular malformations, and skeletal deformities as well as areas of lipohypoplasia (see Table 104.5)[35]. Connective tissue nevi (particularly cerebriform lesions on the palms and soles) and epidermal nevi are also commonly observed in these patients.

The PIK3CA (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha)-related overgrowth spectrum includes: (1) **hemihyperplasia–multiple lipomatosis** which is characterized by multiple lipomas in association with asymmetric (but non-progressive and non-distorting) overgrowth, mild macrodactyly, capillary malformations, and thickened plantar skin with prominent creases; and (2) **CLOVES syndrome** which is characterized by *c*ongenital *l*ipomatous *o*vergrowth (typically not progressive), *v*ascular malformations, *e*pidermal nevi, and *s*keletal/*s*pinal abnormalities (see Table 104.5). Other individuals with Proteus-like features have a germline mutation in *PTEN* plus a postzygotic "second hit" in affected tissues and this results in *s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformations, and *e*pidermal *n*evi (**SOLAMEN**)[36].

Benign symmetric lipomatosis is also known as Madelung disease in the American literature[37], benign symmetric lipomatosis of Launois–Bensaude in the European literature[38], and multiple symmetric lipomatosis in OMIM. It consists of extensive symmetric fat deposits in the head, neck, and shoulder girdle area (Fig. 117.10). When the mediastinum is involved, complications related to a space-occupying mass may ensue. Most patients are men, and a high percentage suffer from alcoholism; this may account for several disorders reported in association with benign symmetric lipomatosis, such as peripheral neuropathy, squamous cell carcinomas of the head and neck, and macrocytic anemia.

Pathogenic variants in *MT-TK*, which encodes mitochondrial tRNA lysine, have been described in a subset of patients with benign symmetric lipomatosis. When patients have additional findings such as partial lipoatrophy, myopathy, and hypertriglyceridemia, the possibility of mutations in *LIPE* (lipase E, hormone sensitive type; see Ch. 101) or *MFN2* (mitofusin 2, a mitochondrial protein) can be considered. In one family, heterozygosity for a pathogenic variant in *CAPSL* was observed, with its protein product, calcyphosine-like, hypothesized to play a role in adipogenesis.

Multiple painful lipomas are present primarily on the arms, trunk, and in the periarticular soft tissue in **adiposis dolorosa (Dercum disease**). This disease most commonly affects premenopausal women, and it is associated with weakness and psychiatric symptoms such as depression[39]. Pain is intermittent, but it may be debilitating, necessitating sophisticated pain management. Pain is caused by lipomas compressing adjacent nerves.

In addition, lipomas may be part of **Gardner syndrome**. This syndrome consists of polyposis of the colon (eventuating in colonic carcinoma unless there is surgical intervention), odontomas, multiple epidermoid cysts (often with foci of matrical differentiation), osteomas, leiomyomas, and desmoid fibromatosis (see Ch. 63). Retinal pigment epithelial hamartomas (RPEH) represent an early characteristic finding in Gardner syndrome. Mutations in *APC* are responsible for this syndrome as well as familial adenomatous polyposis.

Multiple lipomas are also seen in **Bannayan–Riley–Ruvalcaba syndrome** and **Cowden syndrome**, autosomal dominantly inherited hamartoma syndromes due to mutations in the tumor suppressor gene *PTEN*[40,41]. As outlined in Table 63.3, these two disorders have overlapping features and exist along a disease spectrum[30]. Nowadays they are referred to as the PTEN hamartoma tumor syndrome.

Pathology

Lipomas are composed of a uniform population of mature fat cells with small, uniform, and eccentric nuclei (Fig. 117.11). The fat cells are arranged in lobules with capillaries scattered throughout the lesion. Mitotic figures are absent. Microscopically, lipomas may be indistinguishable from mature adipose tissue. Some lipomas contain lipocytes with intranuclear vacuoles that need to be distinguished from lipoblasts. Fibrolipoma and myxolipoma represent lipomas with an admixture of significant amounts of fibrous tissue and myxoid stroma, respectively. Occasionally, foci of cartilaginous tissue and osseous metaplasia may be present. Secondary changes, due primarily to trauma, include focal fat necrosis and/or aggregates of foamy macrophages.

Differential diagnosis

An epidermoid cyst without a pore is the most common entity in the clinical differential diagnosis, including for subfrontalis lipomas of the

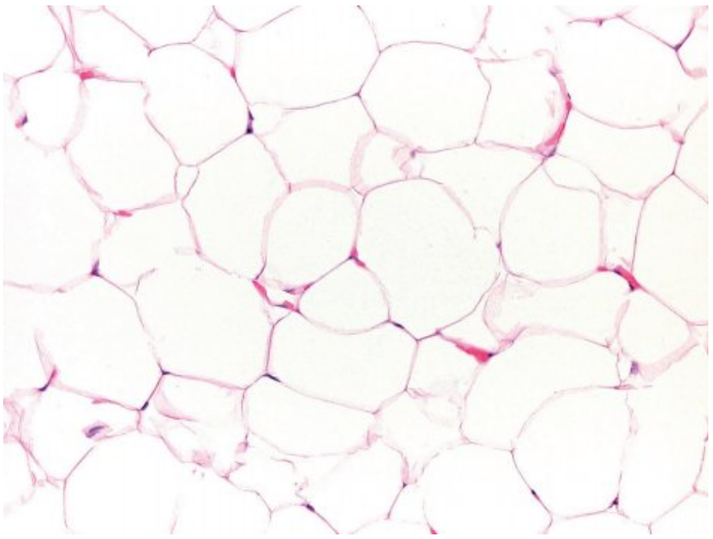

Fig. 117.11 Lipoma (ordinary). A uniform population of mature adipocytes with small and eccentric nuclei is seen.

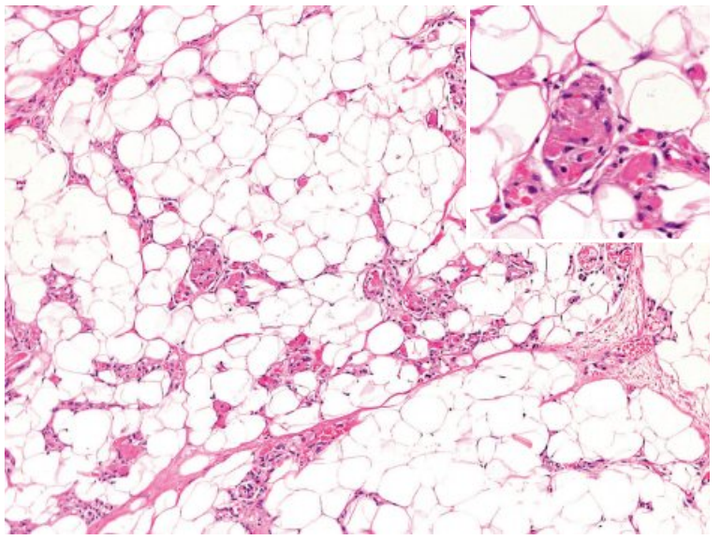

Fig. 117.12 Angiolipoma. Mature fat is admixed with a variable number of small blood vessels. Occasionally, the vessels are occluded by fibrin thrombi (inset).

forehead. An ultrasound examination can be done to distinguish between these two entities (see Fig. 117.1). As lipomas are histologically indistinguishable from normal fat, a definitive diagnosis may not be possible if the specimen is too small to demonstrate the overall architecture.

Treatment

Small solitary lipomas are usually cured by simple excision. Local recurrence after excision is more common with larger-sized lipomas. Larger lesions, or systemic lipomatoses, may be amenable to liposuction (see Ch. 156).

Angiolipoma

Key features

- Soft subcutaneous nodule, usually less than 2 cm in diameter
- Typically located on the forearms of young adults
- More often painful than are ordinary lipomas
- Well-circumscribed lesion composed of mature fat cells intermingled with small, focally thrombosed vessels

Introduction

Angiolipomas are benign subcutaneous tumors composed of mature fat and a vascular component.

Epidemiology

Patients with angiolipomas are typically young adults in their late teens or early twenties; ~5% of cases are familial.

Pathogenesis

The pathogenesis of angiolipomas is not known. A small number of cases are familial, thus suggesting a genetic component. Unlike lipomas, hibernomas, and many other fatty tumors, angiolipomas usually have a normal karyotype. Rarely, rearrangements of chromosome 13 have been observed. In one study of 18 angiolipomas, activating mutations in *PIK3CA* were identified in the majority (78%) of the tumors, with each having the same mutation [c.1634A>C (p.E545A)] within exon 9[42]. These findings suggest that activation of the PI3K/AKT pathway may play a key role in the formation of angiolipomas.

Clinical features

Angiolipomas usually measure <2 cm in diameter and are clinically similar to ordinary lipomas. However, they may be painful. In approximately two-thirds of patients, the tumors are found on the forearms. Less common sites are the trunk and upper arms. An estimated two-thirds of patients have multiple tumors[28].

Pathology

Mature adipose tissue is admixed with a variable number of small vessels (Fig. 117.12). Occasional blood vessels are occluded by fibrin thrombi. A cellular variant is characterized by dense cellular angiomatous tissue with a prominent number of spindle cells. Mast cells are more numerous than in ordinary lipomas, and older lesions may contain areas of fibrosis.

Differential diagnosis

Clinically, angiolipomas cannot be reliably distinguished from other benign fatty tumors, although the presence of pain may be a clue. The histopathologic differential diagnosis includes an ordinary lipoma, but no lower threshold exists for the minimal number of vessels required to warrant the diagnosis of angiolipoma. The identification of thrombosed vessels may be helpful in this situation, as they are usually not seen in ordinary lipomas. Highly vascular or cellular angiolipomas may be difficult to distinguish from Kaposi sarcoma, spindle cell lipoma, and spindle cell hemangioendothelioma.

Treatment

Surgical excision is curative and, to date, no malignant transformation has been reported. Angiolipomas tend to be more circumscribed than ordinary lipomas and are therefore more readily excised *in toto*.

Spindle Cell/Pleomorphic Lipoma

Key features

- Solitary, subcutaneous nodule on the upper back of middle-aged to older men
- Histologic triad of spindle cells, mature fat cells, and strands of dense collagen
- Pleomorphic lipomas also contain an admixture of floret-like cells

Introduction

Spindle cell and pleomorphic lipomas represent a group of histologically distinct tumors composed of mature fat cells, a population of spindle cells, and strands of dense collagen. Pleomorphic lipomas also contain an admixture of bizarre, often multinucleated cells ("floret-like cells"). Not only do spindle cell and pleomorphic lipomas share common karyotypic abnormalities (see Table 117.4), but tumors with intermediate histopathologic features (between classic spindle cell lipoma and pleomorphic lipoma) are sometimes observed. Spindle cell/pleomorphic lipomas usually develop on the posterior neck, upper back, and shoulders of middle-aged and older men, and their clinical appearance is similar to other fatty tumors.

History
Spindle cell lipoma was first described by Enzinger and Harvey in 1975[43].

Epidemiology
Although these tumors have occasionally been reported in women and young men, the vast majority of spindle cell and pleomorphic lipomas have been observed in middle-aged to older men[43].

Pathogenesis
The pathogenesis of spindle cell and pleomorphic lipomas is unknown. Only a small fraction of cases occurs in a familial setting. The spindle cells in spindle cell and pleomorphic lipomas probably represent undifferentiated mesenchymal cells. Partial loss or monosomy of 13q or 16q are the most common clonal chromosomal abnormalities. Of note, the deletions of 13q tend to cluster within the 13q14 region, where *RB1* resides.

Clinical features
A spindle cell/pleomorphic lipoma presents as a solitary, slowly growing, mobile and painless subcutaneous nodule without epidermal changes. These lipomas most commonly develop on the posterior neck, upper back, and shoulders, but can also occur in other sites including the breast, upper aerodigestive tract, and orbit[28,44]. Multiple spindle cell lipomas and familial cases are rare.

Pathology
Histopathologically, the diagnosis of *spindle cell lipoma* requires the presence of three components, admixed in varying proportions: (1) mature fat cells; (2) small, uniform spindle cells; and (3) strands of dense, eosinophilic ("ropey") collagen[45] (Fig. 117.13). In some tumors, variable myxoid areas are seen, whereas in others, spindle cells may predominate; mature fat cells may even be inconspicuous or absent. The spindle cells have bland, uniform nuclei, and pale eosinophilic "bipolar" cytoplasm. Other possible histologic features include a plexiform pattern, foci with nuclear palisading, cleft-like spaces, and numerous mast cells.

Pleomorphic lipomas are characterized by the presence of mature adipocytes admixed with a variable number of bizarre, multinucleated cells ("floret-like cells"), and occasional lipoblasts (Fig. 117.14). By immunohistochemistry, the spindle cells in both spindle cell and pleomorphic lipomas are CD34-positive and rarely S100-positive. In some tumors, demonstration of loss of the *RB1* locus via molecular diagnostics may help to confirm the diagnosis.

Differential diagnosis
Clinically, spindle cell/pleomorphic lipomas are indistinguishable from other benign superficial lipomatous tumors, with anatomic location being the most characteristic finding. The histopathologic appearance is diagnostic, but problems may arise when the spindle cell population is predominant. In the latter situation, immunophenotyping may be helpful. The major entities in the differential diagnosis are nodular fasciitis (actin-positive, CD34-negative) and neurofibroma or schwannoma (both S100-positive).

Treatment
In general, surgical excision is curative; recurrences are rare.

Hibernoma

Synonyms: ■ Lipoma of immature adipose tissue ■ Lipoma of embryonic fat ■ Fetal lipoma

Key features
- Rare benign fatty tumor derived from brown fat
- Except for a larger average size, clinically indistinguishable from a lipoma
- The most common locations are the interscapular area, thighs, neck, and chest

Introduction
A hibernoma is a rare benign tumor that is derived from brown fat. Brown fat is prominent in hibernating animals, but it is also found in humans. Brown fat first appears in the human fetus and persists into childhood. In children, brown fat is most prominent in the interscapular area, neck, mediastinum, anterior abdominal wall, and around some of the intraperitoneal and retroperitoneal organs. Brown fat gradually disappears with increasing age, and, in adults, it only persists in the neck and around the kidneys, adrenal glands, and the aorta. The main function of brown fat is heat production.

History
This neoplasm was first described in 1906 by Merkel[46] as a pseudo-lipoma of the breast. The term hibernoma was first introduced by Gery in 1914[47].

Epidemiology
Hibernomas occur primarily in adults. Individuals who develop these tumors are younger than patients with ordinary lipomas and are typically in their thirties. In a series of 170 hibernomas, patient ages ranged from 2 to 75 years, with a mean age of 38 years. The series included nine children[48].

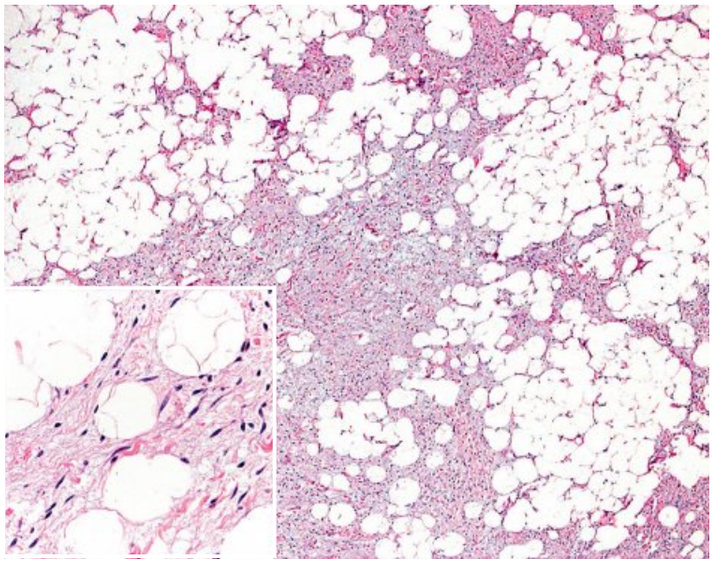

Fig. 117.13 Spindle cell lipoma. Areas of spindle cells are admixed with mature fat cells. The spindle cells are small, uniform, bland, and have inconspicuous cytoplasm (inset).

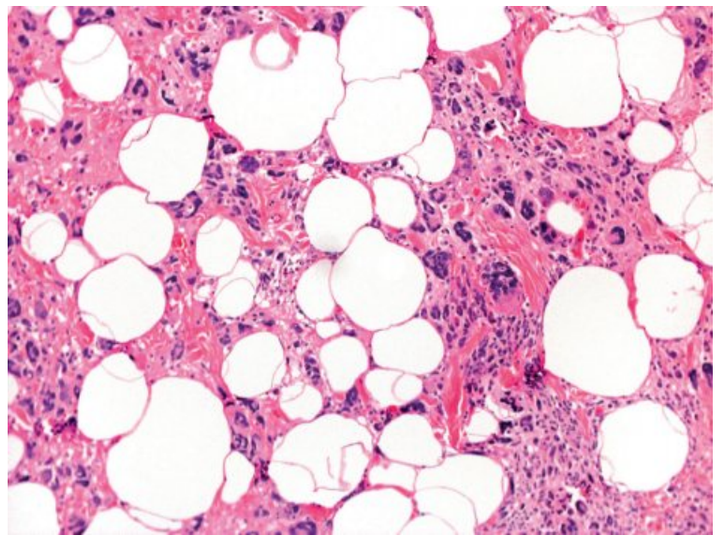

Fig. 117.14 Pleomorphic lipoma. Numerous floret-like multinucleate cells are present in this tumor. Sometimes only a few floret-like multinucleate cells are seen and the majority of cells are mature adipocytes.

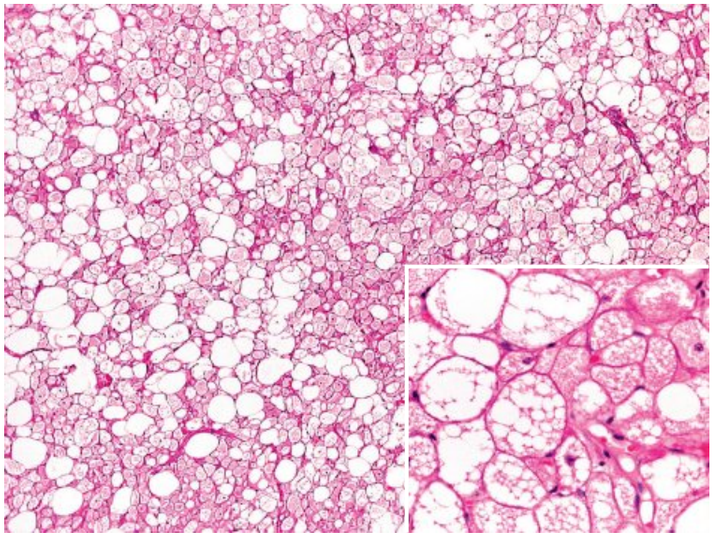

Fig. 117.15 Hibernoma. Irregular aggregates of large cells with abundant cytoplasm. Inset, the cytoplasm of hibernoma cells ranges from multivacuolated to granular (due to multiple tiny vacuoles).

Pathogenesis

Little is known about the pathogenesis of hibernoma. Characteristic clonal chromosomal abnormalities consist of structural rearrangements of 11q13–21.

Clinical features

Hibernomas are slow-growing tumors located in the subcutis or, occasionally, within skeletal muscle. They are clinically indistinguishable from ordinary lipomas, and the most common locations are the upper trunk (interscapular area, shoulder, chest), neck, extremities, and abdominal cavity/retroperitoneum. Hibernomas can measure up to 25 cm in diameter (average size, 10 cm)[5].

Pathology

On cut sections, hibernomas have a characteristic tan to deep red–brown color. Histologic examination shows pronounced lobulation. Highly vascular interlobular septa surround individual lobules. Common to hibernomas are the characteristic brown fat cells with a small central nucleus and multivacuolated to granular eosinophilic cytoplasm (Fig. 117.15). The cellular membrane is distinct. These typical hibernoma cells are admixed with variable numbers of mature fat cells and pale multivacuolated cells. Rarely, myxoid, lipoma-like, or spindle cell variants may be observed[48,49]. Adipocytes stain positively for CD31 and this can aid in establishing the diagnosis (see Table 117.1).

Differential diagnosis

Except for a larger average size, hibernomas are clinically indistinguishable from lipomas. However, their histopathologic features are characteristic.

Treatment

Surgical excision is curative. In a clinicopathologic study of 66 cases, none recurred after complete excision[48].

Nevus Lipomatosus Superficialis

Synonym: ■ Nevus lipomatosis of Hoffman and Zurhelle

Key features

- Hamartoma present at birth or becomes apparent within the first two decades of life
- Grouped soft papulonodules, usually on the hips and upper thighs
- Mature fat cells in the dermis are the defining histopathologic feature

Fig. 117.16 Nevus lipomatosus superficialis. A This hamartoma is characterized by grouped, soft, pedunculated, skin-colored tumors. **B** Histopathologically, irregular aggregates of mature fat cells ectopically located in the dermis are the characteristic feature.

Introduction

Nevus lipomatosus superficialis is a connective tissue nevus or hamartoma that is characterized by grouped soft papulonodules. It is most commonly located on the buttocks or upper thighs.

History

Nevus lipomatosus was first described by Hoffman and Zurhelle in 1921.

Epidemiology

This rare hamartoma is present at birth or becomes apparent during the first two decades of life, and no sex preference has been observed.

Pathogenesis

While the pathogenesis is unknown, there is speculation that precursor cells around dermal blood vessels give rise to mature fat cells in a mosaic pattern.

Clinical features

Nevus lipomatosus superficialis consists of soft, clustered papulonodules that are present at birth, or appear during childhood or adolescence. An initial presentation in adults has been described. The lesions consist of soft, yellow to skin-colored papules or nodules that are clustered, do not cross the midline, and may follow the lines of Blaschko (Fig. 117.16A).

Individual lesions may be sessile or pedunculated, and they have a smooth or cerebriform surface. The pelvic girdle area and upper thighs are the most common locations.

Pathology
The defining histopathologic feature consists of mature fat cells ectopically located within the dermis (Fig. 117.16B). Skin appendages are not displaced.

Differential diagnosis
A solitary acquired papilloma that contains fat cells but no adnexal structures within the dermis is a variant of a skin tag known as a lipofibroma, not a nevus lipomatosus superficialis. The congenital circumferential folds of excess skin in patients with the "Michelin tire baby" phenotype can have the histologic findings of nevus lipomatosus superficialis (see Table 97.7)[50]. In focal dermal hypoplasia (Goltz syndrome), the dermis is either absent and completely replaced by fat cells, or significantly thinned. Adnexal structures are missing. Clinically, agminated neurofibromas may be mistaken for nevus lipomatosus.

Treatment
Most lesions are amenable to excision.

Lipoblastoma/Lipoblastomatosis

Synonym: ■ Embryonic lipoma

Key features
- Benign neoplasm of immature fat cells that arises primarily on the extremities of children
- The circumscribed form is termed lipoblastoma, and the diffuse form is termed lipoblastomatosis
- Histopathologically, indistinguishable from myxoid liposarcoma

Introduction
This is a rare variant of lipoma, and it represents a benign tumor of immature fat cells that occurs almost exclusively in children. When circumscribed, this neoplasm is termed lipoblastoma, and when diffuse, it is known as lipoblastomatosis.

History
The term lipoblastoma was coined by Vellios and colleagues in 1958 when they reported a case of lipoblastomatosis.

Epidemiology
Lipoblastoma and lipoblastomatosis are tumors of infancy. Occasionally, these neoplasms are described in older children, or even teenagers, but the majority occur before the age of 3 years. Congenital tumors have been observed. Boys are affected twice as often as girls.

Pathogenesis
Lipoblastomas are neoplasms of immature (embryonic) white fat, and they probably represent residual areas of immature fat. The latter is suggested by sequential biopsies showing maturation to mature fat and by the almost exclusive occurrence in infancy and childhood. Lipoblastomas commonly display structural alterations, i.e. translocations, inversions, insertions or rings, of 8q11–q13 which lead to rearrangement of *PLAG1*, a finding that argues for a clonal neoplasm.

Clinical features
Most tumors are circumscribed and limited to the subcutis, and hence represent lipoblastomas. They occur primarily on the extremities and less often in the head and neck region or on the trunk. These superficial lesions clinically simulate ordinary lipomas, presenting as slow-growing, soft, mobile, painless nodules, measuring 3–5 cm in diameter.

Lipoblastomatosis affects the deeper soft tissue and often diffusely infiltrates adjacent skeletal muscle. This process can occur in the mediastinum, mesentery, and retroperitoneum. Rare tumors weigh up to 1 kg. Depending on the location, the tumor may result in symptoms of local obstruction or compression.

Pathology
Grossly, lipoblastomas are paler than ordinary lipomas, and they have a myxoid quality. Histologically, it is a lobulated neoplasm. The stroma is often myxoid, contains a plexiform vascular network, and is divided into lobules by connective tissue septa. Deep-seated tumors often lack the lobulation, and they may grow in a diffuse pattern. The tumors are composed of fat cells spanning the range of maturation from immature stellate and spindled mesenchymal cells, to lipoblasts with a single cytoplasmic vacuole that indents a peripherally located nucleus, to small and mature adipocytes. Lipoblastomas are paucicellular, cytologically bland, and lack mitotic activity. Serial biopsies of a lipoblastoma may show gradual maturation to a mature fatty tumor. The adipocytes in lipoblastomas stain positively for S100, CD56, and CD34. Molecular demonstration of *PLAG1* rearrangements may be helpful in confirming the diagnosis.

Differential diagnosis
Histopathologically, lipoblastoma and myxoid liposarcoma may be indistinguishable. Clinical parameters that aid in the differential diagnosis are the age of the patient and the location of the tumor. Myxoid liposarcomas almost always develop in individuals older than 20 years of age, and they are located in the deep soft tissue, rather than the subcutis. Nevertheless, in a child, an immature fat tumor that contains areas of marked cellularity, loss of lobulation, and mitotic figures should raise concern for a myxoid liposarcoma.

Treatment
Lipoblastoma, if treated with complete excision, rarely recurs. Unusual cases of spontaneous resolution without treatment exist[51]. In a series of 14 patients with lipoblastomas/lipoblastomatosis, 22% recurred after excision[52]. Wide excision is the therapy of choice for the diffuse form of the disease.

Atypical Lipomatous Tumor/Liposarcoma

Synonym: ■ Atypical lipoma

Key features
- Sarcoma of deep soft tissue that is only rarely limited to the skin
- Five major histologic subtypes, ranging from locally aggressive tumors without metastatic potential to malignant neoplasms with a significant risk of metastatic dissemination
- Cutaneous involvement may represent superficial extension of a deeply situated tumor
- Tumors confined to the skin ("primary cutaneous liposarcoma") usually have a good prognosis

Introduction
Liposarcoma is the second most common soft tissue sarcoma after malignant fibrous histiocytoma. Five histopathologic subtypes are recognized by the World Health Organization (WHO), with important prognostic, cytogenetic, molecular, and epidemiologic differences. The biologic behavior of the subtypes ranges from locally aggressive tumors without metastatic potential to highly malignant neoplasms with a significant risk of systemic spread. There is considerable controversy among soft tissue pathologists regarding the nomenclature of this tumor when it is confined to the skin. Some experts prefer the term atypical lipomatous tumor for all liposarcomas in the subcutis, because these tumors recur but have virtually no metastatic potential[53,54]. Others prefer to retain the term liposarcoma because histologically and cytogenetically these tumors are the same, regardless of location, and also because these tumors carry a small risk for dedifferentiation, which confers metastatic potential[55].

Epidemiology
The annual incidence of all types of soft tissue liposarcoma is estimated at 2.5 per million, based on a Swedish study. The average age at presentation is 50 years. Rare cases arise in children older than 10 years of age, but virtually never in children younger than 10 years of age.

Fig. 117.17 Liposarcoma. Note the large mass in the right buttock. *Courtesy Ronald P. Rapini, MD.*

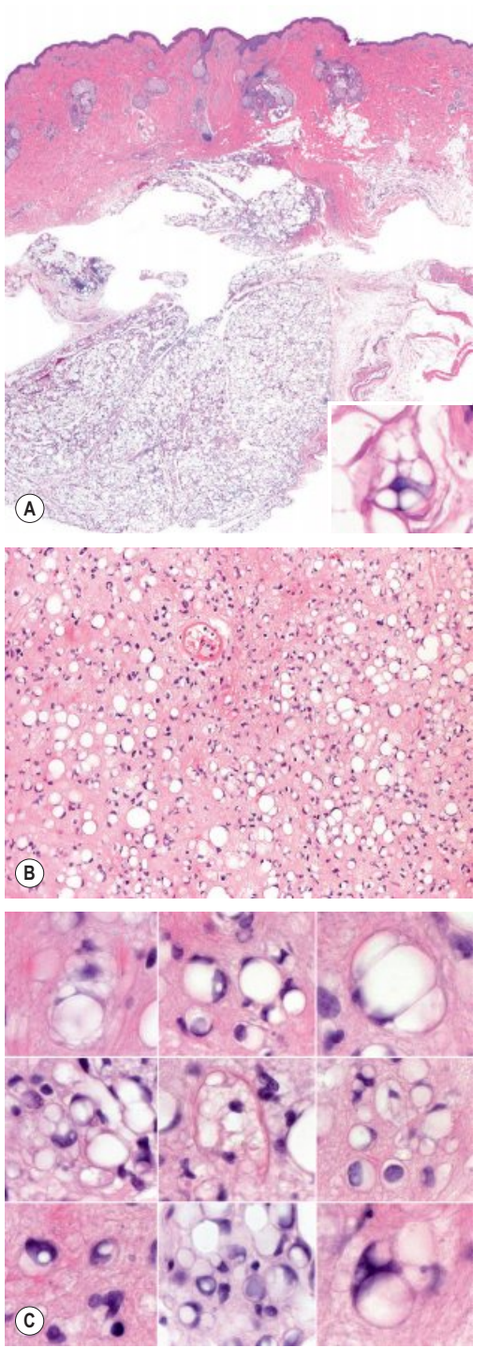

Fig. 117.18 Atypical lipomatous tumor/well-differentiated liposarcoma vs dedifferentiated liposarcoma. A In an atypical lipomatous tumor, irregular aggregates of "hypercellular" fat tissue are seen as are lipoblasts. Lipoblasts are immature fat cells with a hyperchromatic nucleus that is scalloped by cytoplasmic fat vacuoles (inset). Their presence is mandatory for a diagnosis of atypical lipomatous tumor or liposarcoma. **B** In this dedifferentiated liposarcoma, lipocytes and lipoblasts are dispersed in a collagenous stroma and do not form well-differentiated structures. **C** Panel demonstrating the varied morphologic appearances of lipoblasts.

Pathogenesis

It appears that liposarcomas arise *de novo*, rather than from pre-existing lipomas. Chromosomal anomalies differ, depending upon the particular subtype (see Table 117.4). In well-differentiated and dedifferentiated liposarcomas, there is amplification of genes in the 12q13–15 region that are involved in cell cycle regulation (see Fig. 107.4), and this amplification can be detected via fluorescent *in situ* hybridization (FISH). In myxoid or round cell liposarcomas, 12;16 translocations lead to a FUS–DDIT3 fusion oncoprotein.

Clinical features

Liposarcoma is a tumor primarily of the deep soft tissue of the extremities and retroperitoneum. Legs and buttocks are more frequently affected than the upper extremities (Fig. 117.17). It originates in, and is limited to, the dermis or subcutis only in exceptional circumstances[56,57]. Primary cutaneous liposarcomas are described as dome-shaped or polypoid, and they measure between 1 and 20 cm[57]. If a liposarcoma presents in the subcutis, this will often be due to direct extension from an underlying sarcoma of the deep soft tissue.

Tumors limited to the dermis or subcutis can recur, but they do not metastasize or cause patient death. Liposarcomas of the deep soft tissue and retroperitoneum are malignant neoplasms, capable of recurrence, metastasis, and causing patient death. The prognosis depends on the location, degree of differentiation, and the histopathologic subtype.

Pathology

The *sine qua non* for the diagnosis of liposarcoma is the presence of lipoblasts. Lipoblasts are immature fat cells, characterized by a hyperchromatic nucleus that is indented or scalloped by cytoplasmic fat vacuoles (Fig. 117.18). However, the lipoblasts need to be present in the appropriate histopathologic context, as they are not specific for liposarcomas, but can also be found in lipoblastomas and pleomorphic lipomas, or can closely resemble histiocytes found in fat necrosis or fat atrophy.

The histopathologic appearance is highly variable and depends on the particular subtype (Fig. 117.19A,B). A **well-differentiated** liposarcoma (atypical lipomatous tumor) consists of mature fat with a variable number of lipoblasts and cells with hyperchromatic nuclei. **Myxoid** liposarcoma resembles immature fat and can be histologically indistinguishable from a lipoblastoma. Small and uniformly bland spindle cells are set in a myxoid matrix with plexiform vessels. In the more cellular areas, myxoid liposarcoma merges with **round cell** liposarcoma, which is characterized by sheets of primitive round cells. Several classification schemes recognize round cell liposarcoma as a part of the spectrum of myxoid liposarcoma. **Pleomorphic** liposarcoma is the least common subtype; it exhibits an extreme degree of nuclear pleomorphism and resembles a malignant fibrous histiocytoma[58,59]. **Dedifferentiated** liposarcoma is a biphasic tumor comprised of areas of well-differentiated liposarcoma/atypical lipomatous tumor and areas of a non-lipogenic sarcoma.

Given the correlation of molecular findings with liposarcoma subtype (see Table 117.4), chromosomal analysis, immunohistochemistry (CDK4, MDM2, adipophilin)[60], and FISH (*CDK4*, *MDM2*) can assist in diagnosis and classification (Fig. 117.19C).

Differential diagnosis

Liposarcomas of the skin and superficial subcutaneous tissue are exceedingly rare, and they should be diagnosed only after histopathologic mimics, metastases, and direct extension from a deep soft tissue sarcoma have been excluded. In addition, these tumors need to be distinguished from a spindle cell/pleomorphic lipoma, a benign lipomatous tumor that commonly arises on the upper back and posterior neck of older men and is characterized histopathologically by the presence of a variable number of floret-like cells and occasional lipoblasts, admixed with mature adipocytes.

Myxoid liposarcoma can be histologically indistinguishable from lipoblastoma and lipoblastomatosis. This differential diagnosis relies on clinical parameters and is discussed above under lipoblastoma. Of note, silicone granulomas may occasionally mimic liposarcoma histologically.

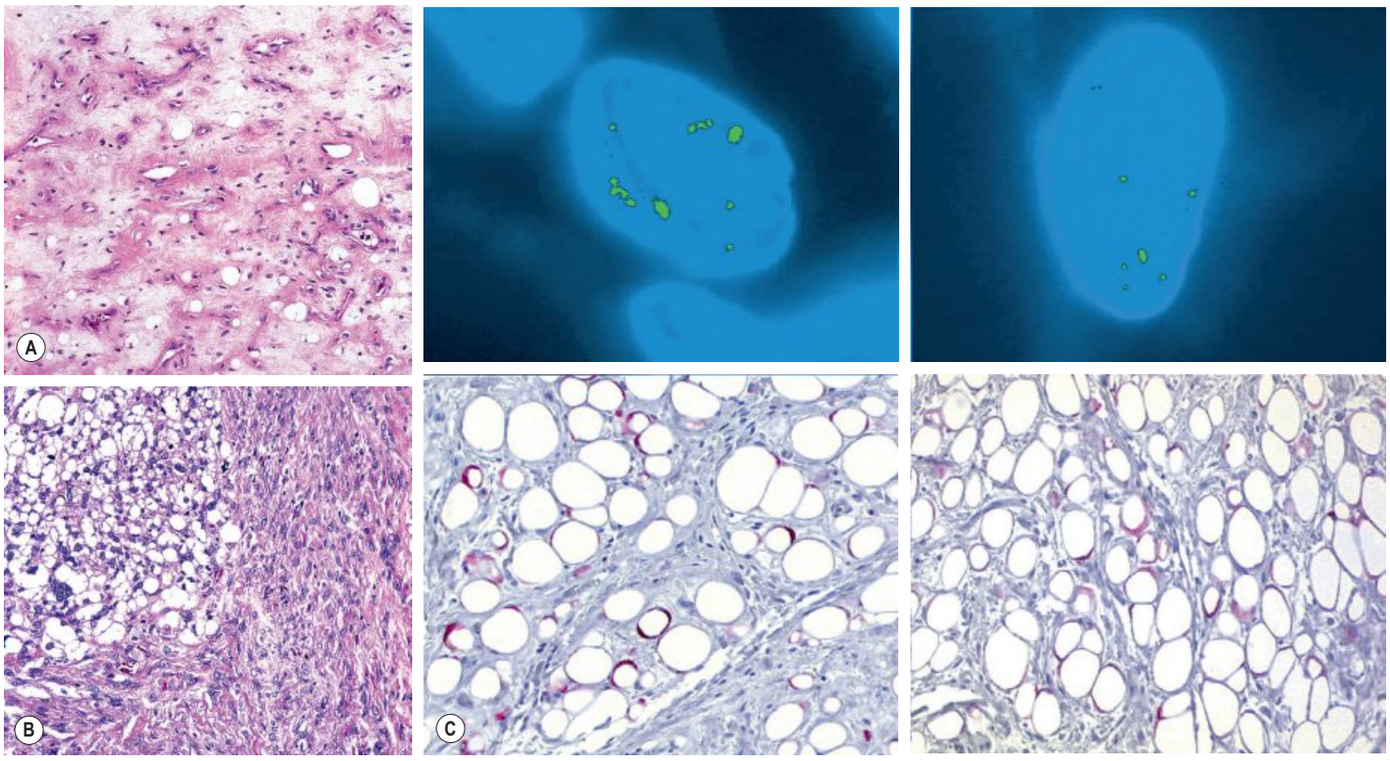

Fig. 117.19 The varied histopathologic features of liposarcoma. A Myxoid liposarcoma – without the clinical context, this tumor can be indistinguishable from lipoblastoma. Bland spindle cells occur in a myxoid matrix with plexiform vessels. **B** Pleomorphic liposarcoma – anaplastic and cellular neoplasm. Lipoblasts may be difficult to find. **C** Demonstration of *MDM2* amplification (left) and *CDK4* amplification (right) via fluorescent *in situ* hybridization (FISH; top) as well as increased protein expression via immunohistochemistry (bottom) can assist in the diagnosis of a well-differentiated liposarcoma (atypical lipomatous tumor). *C, Courtesy Heinz Kutzner, MD.*

Treatment

Wide excision is the treatment of choice. Tumors limited to the dermis and subcutis may be treated by dermatologists. The treatment of most liposarcomas, however, will require an oncologic soft tissue surgeon. It is not uncommon for liposarcomas to have a multinodular growth pattern and extend into muscle and fascial planes. Excision needs to be carefully planned using MRI and other radiographic information.

TUMORS OF CARTILAGE

Extraskeletal Chondroma

Synonym: ■ Chondroma of soft parts

Key features

- Rare benign tumor of mature cartilage
- Most commonly located near the small joints of the hands and feet

Introduction

Cartilage can be found in the skin as a result of metaplasia, as a component of chondroid syringomas, and as the exclusive component of extraskeletal chondromas. By definition, extraskeletal chondromas are not attached to bone and occur outside the synovial space. With the exception of two clinical series[61,62], most of the experience with extraskeletal chondromas is in the form of case reports.

Epidemiology

Extraskeletal chondromas are rare tumors that occur in children as well as adults, but most patients are beyond their third decade.

Clinical features

Extraskeletal chondromas present as solitary painless nodules on the hands and feet, most often the fingers. They grow slowly and are often associated with tendons. Rare locations include the trunk, head, neck, oropharynx, and larynx.

Pathology

On gross examination, chondromas are sharply circumscribed and often lobulated. Most measure less than 2 cm, but larger lesions can occur. Histopathologically, they consist of hyaline cartilage that may be admixed with variable amounts of fibrous tissue or myxoid stroma. The cartilage may compose only a small portion of the tumor. Calcification is common, and lesional cells are S100-positive.

Differential diagnosis

Synovial chondromatosis consists of multiple, discrete, osteocartilaginous nodules and favors the large joints, such as the knee, hip, and elbow. Histologic differentiation of extraskeletal chondromas from grade I chondrosarcoma or myxoid chondrosarcoma may be difficult, but chondrosarcomas rarely affect the hands and feet, and they are in continuity with bone and cartilage.

Treatment

Local excision is usually curative. Up to 20% of extraskeletal chondromas may recur.

Acknowledgment

The author wishes to thank the late Sabine Kohler, MD, for her valuable contribution to this chapter in the previous editions.

118 Mastocytosis

Michael D. Tharp

Key features

- Mastocytosis can develop from birth to adulthood and may involve only the skin (most children and some adults) or multiple organs such as the bone marrow, liver, spleen, and/or lymph nodes (primarily adults)
- Childhood disease is more common and often presents with one or more tan to pink–brown or brown papules or plaques (maculopapular mastocytosis) that frequently resolve by adolescence
- Mastocytomas are thicker plaques or nodules that are few in number and occur primarily in children
- Adults with mastocytosis often have cutaneous lesions; when present, they typically appear as small red–brown macules or papules ("urticaria pigmentosa") and tend to be associated with milder disease
- Adult mastocytosis persists throughout life
- Stroking of mastocytosis lesions often leads to urtication (Darier sign), which is more pronounced in children due to a higher density of mast cells
- Activating mutations in codon 816 of *KIT* are detected in the majority of adults and ~40% of children with mastocytosis; extracellular domain mutations occur more often in childhood-onset than in adult-onset disease
- Patients may have accompanying symptoms of mast cell mediator release such as pruritus, flushing, headaches, abdominal pain, diarrhea, and syncope
- Treatment is primarily directed at controlling symptoms in patients with limited disease and inhibiting activating *KIT* mutations in those with more advanced disease

INTRODUCTION

Mastocytosis represents a spectrum of clinical disorders with a common phenotype of tissue mast cell hyperplasia that can involve the skin, bone marrow, and other organs. Despite significant advances in understanding the pathogenesis of mastocytosis, explanations for the differences in clinical presentations and course between childhood-onset and adult-onset disease are still needed (Fig. 118.1). Childhood mastocytosis has an excellent prognosis, with ~50%–70% of affected children experiencing resolution by adolescence. In contrast, adult-onset mastocytosis typically has a chronic course and is more often associated with extracutaneous involvement and systemic symptoms[1]. Therapy for mastocytosis usually centers on inhibiting the effects of secreted mast cell mediators[2–4], with tyrosine kinase inhibitors such as midostaurin, avapritinib, and imatinib representing options in patients with more advanced systemic disease[5–8]. Cytoreductive therapies (e.g. cladribine) and rarely hematopoietic stem cell transplantation may also be utilized in advanced systemic disease[4].

HISTORY

The original description of mastocytosis was by Nettleship and Tay, who told of a 2-year-old girl with hyperpigmented papules that spontaneously urticated[9]. Eight years later, in 1877, Paul Ehrlich formally discovered the mast cell. The next year, Sangster suggested the name "urticaria pigmentosa". Unna was the first to demonstrate that mast cells were responsible for the cutaneous findings in mastocytosis patients[10].

EPIDEMIOLOGY

Mastocytosis can be present at birth or develop any time thereafter, including into late adulthood. Childhood-onset mastocytosis is defined as presenting prior to puberty. In a pediatric series (n=101), cutaneous mastocytosis appeared by ages 6 months and 2 years in 73% and 97% of children, respectively[11]. Adult-onset mastocytosis most often develops in the third or fourth decade of life, has no sex preference, and occurs in all races[12,13].

While most individuals with mastocytosis have no family history of the disorder, there have been over 70 familial cases reported, including at least 15 sets of monozygotic twins; however, twin pairs discordant for the disease have also been described. Mastocytosis has been documented in three generations of a single kindred[14,15].

PATHOGENESIS

Mast cells are derived from pluripotent $CD34^+$ precursors in the bone marrow that then circulate in the peripheral blood as agranular, monocytic-appearing cells. After migrating into tissues, these immature mast cells assume their typical granular morphology (see Ch. 18). Circulating mast cell precursors express CD34, the tyrosine kinase receptor KIT (CD117), and IgG receptors (FcγRII), but not high-affinity IgE receptors (FcεRI)[16]. The KIT receptor is expressed on mast cells, melanocytes, primitive hematopoietic stem cells, primordial germ cells, and interstitial cells of Cajal. Activation of KIT by its ligand (stem cell factor [SCF]) induces mast cell growth and maturation, and it extends cell survival by preventing apoptosis. Membrane-bound and soluble forms of SCF exist, and both induce KIT activation. SCF is produced by bone marrow stromal cells, fibroblasts, keratinocytes, endothelial cells, and reproductive Sertoli and granulosa cells. Peripheral blood mast cell precursors cultured in the presence of SCF and other cytokines (e.g. interleukin [IL]-3, -4, -6, -9) become $KIT^+/CD34^-/Fc\gamma RII^-/Fc\varepsilon RI^+$ and develop characteristic cytoplasmic mast cell granules, as seen in mature tissue mast cells[16,17].

Alterations in KIT structure and activity are central to the pathogenesis of mastocytosis. *Somatic* activating mutations in *KIT* involving codon 816 represent the most common genetic abnormality in patients with sporadic mastocytosis. The result is a substitution of the amino acid aspartic acid (D) with valine (V), i.e. D816V, or less commonly another amino acid (Fig. 118.2). These mutations lead to constitutive, ligand-independent activation of the receptor. Less common activating mutations and a rare dominant inactivating mutation have also been identified in children and adults with mastocytosis (see Fig. 118.2). In addition, rare *germline* mutations have been reported[15,18–20].

In a study in which the entire *KIT* sequence was analyzed in skin biopsy specimens from 50 children (ages 0–16 years) with primarily maculopapular mastocytosis, codon 816 mutations were found in 42% and other activating mutations in 44% of the patients[18]. However, the mechanism by which childhood disease often resolves spontaneously, despite the presence of underlying somatic *KIT* mutations, remains unknown[14,18].

In a transgenic mouse model of mastocytosis in which human activated *KIT* (D816V) was expressed, only 8 of 28 genetically identical animals developed clinical features of mastocytosis, ranging from indolent mast cell hyperplasia to an invasive mast cell tumor[21]. In another model utilizing the homologous mouse *Kit* D814V, results ranged from advanced mast cell disease when this mutation appeared in undifferentiated bone marrow progenitors to variable mast cell tumors/skin disease when *Kit* D814V was only expressed in committed mast cell progenitors or mature mast cells[22]. The diverse phenotypic expression of gain-of-function *KIT* mutations, along with the lack of *KIT* mutations in some patients and families with mastocytosis, points to

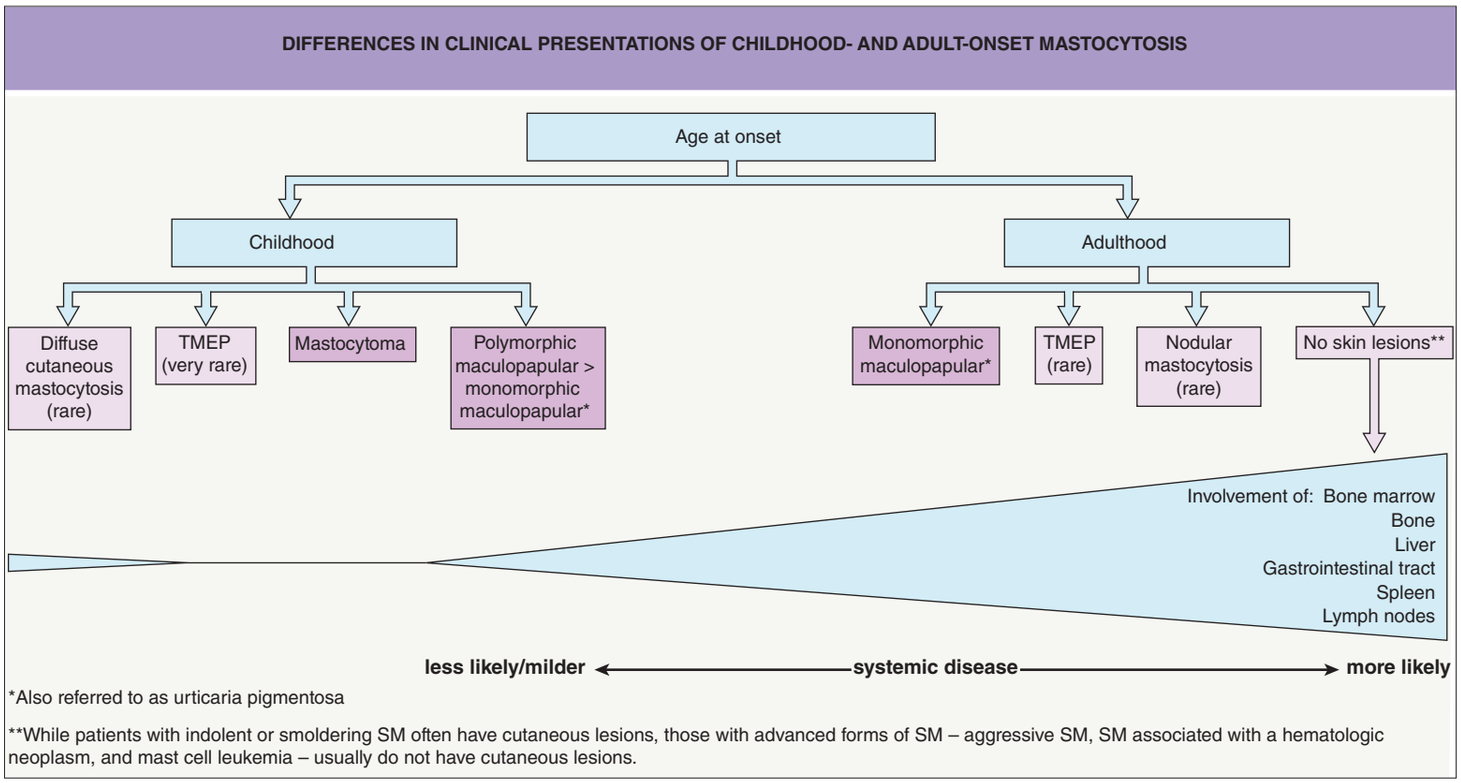

Fig. 118.1 Clinical presentations of childhood and adult-onset mastocytosis. The darker boxes represent the most common forms. Based upon the WHO classification scheme (see Tables 118.1 & 118.2), most children and a small proportion of adults have isolated cutaneous mastocytosis. Most adults with skin lesions have indolent systemic mastocytosis (SM), while those with advanced forms of SM usually do not have cutaneous involvement. In general, children have a benign course with a tendency for spontaneous remission. SM, systemic mastocytosis; TMEP, telangiectasis macularis eruptive perstans.

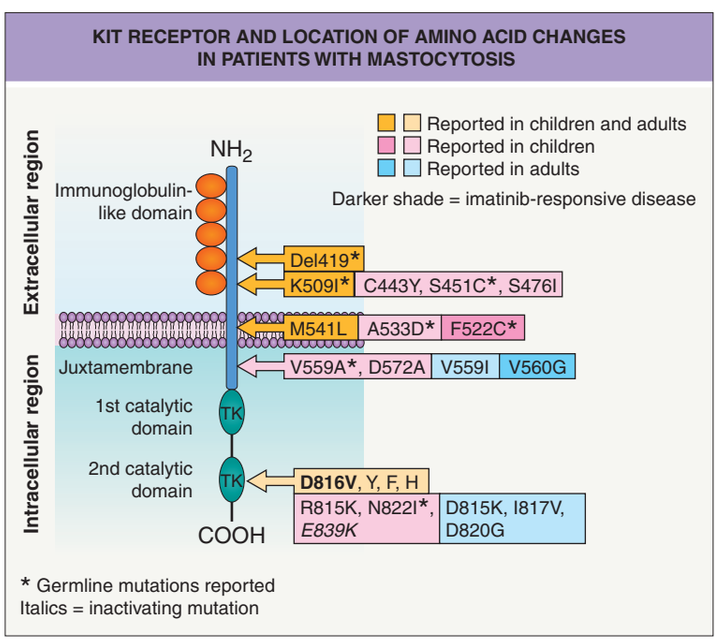

Fig. 118.2 KIT receptor and location of amino acid changes (due to *KIT* mutations) in pediatric and adult patients with mastocytosis. For example, D816V means that a mutation in codon 816 resulted from valine (V) being replaced by aspartic acid (D). The plasma membrane-bound KIT receptor is composed of three distinct regions: (1) the extracellular region (five immunoglobulin-like repeats [orange]); (2) the transmembrane region; and (3) the intracellular region (two tyrosine kinase domains [green]). The most common site for activating mutations is exon 17, which contains codon 816. The result is constitutive ligand-independent activation of the receptor. TK, tyrosine kinase domain (one binds ATP and the other has phosphotransferase activity).

additional pathogenic factors in mastocytosis. Indeed, in adult patients with advanced systemic mastocytosis, somatic mutations have been identified in *KIT* plus a variety of other genes such as *TET2, ASXL1, JAK2, SRSF2, RUNX1*, and *CBL*, which encode *Tet* methylcytosine dioxygenase *2*, *a*dditional *s*ex combs *l*ike *1*, transcriptional regulator, *J*anus *k*inase *2*, *s*erine and arginine *r*ich *s*plicing *f*actor *2*, runt related transcription factor 1, and *Cbl* proto-oncogene, respectively[23,24].

CLINICAL FEATURES

Signs and Symptoms

Many children and adults with cutaneous mastocytosis have few, if any, symptoms. When symptoms do occur, they are due to the diverse physiologic effects of secreted mast cell mediators, such as histamine, eicosanoids, and cytokines (Fig. 118.3). These complaints and findings may range from pruritus and flushing to abdominal pain and diarrhea to palpitations, dizziness, and syncope. Of interest is the relative absence of pulmonary symptoms in mastocytosis. Complaints of fever, night sweats, malaise, weight loss, bone pain, epigastric distress, and problems with mentation (cognitive disorganization) often signal the presence of systemic disease. There are even rare reports of deaths in children and adults in association with extensive mast cell mediator release[2,13,14].

Symptoms of mastocytosis can be exacerbated by exercise, heat, friction, or other trauma to skin lesions. In addition, alcohol, narcotics, salicylates and other nonsteroidal anti-inflammatory drugs (NSAIDs), polymyxin B, and anticholinergic medications have been implicated in precipitating symptoms of mastocytosis. Some systemic anesthetic agents may potentially induce anaphylaxis (see below)[12].

Cutaneous Lesions

Childhood-onset mastocytosis, which almost always affects the skin, has three major clinical presentations: (1) solitary or few (≤3) lesions, referred to as "mastocytomas": 15%–50% of patients; (2) multiple

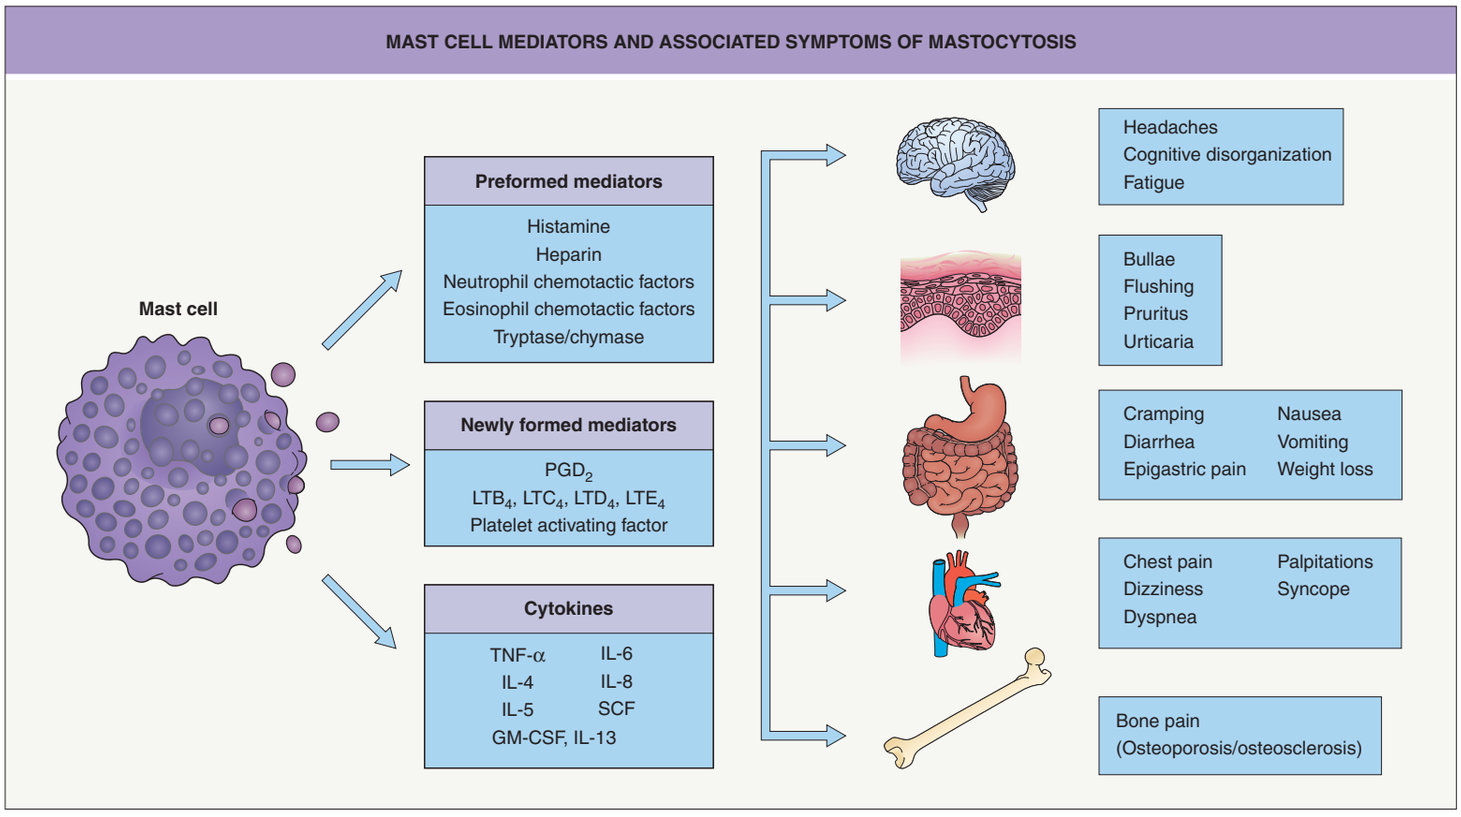

Fig. 118.3 Mast cell mediators and associated symptoms of mastocytosis. GM-CSF, granulocyte–macrophage colony-stimulating factor; IL, interleukins; LT, leukotrienes; PGD_2, prostaglandin D_2; SCF, stem cell factor; TNF, tumor necrosis factor.

Tan (**A**) and pink–tan (**B**) plaques with a leathery surface. **C** Swelling and a subtle rim of erythema resulting from urtication of a yellowish nodule on the wrist. **D** Bullae formation within a pink–brown plaque on the back. *A, Courtesy Antonio Torrelo, MD; B–D Courtesy Julie V. Schaffer, MD.*

(<10 to >100) lesions, referred to as "maculopapular" mastocytosis: 45%–75% of patients; and (3) diffuse cutaneous involvement: <5%–10% of patients. A mastocytoma appears as a tan or yellow–tan to brown nodule or plaque, which may be only slightly elevated and typically has a leathery texture (Fig. 118.4). These lesions can be congenital or become evident during infancy, and they favor the distal extremities[11,12,14]. Bullae may arise within a mastocytoma, leading to misdiagnoses such as bullous impetigo.

Children with multiple lesions of mastocytosis most often present with *large, polymorphic* yellow–tan to pink–brown or brown plaques and nodules, which are frequently admixed with smaller lesions (Fig. 118.5D–F). This cutaneous variant is associated with an earlier onset during infancy and is more likely to spontaneously resolve[14,25]. Less often, only *small, monomorphic* tan to reddish-brown macules or papules are evident (Fig. 118.5A,B), similar to the typical urticaria pigmentosa presentation in adults (see below)[14]. Multiple lesions favor the trunk and classically spare the central face, palms, and soles.

Diffuse cutaneous mastocytosis presents within the first few months of life as thickened skin with a leathery texture and variable hyperpigmentation in a generalized distribution (Fig. 118.6); however, systemic disease is typically absent and spontaneous resolution usually occurs[26]. This term should be reserved for diffuse skin involvement rather than the confluence of individual lesions. Less common presentations of mastocytosis in children include ill-defined tan or telangiectatic patches; small, firm brown nodules; and yellowish patches with superimposed doughy papules ("xanthelasmoid" mastocytosis)[12].

Blistering following urtication is common in infants and young children with mastocytosis, especially those with large, thick lesions or the diffuse form. The latter patients may present with extensive bullae and erosions (see Fig. 118.6; see Ch. 34). The tendency to blister usually remits by 3 to 5 years of age, and it is believed to result from the release of mast cell serine proteases[14,17].

The most common cutaneous lesions of *adult-onset mastocytosis* are small (<1 cm), monomorphic, reddish-brown macules and papules (Fig. 118.7). This pattern is now referred to as maculopapular but the term urticaria pigmentosa is still commonly employed. In patients with skin type I, the macules and papules may appear pink to red in color. Lesions are most numerous on the trunk and proximal extremities and appear less frequently on the face, distal extremities, or palms and soles. Individual lesions can resolve, but the total number usually increases over time. Close inspection reveals variable hyperpigmentation and fine telangiectasias. These lesions are most often associated with indolent systemic mastocytosis[1,12] (see below).

Less commonly, yellow–tan to red–brown or violaceous nodules or papulonodules develop, representing a hallmark of indolent disease (see below)[12,27]. Severe infiltrative mastocytosis may progress to diffuse thickening of the skin, especially in flexural sites; facial involvement may acquire a leonine appearance. A rare form of cutaneous mastocytosis

Fig. 118.5 Maculopapular cutaneous mastocytosis in children. Patients can present with variable numbers and sizes of papules, which may be scattered (**A**), clustered (**B**), or nearly confluent (**C**), as well as predominantly plaques (**D, E**) or papulonodules (**F**). As in solitary lesions, the degree of associated hyperpigmentation can vary. Note the Darier sign (**C**, **D**). *A, C, Courtesy Antonio Torrelo, MD; B, D, E Courtesy Julie V. Schaffer, MD.*

This appearance has been compared to pigskin. **C** Spontaneous blister superimposed on a plaque. *A, Courtesy Antonio Torrelo, MD.*

is telangiectasia macularis eruptiva perstans (TMEP), which is characterized by macules and patches composed of telangiectasias without significant hyperpigmentation (Fig. 118.8). Mastocytomas are extremely rare in adults[1,12].

Formation of an urticaria-like wheal upon firmly stroking or rubbing of skin lesions (Darier sign) results from release of mast cell mediators and is indicative of the diagnosis (Fig. 118.9). Darier sign is readily demonstrated in pediatric patients, especially with nodular lesions, and if vigorously induced may precipitate systemic symptoms[11,14]. This sign tends to be more subtle in typical adult mastocytosis lesions and TMEP. These differences reflect lesional mast cell density, which is higher in mastocytomas and childhood maculopapular mastocytosis than in adult-onset cutaneous mastocytosis[28]. Dermographism may also be observed in the uninvolved skin of pediatric and adult mastocytosis patients[1,14,28].

Systemic Manifestations

Skeletal lesions frequently occur in adult patients with mastocytosis but are rare in children (see Fig. 118.1)[11,14]. Bone involvement can be associated with skeletal pain. In one study of 142 adults with mastocytosis, 40% had skeletal involvement, with a similar frequency in those with childhood-onset and adult-onset disease[29]. Bony lesions may appear as radio-opacities, radiolucencies, or a mixture of the two. The skull, spine, and pelvis are most commonly involved. In an earlier study of 58 adult systemic mastocytosis patients, 57% had diffuse bone involvement, whereas only 2% had focal lesions. Demineralization was the most common change in patients with diffuse skeletal disease, followed by osteosclerosis and mixed lesions of osteosclerosis and osteoporosis[30]. Osteoporosis is more prevalent in men with mastocytosis and may be the presenting manifestation of the disease[30,31].

Undecalcified iliac crest biopsies from adult mastocytosis patients have demonstrated increased numbers of mast cells and evidence of enhanced cortical and trabecular bone turnover. These observations led to the hypothesis that mast cells and their mediators are directly responsible for the associated skeletal changes. For example, mast cell-derived heparin and SCF have been implicated in promoting osteoporosis via stimulation of osteoclastic activity. Osteoclasts have been shown to express KIT receptors on their surface and to be activated by SCF. Mast cell histamine, however, is also capable of promoting bone sclerosis through activation of fibroblasts, and mast cell-derived IL-6 appears to induce both bone resorptive and fibrotic activities[30,32].

The **bone marrow** is involved in nearly all adult patients with systemic mastocytosis. In general, a bone marrow biopsy appears to be more reliable than an aspirate for identifying abnormal mast cell morphology and distribution[33]. Multifocal mast cell aggregates are typically located in perivascular and paratrabecular locations. Bone marrow involvement is relatively uncommon in children with mastocytosis, and bone marrow biopsy is not routinely recommended[14,34].

Splenomegaly is relatively common in patients with advanced systemic mastocytosis but rare in those with indolent systemic disease[35,36]. Increased numbers of mast cells and eosinophils are frequently observed in the spleen, as are various degrees of fibrosis and hematopoiesis. In general, **lymph node** enlargement is uncommon in mastocytosis patients but it does occur in those with more advanced systemic disease. Among 58 systemic mastocytosis patients, 26% had peripheral lymphadenopathy, whereas 19% had central nodal disease[37]. Histologically, early involvement of lymph nodes often consists of only clusters of mast cells, while in more advanced disease, mast cell infiltrates involve the paracortex and are often accompanied by eosinophils[37,38].

Gastrointestinal (GI) symptoms such as abdominal pain, diarrhea, nausea and vomiting resulting from mast cell mediator release may occur spontaneously or be precipitated by alcohol, aspirin, NSAIDs, or certain foods[36,39]. Approximately 25% of patients with isolated cutaneous disease and 70% of those with systemic mastocytosis report GI symptoms[39]. Diarrhea in patients with mastocytosis is usually episodic; it can result from malabsorption, increased motility, and/or acid hypersecretion, with the former due to mast cell infiltration and the latter two symptoms likely related to the release of mast cell histamine and prostaglandins. Patients with systemic mastocytosis are at increased risk of gastritis and peptic ulcers, which occasionally lead to

GI hemorrhage. A number of radiographic changes in the GI tract have been described, including urticaria-like lesions and thickened gastric, duodenal and jejunal folds, as well as mucosal nodules and/or peptic ulcers. Biopsies of mucosal nodules have demonstrated numerous mast cells with varying numbers of eosinophils[40]. Gastrointestinal stromal tumors (GISTs) frequently have underlying *somatic* activating KIT mutations and are occasionally seen together with cutaneous mastocytosis in families with *germline* activating *KIT* mutations (see Fig. 118.2)[41]. **Hepatomegaly** most commonly occurs in advanced systemic mastocytosis and is not always associated with abnormal liver function tests[35,36].

A mixed organic **brain** syndrome with a constellation of symptoms – including irritability, fatigue, headache, poor attention span and motivation, limited short-term memory, inability to work effectively, and difficulty in interacting with other people – has been described in patients with mastocytosis. It has been hypothesized that these symptoms may be secondary to mast cell mediators. Electroencephalographic studies in these patients range from normal to changes consistent with a toxic or metabolic process[42].

Classification of Mastocytosis

The World Health Organization (WHO) classification scheme for mastocytosis was proposed in 2001 and then modified in 2008 and 2016 (Table 118.1)[36]. *Cutaneous mastocytosis* represents the largest group and includes nearly all affected children and some adults. Childhood-onset mastocytosis resolves by adolescence in ~50%–70% of patients, with persistence into adulthood in the remainder[13,14]. The WHO has also established criteria for the diagnosis of *systemic mastocytosis* (SM; Table 118.2)[36]. From a dermatologic perspective, appreciation of indolent and smoldering SM is important as these patients frequently have cutaneous lesions.

Although patients with *indolent systemic mastocytosis* (ISM) have detectable mast cell infiltrates in multiple organs (e.g. bone marrow, liver, spleen, lymph nodes), organ impairment is generally absent and there are few, if any, systemic symptoms. Patients with ISM frequently have slightly increased numbers of spindle-shaped, hypogranulated bone marrow mast cells (BMMCs) that express CD25 ± CD2, which are not expressed in normal BMMCs. CD25 appears to be the most reliable marker for BMMCs with gain-of-function *KIT* mutations in exon 17 (see Fig. 118.2)[33,36]. Progression of ISM to more severe forms of SM appears to be unusual. In a study of 145 adults with ISM, the cumulative probabilities of disease progression to more advanced SM at 10 and 25 years were 1.7% and 8.4%, respectively[43].

Compared to individuals with ISM, patients with the *smoldering SM* (SSM) have increased disease burden manifesting as "B" findings – e.g. hepatosplenomegaly, lymphadenopathy, serum tryptase levels >200 ng/ml (see Table 118.2) – and are more likely to be anemic and an older age. The overall prognosis for SSM patients is less favorable than ISM due to an increased risk for developing more advanced systemic disease[43–46].

SM with an associated hematologic neoplasm (SM-AHN) does not usually present with cutaneous lesions, but affected individuals may have "B" and "C" findings (see Table 118.2). In some patients, the hematologic neoplasm precedes the development of SM. The overall prognosis of SM-AHN patients depends upon the severity of the hematologic disease[44,45].

Patients with *aggressive SM* (ASM) have "C" findings with organ dysfunction secondary to mast cell infiltrates, notably in the liver (e.g. ascites, portal hypertension), bone (pain, pathologic fractures), gastrointestinal tract (malabsorption), and spleen (hypersplenism) (see Table 118.2). They also may develop cytopenias, leukocytoses (eosinophilia, basophilia, monocytosis), and/or thrombocytosis as a reflection of abnormal myelopoiesis. Serum tryptase levels are often elevated, reflecting a significantly increased total body mast cell burden. The overall prognosis appears to depend upon the response to treatment (Fig. 118.10)[33,44,45].

Mast cell leukemia (MCL) is rare and is divided into acute and chronic forms. Diagnosis requires ≥10% mast cells among nucleated peripheral blood cells and ≥20% atypical mast cells in the bone marrow[1,36,44]. However, because mature mast cells are rarely observed in the blood

WHO 2016 CLASSIFICATION OF MASTOCYTOSIS
Cutaneous mastocytosis (CM)
• Maculopapular CM (urticaria pigmentosa) • Diffuse CM • Mastocytoma of skin (cutaneous mastocytoma)
Systemic mastocytosis (SM)
• Indolent SM* • Smoldering SM* • SM with an associated hematologic (non-mast cell lineage) neoplasm • Aggressive SM • Mast cell leukemia
Mast cell sarcoma
*Forms of SM most likely to have cutaneous involvement; see Table 118.2 for defining criteria.

Table 118.1 WHO 2016 classification of mastocytosis.

WHO CRITERIA FOR THE DIAGNOSIS OF SYSTEMIC MASTOCYTOSIS AND RELATED B & C FINDINGS
WHO criteria for systemic mastocytosis (SM)
Major criterion
Multifocal, dense infiltrates of MCs (aggregates of ≥15 MCs) in BM biopsies and/or in sections of other extracutaneous organ(s)
Minor criteria
• In BM smears, >25% of all MCs are atypical – *or* – >25% of MCs are spindle-shaped in infiltrates within extracutaneous organ(s) • *KIT* point mutation at codon 816 in the BM or another extracutaneous organ • MCs in BM, blood, or another extracutaneous organ express CD2 and/or CD25 • Baseline serum tryptase level >20 ng/ml (if there is an unrelated myeloid neoplasm, this is not valid as an SM criterion)
SM diagnosis requires either the major criterion plus 1 minor criterion or 3 minor criteria
Criteria for B and C findings in patients with SM
B findings: indicate a high burden of MCs and/or expansion of the neoplastic process into multiple hematopoietic lineages, without impairment of organ function
• MC infiltration of the BM >30% and basal serum tryptase level >200 ng/ml • Hypercellular BM with loss of fat cells, discrete signs of dysmyelopoiesis without substantial cytopenias, or WHO criteria for a myelodysplastic syndrome or myeloproliferative neoplasm • Organomegaly: palpable hepatomegaly with normal liver function, palpable splenomegaly without hypersplenism, and/or lymphadenopathy on palpation or imaging (>2 cm)
C findings: indicate organ damage produced by mast cell infiltration (should be confirmed on biopsy if possible)
• Cytopenia(s) caused by MCs: absolute neutrophil count <1000/mcl, hemoglobin <10 g/dl, or platelet count <100 000/mcl • Hepatomegaly with abnormal liver function, ascites, and/or portal hypertension • Splenomegaly with associated hypersplenism • Skeletal osteolytic lesions with pathologic fractures (fractures from osteoporosis alone is not a C finding) • Malabsorption with hypoalbuminemia and weight loss due to gastrointestinal MCs
*In SM patients with <2 B findings and no C findings, the diagnosis is **indolent SM**.* *When ≥2 B findings but no C findings are present, the diagnosis is **smoldering SM**.* *When ≥1 C findings (± B findings) are present, the diagnosis is either **aggressive SM** (<20% MCs in BM smears) or **MC leukemia** (≥20% MCs in BM smears)*

Table 118.2 WHO criteria for the diagnosis of systemic mastocytosis (SM) and related B & C findings. BM, bone marrow; MC, mast cell.

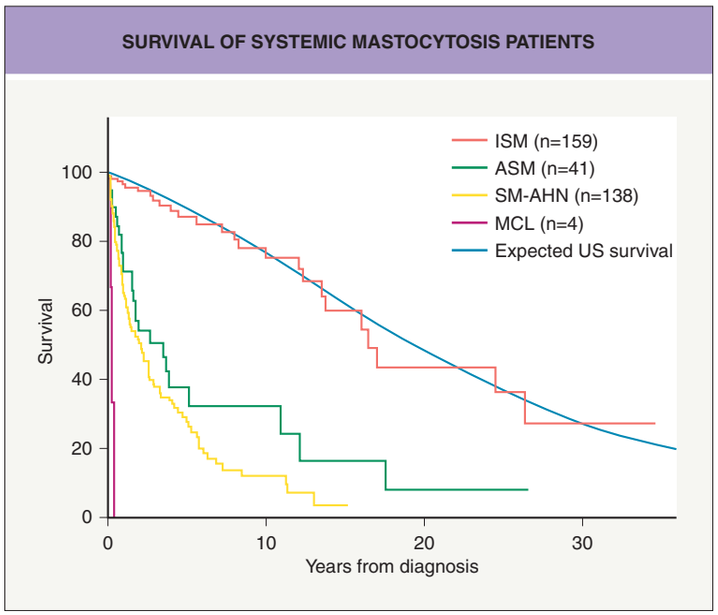

Fig. 118.10 Survival of patients with systemic mastocytosis (SM). The life expectancy of patients with indolent SM (ISM) was not significantly different from the age- and sex-matched US population from the appropriate time period, and leukemic transformation rarely occurred. Based upon these data, the authors recommended that, in general, therapy for ISM should be symptom-directed. ASM, aggressive SM; SM-AHN, SM with associated hematologic neoplasm; MCL, mast cell leukemia. *From Lim K-H, Tefferi A, Lasho TL, et al. Systemic mastocytosis in 342 consecutive adults: survival studies and prognostic factors. Blood 2009;113:5727–36.*

of normal individuals, their presence should raise the suspicion of an "aleukemic" form of MCL in which patients have fewer circulating mast cells[47]. Most MCL patients do not have cutaneous lesions, but those with an acute onset frequently exhibit "B" and "C" findings. Multi-organ failure, including of the bone marrow, often occurs over weeks to a few months in the acute form, with an expected survival of a year or less from the time of diagnosis[44,45]. Chronic MCL, however, has a more indolent course and survival is similar to SSM[47].

The presence of mutations in *KIT* and other genes may also have clinical implications in patients with mastocytosis. Advanced forms of mastocytosis are associated with gain-of-function *KIT* mutations in not only BMMC progenitors but also bone marrow mesenchymal stem cells, leading to involvement of lymphocytic or myeloid cell lineages[22,23,33,48]. In a study of 39 SM patients with a *KIT* D816V mutation, additional mutations in genes such as *TET2, SRSF2, ASXL1, RUNX1*, and *CBL* were found in 25% of those with ISM/SSM and 89% of those with more advanced forms of SM. These additional mutations were associated with decreased overall survival[24]. In contrast, patients with familial disease often lack *KIT* mutations in codons 815 and 816; their overall prognosis appears to be good but is less well defined[15,49].

An approach to the initial evaluation of a patient with cutaneous mastocytosis is presented in Fig. 118.11. A thorough history is crucial, with inquiries into the duration and progression as well as factors that provoke symptoms. For *childhood-onset* mastocytosis, the diagnosis is usually established clinically by recognition of characteristic skin lesions with a positive Darier sign (see Fig. 118.9). If the diagnosis is in doubt, confirmation can be achieved via a skin biopsy. No further testing is indicated for most children. However, additional evaluation should be performed in children who develop severe mast cell mediator-related symptoms or have evidence of hepatosplenomegaly, with the latter representing a marker of systemic involvement[14,50] (see Fig. 118.11).

Dermatologists have an opportunity to make the initial diagnosis of mastocytosis in adults who have cutaneous involvement, which can be confirmed by a skin biopsy demonstrating increased numbers of mast cells and/or the presence of an activating *KIT* mutation. Most of these patients have ISM, with fewer individuals having isolated cutaneous disease. For adults with skin lesions of mastocytosis, a baseline CBC with differential, serum tryptase level, liver function tests (LFTs), and DEXA scan of the lumbar spine and femur should be performed (see Fig. 118.11).

Recent guidelines from the American Initiative in Mast Cell Diseases (AIM) and European Competence Network on Mastocytosis (ECNM) recommend complete staging including a bone marrow biopsy in all adult mastocytosis patients to assist with prognostication[1,33,44,51]. However, other clinicians (including the author) do not believe that a bone marrow biopsy is required in adults with cutaneous lesions who have a normal or slightly elevated serum tryptase level[4] as well as a normal CBC and normal LFTs[50]. Of note, there is agreement that a bone marrow biopsy is indicated in those who have B or C findings (see Table 118.2)[1,44,50,51]. Detection of the *KIT* D816V mutation in the peripheral blood can help to determine the likelihood of SM and follow disease progression over time[52,53]. A provisional diagnosis of "mastocytosis in the skin" is given to adults with skin lesions of mastocytosis in whom a bone marrow biopsy has not been performed, and a scoring system has been developed to assess the risk of SM in these individuals[51,54] (see Fig. 118.11).

PATHOLOGY

Direct Studies

The diagnosis of mastocytosis is established by the presence of characteristic mast cells in one or more organs. For patients with cutaneous lesions, an increased number of mast cells can be demonstrated in a biopsy of lesional skin (Fig. 118.12). Eosinophils may be found within the dermis; hyperpigmentation of the basal layer of the epidermis with a few melanophages in the upper dermis is a common finding. Special stains, such as toluidine blue, Leder, and Giemsa, or monoclonal antibodies that recognize CD117 (KIT) or tryptase are helpful in identifying tissue mast cells[1] (Fig. 118.13).

Mast cell densities in childhood maculopapular mastocytosis and mastocytomas are 40-fold and 150-fold higher than in normal skin, respectively, and are therefore relatively easy to identify. In comparison, the density is ~30% lower in adults[28]. For nodular, papular, and macular lesions (including TMEP) of mastocytosis, mast cells have been quantified using a morphometric technique and shown to have densities of 63.2% (± 8.2% SEM), 16.1% (± 4.8% SEM), and 3.5% (± 1.8% SEM), respectively, compared to 0.4% (± 0.1% SEM) in normal skin[28]. In childhood mastocytosis, mast cells in lesional skin typically have a round or cuboidal shape, whereas they tend to appear fusiform or dendritic in adults. *KIT* mutations can often be detected in lesional skin and may help to confirm the diagnosis[18].

Biopsies of normal-appearing skin from patients with mastocytosis have normal concentrations of mast cells and thus are not useful for diagnosis[28]. A biopsy of the GI tract or bone marrow may be indicated in patients with mast cell mediator-related symptoms who lack skin lesions. Increased mast cell numbers in association with variable numbers of eosinophils can be observed in GI biopsies[1,33,39,50]. The bone marrow of patients with systemic disease frequently shows multifocal, spindle-shaped mast cells that express CD25 ± CD2. The detection of >25% atypical mast cells in extracutaneous tissues and the expression of CD25 and/or CD2 represent minor WHO diagnostic criteria for SM (see Table 118.2). Although coexpression of CD30 in BMMCs was initially reported to predict more advanced mastocytosis, a study of 142 patients demonstrated similar CD30 positivity across all systemic mastocytosis subgroups[55]. Because mast cells may appear hypogranular in tissues of patients with systemic disease, the combination of monoclonal antibodies against CD117 (KIT) and tryptase may be useful for their identification[36,56].

Indirect Studies

Detection of circulating mast cell mediators and/or their metabolites can offer indirect evidence of mastocytosis. Two forms (α and β) of mast cell tryptase have been identified[1,57]. Serum α-tryptase levels are elevated in patients with SM, regardless of whether or not they are experiencing acute symptoms, and therefore may be useful in assessing total body mast cell burden. However, β-tryptase is often detected both in mastocytosis patients and in patients *without* mastocytosis who are experiencing anaphylactic symptoms. Total (α and β) serum tryptase levels correlate with the extent of mast cell disease. In one study, half of those patients with total serum tryptase levels between 20 and 75 ng/ml had evidence of SM, whereas all patients

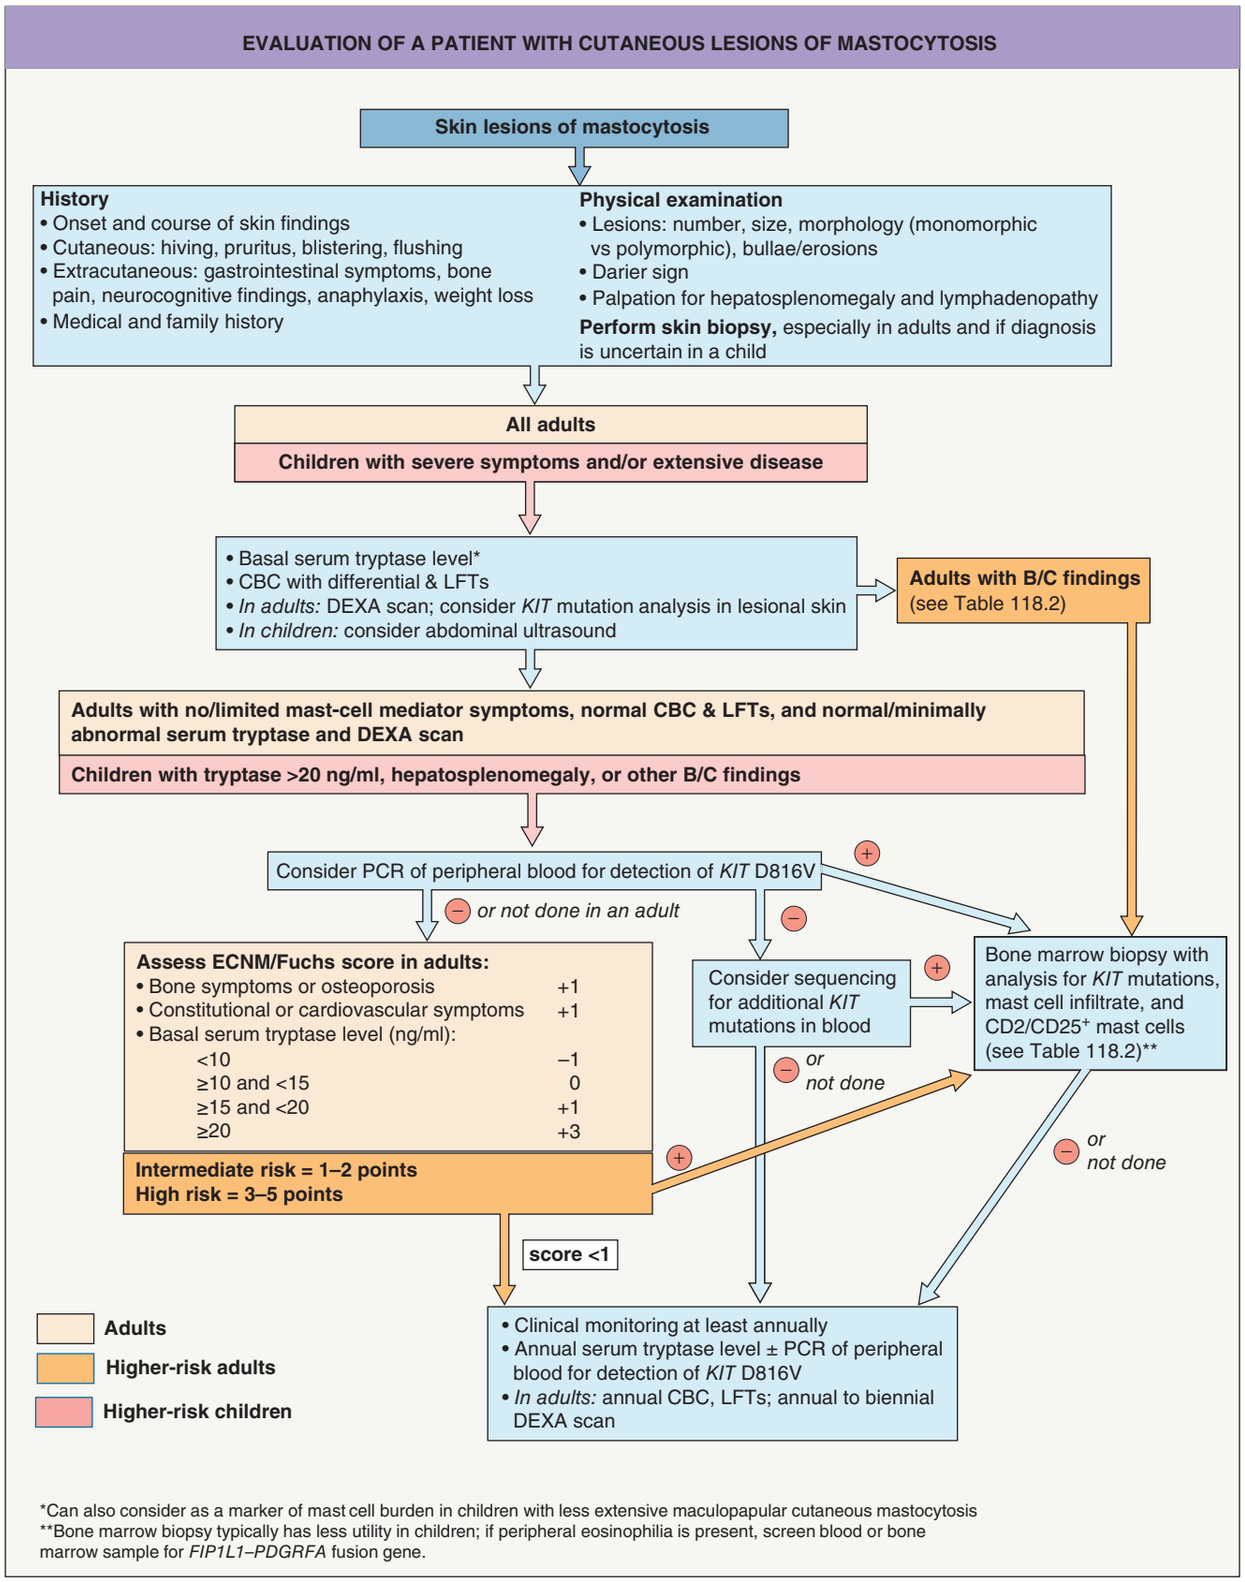

Fig. 118.11 Evaluation of a patient with cutaneous lesions of mastocytosis. Diagnosis of mastocytosis in the skin requires one major criterion – clinically typical skin lesions associated with the Darier sign – plus one minor criterion. The minor criteria are: (1) increased number of mast cells in lesional skin; and (2) detection of an activating *KIT* mutation in lesional skin. Additional investigations can be performed as directed by extracutaneous findings.

with levels >75 ng/ml had systemic involvement[5,57]. Of note, a total serum tryptase level >20 ng/ml represents one of the minor criteria for SM (see Table 118.2)[36].

Urinary excretion of histamine, MeImAA (1,4-methylimidazole acetic acid [histamine's major metabolite that is more persistently elevated]), and PGD_2M (major prostaglandin D_2 metabolite) are historical markers of mastocytosis disease that have low sensitivity and specificity. Plasma levels of IL-6 are also elevated in patients with mastocytosis, correlating with severity of bone marrow pathology, organomegaly, and extent of skin involvement[58].

DIFFERENTIAL DIAGNOSIS

The lesions of childhood and adult mastocytosis are so characteristic that they are only occasionally confused with other skin disorders. Mastocytomas may be misdiagnosed as café-au-lait macules, arthropod bites, Spitz or congenital melanocytic nevi, pseudolymphomas, or juvenile xanthogranulomas[11,14,49]. Childhood maculopapular lesions that spontaneously urticate may be mistaken for urticaria but are distinguished by the associated hyperpigmentation. The differential diagnosis for blisters due to mastocytosis in children may include bullous

arthropod bites, bullous impetigo, herpes simplex viral infection, linear IgA bullous dermatosis and, less often, other autoimmune bullous dermatoses. Infants with diffuse cutaneous mastocytosis can develop widespread blisters, which may be mistaken for epidermolysis bullosa or toxic epidermal necrolysis. Demonstration of increased mast cells in either the blister fluid or a skin biopsy helps to establish the diagnosis of mastocytosis. Nodular scabies in children has occasionally been misdiagnosed as mastocytosis.

The smaller maculopapular lesions typical of adult mastocytosis may at first glance appear as lentigines or melanocytic nevi, but mastocytosis lesions usually have associated erythema[56]. The differential diagnosis of TMEP includes other telangiectatic conditions, but some hyperpigmented maculopapular lesions are often evident. Lastly, if mast cells are not readily detected due to the presence of other leukocytes within the dermis, the patient may be misdiagnosed as having a histiocytic disorder or vasculitis[59].

Mast cell activation syndrome (MCAS) is characterized by symptoms of mast cell mediator release, but unlike mastocytosis there is no evidence of mast cell proliferation or persistent skin lesions. Serum tryptase levels may be slightly elevated in MCAS, and treatment with antihistamines, leukotriene inhibitors, and/or omalizumab is often of benefit[2,3]. Of note, the term mast cell activation *disorders* is sometimes used to encompass the various forms of mastocytosis and MCAS[60].

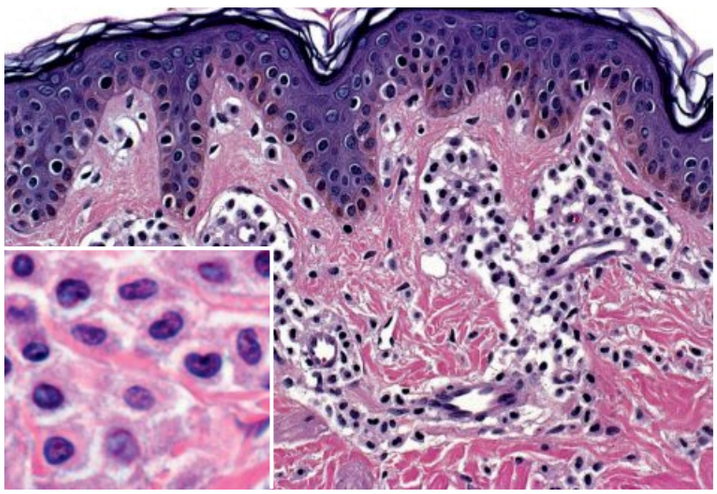

Fig. 118.12 Cutaneous mastocytosis – histologic features. Mast cells within the dermis have a rounded or cuboidal appearance. Granules are seen within the amphophilic cytoplasm (inset). *Courtesy Lorenzo Cerroni, MD.*

TREATMENT

Treatment of patients with mastocytosis is directed primarily at alleviating symptoms, since there is no cure for this disorder. Many patients with cutaneous mastocytosis and ISM have few, if any, symptoms and therefore require little or no therapy. Mastocytosis patients should be provided with information on environmental triggers (e.g. friction, heat) and potential mast cell degranulating agents (Table 118.3)[61]. Systemic anesthetic agents that have been directly or indirectly implicated in precipitating anaphylactoid reactions in mastocytosis patients are also listed in Table 118.3. In contrast, local injections of lidocaine can be used safely in these patients. It has been recommended that mastocytosis patients undergoing general anesthesia be monitored postoperatively for at least 24 hours, since delayed anaphylaxis can occur[62,63].

Antihistamines are often helpful in controlling the symptoms associated with mastocytosis[36,44]. The second-generation antihistamines cetirizine, loratadine, and fexofenadine are preferred because they have longer half-lives and more specific antagonism of the H1 receptor (see Table 18.5). Use of multiple agents and higher than standard doses are often required for symptom control. For example, the author recommends fexofenadine 360 mg in the morning and up to 40 mg of cetirizine at night for control of histamine-related symptoms in adults. In some instances, the addition of an H2 antagonist (e.g. cimetidine, famotidine, nizatidine) may prove beneficial, especially in patients with gastric acid hypersecretion[44].

Oral **cromolyn** sodium (disodium cromoglycate; 400–800 mg/day), a mast cell stabilizer with poor oral absorption, may alleviate GI manifestations and (to a lesser degree) cutaneous and CNS symptoms associated with mastocytosis. Use of topical cromolyn for cutaneous mastocytosis has also been described but has limited efficacy.

Narrowband ultraviolet B or psoralen plus UVA (PUVA) **phototherapy** administered up to four times a week may help to control pruritus and cutaneous whealing in patients with mastocytosis. While this treatment can reduce skin mast cell histamine content, it does not eliminate the mast cell infiltrates[59,64].

Potent topical **corticosteroids**, especially under occlusion for 6 weeks or more, may eliminate pruritus and cutaneous whealing as well as reduce the number of lesional skin mast cells, but this can also lead to skin atrophy[65]. Intralesional injections of triamcinolone acetonide have also been successful in clearing cutaneous mast cell infiltrates. In SM patients, relief of cutaneous and GI symptoms with prednisone alone or in combination with cyclosporine has been described[66]. However, if possible, systemic corticosteroids should be avoided due to the risk of worsening associated osteoporosis. Mastocytosis patients with decreased bone density may benefit from treatment with bisphosphonates or denosumab, a RANK ligand inhibitor[30].

Some patients with severe mastocytosis experience recurrent, life-threatening episodes of hypotension following mast cell mediator release, and therefore should be provided with a premeasured **epinephrine** (adrenaline) preparation (e.g. EpiPen®, Auvi-Q®) for

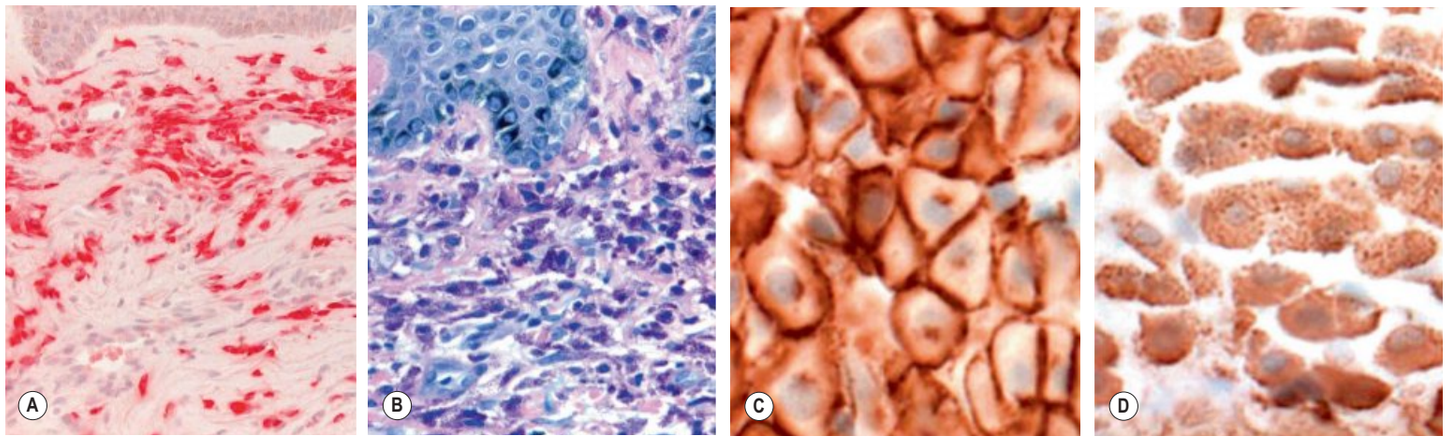

Fig. 118.13 Special stains to detect dermal mast cells. A The Leder method utilizes naphthol AS-D chloroacetate esterase and the mast cell granules appear red. **B** With the Giemsa stain, the mast cell granules stain metachromatically purple. Immunohistochemical staining with monoclonal antibodies that recognize CD117/KIT receptor (**C**) or tryptase (**D**) can also be employed. *A, B, Courtesy Lorenzo Cerroni, MD; C, D, Courtesy Antonio Subtil, MD.*

THERAPEUTIC LADDER FOR MASTOCYTOSIS
Avoidance of relevant mast cell stimuli
Physical
Friction Exercise Heat (e.g. hot bath) or cold (e.g. swimming)
Dietary
Hot beverages Spicy foods Alcohol
Medications
Aspirin Nonsteroidal anti-inflammatory drugs Narcotics (e.g. morphine, codeine) Anticholinergics (e.g. scopolamine) Dextromethorphan (a cough suppressant) Polymyxin B sulfate Some systemic anesthetics, including lidocaine*, d-tubocurarine, metocurine, etomidate, thiopental, succinylcholine hydrochloride (suxamethonium chloride), enflurane, isoflurane (see text for alternatives) Iodine-based radiographic dyes Dextran (in some IV solutions)
Local therapy for symptom control
Potent and superpotent topical corticosteroids, including under occlusion (2) Topical calcineurin inhibitors (3) Intralesional corticosteroids (3) Hydrocolloid dressing (for mastocytoma; 3)
Systemic therapy for symptom control
Oral antihistamines (1) Oral cromolyn sodium (1) Omalizumab (2) Oral PUVA [psoralens plus ultraviolet A] (2) Narrowband ultraviolet B (3) Oral corticosteroids (3) UVA1 (3) Pre-measured epinephrine with auto-injector (EpiPen®, Auvi-Q®) (3)
Systemic therapy for advanced mastocytosis
Midostaurin (2) Avapritinib (2) Imatinib mesylate (non-codon 816 *KIT* mutation; 1) Cladribine (2) Interferon-α-2b (2; limited success) Hematopoietic stem cell transplantation (2)
*Local lidocaine injections are safe; although no large case series exist, systemic anesthetics that have been safely administered to patients with mastocytosis include fentanyl, midazolam, propofol, sufentanil, remifentanil, ketamine, desflurane, sevoflurane, cisatracurium, pancuronium, and vecuronium bromide.

Table 118.3 Therapeutic ladder for mastocytosis. Clinically relevant triggers for mast cell degranulation vary substantially among mastocytosis patients; avoidance of environmental and dietary exposures as well as medications should be approached on an individual basis, considering the patient's previous experiences[61]. Additional tyrosine kinase inhibitors under investigation for the treatment of systemic mastocytosis include repretinib and (for patients with non-codon 816 KIT mutations) masitinib. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

emergency use. In some instances, these patients may experience additional similar attacks within hours of the initial event; prednisone 20–40 mg/day for 2–4 days may suppress these recurrent reactions[36,44].

Omalizumab, a humanized murine monoclonal antibody to IgE approved for the treatment of asthma and chronic spontaneous urticaria, has been reported to control symptoms in patients with mastocytosis who are resistant to antihistamine therapy. In a series of 40 adults with cutaneous mastocytosis or ISM, omalizumab (150–300 mg every 2 weeks) induced a >50% reduction in mast cell mediator-related symptoms in 22 patients (55%), with a median time to response of 2 months[2]. In this and most other reports, omalizumab reduced symptoms, but not serum tryptase levels or skin lesions, in mastocytosis patients[2]. However, a 50%–90% reduction in maculopapular lesions was reported in two mastocytosis patients treated with omalizumab (300 mg monthly) for 5–7 months[3]. At present, omalizumab's mechanism of action in mastocytosis remains unclear[2,3].

Multitargeted **tyrosine kinase inhibitors** are capable of limiting proliferation and promoting apoptosis of D816V-expressing mast cells. Among such agents, midostaurin and avapritinib are FDA-approved for the treatment of aggressive SM (including ASM, SM-AHN, and MCL), with overall response rates of ≥60% and ≥75%, respectively, and a median survival of ~30–40 months for midostaurin in this patient group[6,67]. Imatinib mesylate is a tyrosine kinase inhibitor that blocks KIT and PDGF receptors, as well as the BCR-ABL oncoprotein associated with chronic myelogenous leukemia. However, the active site for imatinib within the KIT receptor is proximal to the location affected by the common codon 816 mutations (see Fig. 118.2). The resulting amino acid substitutions impede the binding of imatinib to KIT and thereby negate its potential therapeutic effect[5]. On the other hand, imatinib may alleviate the signs and symptoms of mastocytosis in patients with other *KIT* mutations (e.g. del419, K509I, F522C, V560G; see Fig. 118.2)[5,44,49,67] as well as in those with wild type *KIT* or a myeloproliferative disorder associated with the *FIP1L1–PDGFRA* fusion gene[68]. Other genes mutated in SM and their respective pathways may serve as potential therapeutic targets in the future.

Among chemotherapeutic agents, intravenous cladribine has the most evidence of efficacy in reducing skin lesions and BMMCs in patients with advanced SM, including those with the D816 *KIT* mutation[4,44]. However, a recent registry-based analysis found significantly longer overall and disease-free survival of patients with advanced SM treated with midostaurin compared to those who received cladribine[7]. For patients with SM-AHN, chemotherapy should be directed at the associated hematologic disorder[36,44].

Local radiation therapy with ~20–40 Gy over a 7- to 14-day period may benefit patients with pain due to bone involvement[69]. Splenectomy can be helpful in mastocytosis patients with hypersplenism who experience significant cytopenias and may improve survival in patients with aggressive disease[44,70]. Interferon α-2b has been used with limited success in patients with aggressive forms of mastocytosis[71], and non-myeloablative allogeneic hematopoietic stem cell transplantation has been performed with variable benefit in patients with life-threatening SM[72].

119 B Cell Lymphomas of the Skin

Lorenzo Cerroni and Isabella Fried

Synonyms: ■ Cutaneous B cell lymphomas ■ *S*kin-*a*ssociated *l*ymphoid *t*issue (SALT)-related B cell lymphomas

Key features

- Cutaneous B cell lymphomas represent a group of lymphomas whose primary site is the skin; they are derived from B lymphocytes in different stages of differentiation. The skin can also be the site of secondary involvement by extracutaneous (usually nodal) B cell lymphomas
- Most primary cutaneous B cell lymphomas (>80%) are low-grade malignancies, and they are characterized by indolent behavior and a good prognosis
- Precise classification can be achieved only after a complete synthesis of clinical, histopathologic, immunophenotypic, and molecular features. The WHO-EORTC and ICC classifications provide the basis for a consistent classification of patients
- Treatment options for low-grade types include primarily "watchful waiting", intralesional corticosteroids and local radiotherapy; when solitary lesions are present, surgical excision is an option. Systemic or intralesional anti-CD20 antibody may be used in some patients, while systemic chemotherapy is only required in patients with high-grade tumors

CLASSIFICATION OF B CELL LYMPHOMAS WITH PRIMARY CUTANEOUS MANIFESTATIONS	
WHO-EORTC 2018	**ICC 2022**
• Primary cutaneous follicle center lymphoma	• Primary cutaneous follicle center lymphoma
• Primary cutaneous marginal zone B cell lymphoma*	• Primary cutaneous marginal zone lymphoproliferative disorder
• Primary cutaneous diffuse large B cell lymphoma, leg type	• Primary cutaneous diffuse large B cell lymphoma, leg type
• Primary cutaneous diffuse large B cell lymphoma, other	• Diffuse large B cell lymphoma, NOS
• EBV^+ mucocutaneous ulcer (provisional)	• EBV^+ mucocutaneous ulcer
• Intravascular diffuse large B cell lymphoma	• Intravascular diffuse large B cell lymphoma
*Includes cases previously designated as primary cutaneous immunocytoma and primary cutaneous plasmacytoma.	

Table 119.1 Classification of B cell lymphomas with primary cutaneous manifestations – WHO-EORTC 2018 and ICC 2022. EBV, Epstein–Barr virus; ICC, International Consensus Classification; NOS, not otherwise specified.

INTRODUCTION

Although B cell lymphomas represent the majority of non-Hodgkin lymphomas (NHLs) arising within *lymph nodes*, they represent a minority of the NHLs whose primary site is the *skin*. In the classification of cutaneous lymphomas published by the World Health Organization (WHO) and the European Organization for Research and Treatment of Cancer (EORTC) Cutaneous Lymphoma Project Group (Table 119.1), B cell lymphomas represented ~25% of all cutaneous lymphomas[1]. The WHO-EORTC classifications of 2005 and 2018 have been integrated with only minor changes into the International Consensus Classification (ICC) of Mature Lymphoid Neoplasms published in 2022 (see Table 119.1)[2,3].

Primary cutaneous lymphomas are defined as *malignant lymphomas confined to the skin at presentation after complete staging procedures*[1,4]. In general, most patients with primary cutaneous B cell lymphoma (pCBCL) are diagnosed by dermatologists, as extracutaneous symptoms and signs are observed only very rarely at the onset of the disease. Consequently, dermatologists should be conversant with the clinicopathologic features of this group of diseases, in order to be able to establish the diagnosis in its early stages. Additionally, as aggressive treatment modalities are needed only in selected cases, these patients should be managed primarily by dermatologists with special expertise in cutaneous lymphomas.

HISTORY

In the past, cutaneous B cell lymphomas were thought to be invariably secondary, that is, due to dissemination of extracutaneous (usually nodal) B cell lymphomas to the skin. In the 1980s, it was recognized that B cell lymphomas whose primary site is the skin, i.e. pCBCLs, represent a distinct group of extranodal lymphomas[4]. The widespread use of immunohistochemical and molecular genetic techniques that can establish clonality, in particular the detection of rearrangements of immunoglobulin genes by PCR (utilizing routine biopsy samples), has shown that some of the cases previously classified as cutaneous B cell pseudolymphomas harbor a monoclonal population of lymphocytes, thus representing low-grade malignant B cell lymphomas of the skin[4,5].

EPIDEMIOLOGY

For the past several decades, the incidence of pCBCL had been rising, but now appears to have stabilized[6]. pCBCLs may occur more frequently in specific regions of the world. For example, analysis of data from four academic centers in the US showed that they represented only 4.5% of all the cases of primary cutaneous lymphoma registered in those centers[7]. In contrast, pCBCL represented ~25% of all the cases of primary cutaneous lymphoma in the Dutch and Austrian registries for cutaneous lymphomas[1].

Regional variations have also been observed with regard to the incidence of specific types of pCBCL. In the two largest series published to date, the relative frequencies of follicle center lymphoma and marginal zone lymphoma varied considerably. Follicle center lymphoma represented 71% of all pCBCLs in the Netherlands, but only 41% in Graz; conversely, marginal zone lymphoproliferative disorder (at that time classified as lymphoma) represented 42% of all cases of pCBCL in Graz, but only 10% in the Netherlands. On the other hand, the relative frequency of the third most common type of pCBCL, the diffuse large B cell lymphoma, leg type, was similar in the two series (~15%), indicating that, in these two series, differences in the relative frequencies were confined to B cell lymphomas characterized by an indolent behavior. This suggests that these variations may be due, at least in part, to a different classification of patients in different centers.

In addition to differences in diagnostic and classification standards, true regional variations in the incidence of special types of pCBCL may be due to the presence of different etiologic factors. For example, the association between pCBCL and infection with specific *Borrelia* subspecies in endemic areas has been known for many years (see below and Ch. 74). This association may explain, in part, regional differences in the incidence of pCBCLs, but the relatively low percentage of such cases (even in countries with endemic *Borrelia* infections) suggests that other etiologies are also involved in regional variations.

pCBCL affects adults of both sexes. With the exception of precursor B lymphoblastic lymphoma/leukemia (which only rarely represents an example of true pCBCL), CBCLs are uncommon in children and adolescents.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of pCBCL is unknown. In contrast to the many nodal B cell lymphomas that have been linked to specific genetic alterations (e.g. nodal follicular lymphomas and interchromosomal 14;18 translocations), there are relatively limited data on the specific genetic features of pCBCLs, especially for low-grade subtypes (for details see below).

Some similarities to the clinicopathologic features observed in B cell lymphomas arising in the gastric mucosa (so-called *mucosa-associated lymphoid tissue* [MALT] lymphomas) led to the hypothesis that pCBCLs are caused by longstanding antigenic stimulation, possibly due to chronic infection with specific microorganisms. In fact, it has been long established that MALT lymphomas originating in the stomach are linked to chronic antigenic stimulation due to infection with *Helicobacter pylori*. As previously mentioned, *Borrelia* spp. are thought to play an etiologic role in a minority of cases of pCBCL, particularly in Europe. In patients from a region in Austria with endemic *Borrelia* infections, specific DNA sequences of *Borrelia* were detected in 18% of all cases of pCBCL[8]; similar findings have been reported from Scotland[9].

At present, no other microorganism has been convincingly linked to the development of pCBCL. However, it should be noted that pCBCLs have been described in immunosuppressed patients, including those with AIDS and solid organ transplant recipients, and reversible pCBCLs have been observed in patients undergoing therapy with methotrexate (in particular those with rheumatoid arthritis), thus suggesting that immune dysregulation may play a role in the development of this disease[10–12].

CLINICAL FEATURES

In the WHO-EORTC 2018 and ICC 2022 classification schemes, pCBCLs have been divided into five major types (see Table 119.1)[1,3]. Follicle center lymphoma and marginal zone B cell lymphoproliferative disorder are characterized by an indolent clinical behavior, whereas diffuse large B cell lymphoma, leg type, and intravascular diffuse large B cell lymphoma have an aggressive clinical behavior. A further type, Epstein–Barr virus (EBV)-positive mucocutaneous ulcer, is characterized by an indolent behavior. It must be emphasized that, in addition to pCBCLs, the skin can be a site of secondary involvement for practically all types of extracutaneous (usually nodal) B cell lymphomas and leukemias. Complete staging should be performed in all patients with a confirmed diagnosis of high-grade B cell lymphoma involving the skin. This includes a complete blood examination, flow cytometry of peripheral blood, CT examination of the chest, abdomen and pelvis, and, if possible, positron emission tomography (PET)[13]. On the other hand, cutaneous low-grade B cell lymphomas without extracutaneous symptoms are only rarely upstaged by CT of the chest, abdomen and pelvis, functional imaging (PET-CT scan), or bone marrow biopsy[13]. Thus, extensive radiologic imaging and bone marrow biopsy is viewed as superfluous in the staging and follow-up of patients with indolent types of pCBCL confined to the skin[13,14]. A recommended staging evaluation for patients with CBCL is summarized in Table 119.2.

Primary Cutaneous Follicle Center Lymphoma

*P*rimary *c*utaneous *f*ollicle *c*enter *l*ymphoma (PCFCL) is defined as a neoplastic proliferation of germinal center cells confined to the skin. It represents a common subtype of pCBCL.

Clinically, patients present with solitary or grouped, pink- to plum-colored papules, plaques or tumors, which, especially on the trunk, can be surrounded by patches of erythema (Fig. 119.1 & 119.2)[15]. The term *Crosti's lymphoma* has been used to denote those patients with a peripheral patch of erythema. Ulceration is uncommon. Occasionally patients present with miliary and/or agminated small papules that can have an acneiform appearance[16]. Preferential locations are the scalp and forehead or the back. The skin lesions are usually asymptomatic, and, as a rule, B symptoms (i.e. fever, night sweats, weight loss) are rare. The serum level of lactate dehydrogenase (LDH), which is a powerful prognostic factor in systemic lymphomas, is within normal limits.

The prognosis is favorable[1,17]. Recurrences are observed in up to 50% of patients, but dissemination to lymph nodes or internal organs is rare.

RECOMMENDED STAGING INVESTIGATIONS FOR PATIENTS WITH A CONFIRMED DIAGNOSIS OF B CELL LYMPHOMA INVOLVING THE SKIN

Type of cutaneous lymphoma	Low-grade (without extracutaneous symptoms)	High-grade
History and physical examination		
• Presence/absence of "B" symptoms, including fever, night sweats, weight loss, malaise	√	√
• Complete lymph node examination	√	√
• Palpation of abdomen for hepatosplenomegaly	√	√
• Examination of oral cavity	√	√
• History of organ transplantation and/or other immune suppression (e.g. HIV, iatrogenic, congenital)	√	√
Laboratory studies		
• Complete blood count with differential and platelet count	√	√
• Comprehensive serum chemistries including LDH	√	√
• Flow cytometry of peripheral blood mononuclear cells	√ (optional)	√
Imaging studies		
• Ultrasound of abdomen and superficial lymph nodes as screening prior to PET-CT or CT scan	√	√
• Whole-body PET-CT scan or CT scan if PET-CT not available	√*	√
Additional studies as clinically indicated		
• Bone marrow biopsy	√*,†	√
• Excisional biopsy of enlarged lymph nodes or other suspicious lesions	√*	√
• PCR analysis for *Borrelia* spp. DNA in patients from endemic areas (Europe) or travelers to endemic areas	√	√

*Only if suspicion for extracutaneous lymphoma.
†In the US, often replaced by flow cytometry plus PET-CT.

Table 119.2 Recommended staging investigations for patients with a confirmed diagnosis of B cell lymphoma involving the skin. CT, computed tomography; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; PCR, polymerase chain reaction; PET, positron emission tomography.

Fig. 119.1 Cutaneous follicle center lymphoma. Prominent pale pink nodule of the lateral eyebrow. The nodule is accompanied by infiltrated darker pink plaques on the forehead.

Fig. 119.2 Cutaneous follicle center lymphoma. Large nodule on the upper back. Note the surrounding erythematous papules, patches, and plaques (Crosti's lymphoma).

Fig. 119.3 Cutaneous marginal zone B cell lymphoproliferative disorder. Well-circumscribed, erythematous nodule on the back that was firm to palpation (inset).

Primary Cutaneous Marginal Zone B Cell Lymphoproliferative Disorder

*P*rimary *c*utaneous *m*arginal *z*one B cell *l*ymphoproliferative *d*isorder (PCMZLD) has been recognized as a distinct variant of low-grade malignant pCBCL[5,18]. In the ICC classification of 2022 it is no longer grouped with other marginal zone lymphomas of mucosa-associated lymphoid tissue, and it has been downgraded to a lymphoproliferative disorder rather than a true lymphoma[3]. It is still listed as a lymphoma in the 5th edition of the WHO classification[18a]. Of note, cases classified in the past as *primary cutaneous immunocytoma* or *primary cutaneous plasmacytoma* represent examples of PCMZLD with prominent lymphoplasmacytic or plasmacytic differentiation, respectively, and the terms cutaneous immunocytoma and cutaneous plasmacytoma are not used in the WHO-EORTC and ICC 2022 classification schemes[1–3].

Clinically, patients present with recurrent pink–violet to red–brown papules, plaques, and nodules that favor the extremities (upper > lower) or trunk (Fig. 119.3 & 119.4). Generalized lesions can be observed in a small number of patients. Ulceration rarely occurs and skin lesions are usually asymptomatic. As a rule, B symptoms (i.e. fever, night sweats, weight loss) are not present. The serum level of LDH is within normal limits. In some instances, resolution of lesions may be accompanied by secondary anetoderma due to loss of elastic fibers in the area of the tumor infiltrate.

The prognosis of PCMZLD is excellent. In a study of 32 patients with PCMZLD, none of them developed lymph node or internal involvement during a mean follow-up of more than 4 years[5].

Of note, PCMZLD can arise in areas affected by acrodermatitis chronica atrophicans and it may be linked to infection by *Borrelia* spp. more frequently than are other types of pCBCL, particularly in Europe[8].

Fig. 119.4 Cutaneous marginal zone B cell lymphoproliferative disorder. Two thick pink–violet plaques on the foot, one of which has a flat surface. Molecular analysis revealed *Borrelia* DNA within the infiltrate. In the past, these tumors, which demonstrated prominent lymphoplasmacytic differentiation histologically, were classified as cutaneous immunocytomas.

Primary Cutaneous Diffuse Large B Cell Lymphoma, Leg Type

Primary cutaneous *d*iffuse *l*arge *B c*ell *l*ymphoma, *l*eg *t*ype (DLBCLLT), represents a form of pCBCL that is characterized by a predominance of large round cells (centroblasts, immunoblasts) positive for Bcl-2, MUM-1 (*mu*ltiple *m*yeloma oncogene *1* or interferon regulatory factor 4 [expressed by post germinal center B cells and plasma cells]), and FOX-P1[1]. It occurs almost exclusively in elderly patients, predominantly women.

Clinically, patients present with solitary or clustered, erythematous to red–brown nodules, located primarily on the distal aspect of one leg (Fig. 119.5). In some patients, lesions may arise on both lower extremities contemporaneously or within a short interval of time. Ulceration may also occur. Small erythematous papules can be seen adjacent to larger nodules. It must be emphasized that in ~20% of patients, tumors with similar morphologic and phenotypic features can arise in areas other than the lower extremities, but the designation DLBCLLT is still applied[19].

The prognosis of DLBCLLT is less favorable than that of other types of pCBCL, with an estimated disease-specific 5-year survival rate of 50%–60%[1].

It must be stressed that some patients with *nodal* large B cell lymphoma can present with secondary cutaneous lesions located exclusively on the legs, underlying the need for complete staging investigations before a diagnosis of DLBCLLT can be established. PET scans are superior to CT studies for discovering evidence of systemic disease.

Intravascular Diffuse Large B Cell Lymphoma

*Intrav*ascular *d*iffuse *l*arge *B c*ell *l*ymphoma (IVDLBCL) is a rare malignant proliferation of large B lymphocytes within blood vessels[4]. Most patients have a B cell phenotype, but a T cell variant has been reported. In occasional patients, the skin may be the only affected site, although more often there is systemic involvement (including the CNS) from the onset. Clinically, patients present with indurated, erythematous or violaceous patches and plaques, preferentially located on the trunk and thighs and often with prominent telangiectasias. The clinical appearance is not typical of cutaneous lymphoma, and it may sometimes suggest a diagnosis of panniculitis or vascular tumors. Interestingly, in several patients, IVDLBCL was observed to be confined to cherry angioma lesions. The prognosis of IVDLBCL is poor, and the disease usually runs an aggressive course[20].

Fig. 119.5 Cutaneous diffuse large B cell lymphoma, leg type. On both lower legs, multiple violet–brown nodules as well as a large flat tumor.

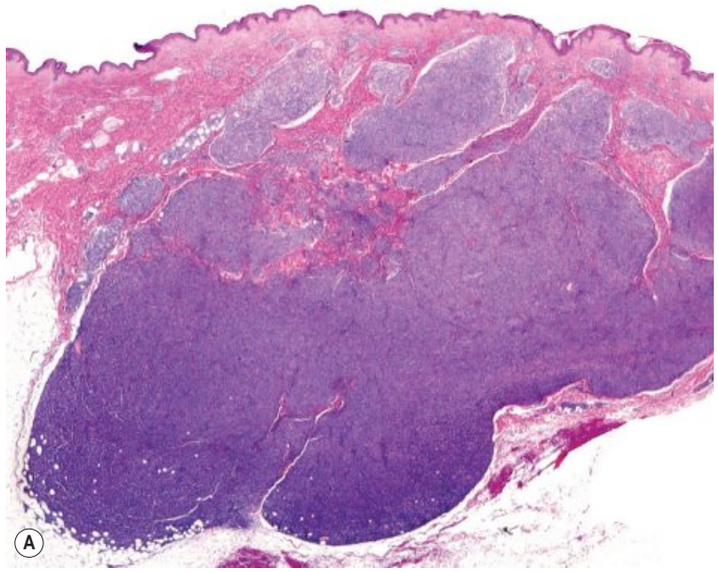
Precursor B Lymphoblastic Lymphoma/Leukemia

B cell lymphoblastic lymphomas/leukemias are malignant proliferations of precursor B lymphocytes. Reports of patients whose primary site is the skin have been rare. It should be emphasized, however, that all patients should be assumed to have, and treated for, systemic disease, even in the absence of documented systemic involvement at the time of presentation.

In contrast to the other cutaneous B cell lymphomas, this disease shows a clear-cut predilection for children and young adults[21]. Clinically, patients present with solitary large erythematous tumors, commonly located on the head and neck. Patients with primary skin disease often have asymptomatic lesions of a few weeks' duration. Those with secondary skin lesions may have systemic symptoms, e.g. weight loss, fever, fatigue, night sweats. The serum level of LDH is often elevated, reflecting the aggressive, and often systemic, nature of the disease. The disease is highly aggressive, and the prognosis of untreated patients is poor.

Other Cutaneous B Cell Lymphomas

Rare cases of pCBCL do not fit within the subtypes reviewed above. In the ICC 2022 classification, these patients are divided amongst several categories, including (but not limited to) large B cell lymphomas arising in the setting of immune suppression, plasmablastic lymphoma, and diffuse large B cell lymphoma, not otherwise specified (NOS)[2,3]. Plasmablastic lymphoma is a rare lymphoma that usually arises within the oral cavity in patients with severe immunosuppression, especially HIV-related[4], but can also be observed in immunocompetent patients. It is often associated with infection by EBV.



EBV-positive mucocutaneous ulcer is a low-grade B cell malignancy that usually arises within the context of immune senescence or in immunocompromised hosts. It most commonly presents as ulcers of the oral mucosa.

PATHOLOGY

In addition to routine histology and immunohistochemical phenotyping, which when combined are sufficient for the diagnosis of most cases of pCBCL, molecular investigations are becoming increasingly important for precise stratification of patients with aggressive B cell lymphomas.

Primary Cutaneous Follicle Center Lymphoma

In PCFCL, nodular or diffuse infiltrates are seen within the entire dermis, often extending into the subcutaneous fat (Fig. 119.6A)[4]. The epidermis is usually spared. A clear-cut follicular pattern with formation of neoplastic germinal centers was observed in only a minority of cases (25%) in the series from Graz (Fig. 119.7)[17]. However, a higher percentage of cases may show at least some follicular architecture. In those with a follicular pattern, the neoplastic follicles show morphologic features of malignancy, including the presence of a reduced or absent mantle zone, the lack of tingible body macrophages, and a monomorphism of the follicles – so-called "dark" and "clear" areas are no longer recognizable (see Fig. 119.7 [inset])[17].

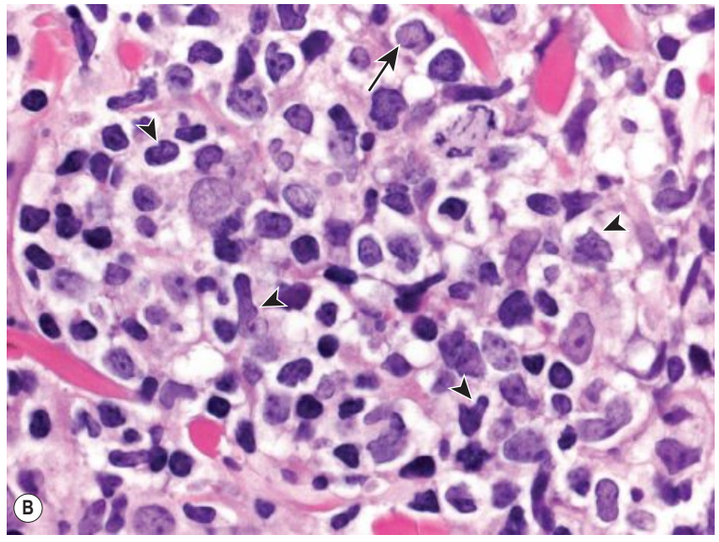


Fig. 119.6 Cutaneous follicle center lymphoma, diffuse type. A Diffuse infiltrate *without* a follicular pattern. **B** Centroblasts (arrow) and medium- and large-sized centrocytes (cleaved cells; arrowheads) predominate.

In both the follicular and diffuse variants, centrocytes (small to large, cleaved follicle center cells) predominate within the neoplastic infiltrate (Fig. 119.6B) and are admixed with a variable number of centroblasts (large, non-cleaved follicle center cells with prominent nucleoli), immunoblasts, small lymphocytes, histiocytes, and, in some cases, eosinophils and plasma cells. In contrast to nodal FCLs, grading is not used for the classification of PCFCL. On a cytomorphologic basis, some cases of PCFCL with a diffuse pattern of growth and a predominance of large centrocytes have the appearance of a large cell lymphoma, but the prognosis of these cases is similar to that of lesions without the large cell morphology[1,19]. Patients with a monotonous proliferation of centroblasts and/or immunoblasts should be classified as having diffuse large B cell lymphoma. An accompanying infiltrate of small T lymphocytes and histiocytes/macrophages is usually present, and, in some instances, these cells can be predominant. In rare cases, a population of monoclonal

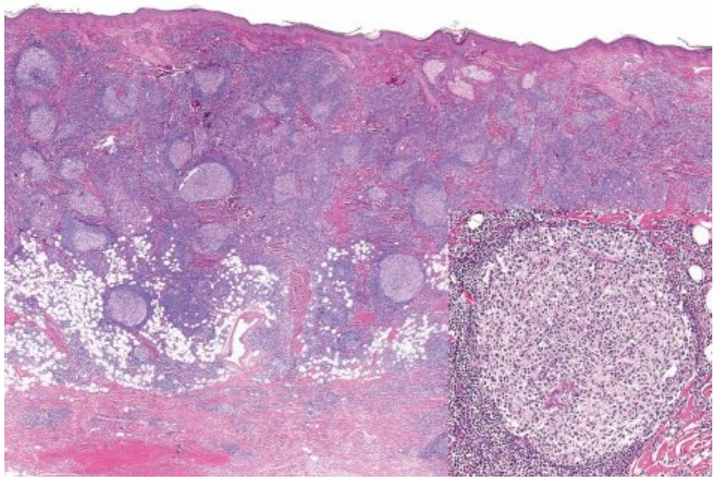

Fig. 119.7 Cutaneous follicle center lymphoma, follicular type. Neoplastic follicles with a monomorphous morphology (lack of polarization) within the entire dermis and superficial subcutis. Note the absence of dark and clear areas within the central portion of the follicle (inset).

plasma cells belonging to the neoplastic clone can be observed, representing a pitfall in the differential diagnosis with PCMZLD[21a,21b].

In addition to cases characterized by numerous large cells, morphologic variants of PCFCL include those with a predominant spindle cell morphology, which can simulate sarcomas or other spindle cell tumors histopathologically, thus representing a diagnostic pitfall[22]. Lesions in which a few B cell blasts are admixed with numerous T lymphocytes have been classified as "T cell/histiocyte-rich B cell lymphomas", and in the skin probably represent another rare morphologic variant of PCFCL[4]. Of note, when there is nodal involvement with this latter morphologic variant, it is classified as a large B cell lymphoma.

The tumor cells express B cell-associated antigens (CD20, CD79a, PAX-5); they are $CD5^-$ and $CD43^-$ (see Table 0.13 for the specificities of CD markers). When follicles are present, they are characterized by an irregular network of $CD21^+$ follicular dendritic cells. Bcl-6 (a marker of germinal center cells and other lymphoid cells) is positive in virtually all cases, irrespective of the pattern of growth. In most cases with a follicular growth pattern, and in a minority of those with a diffuse growth pattern, neoplastic cells also stain positively for CD10. The presence of small clusters of $Bcl\text{-}6^+$ cells outside the follicles is considered strongly suggestive of a diagnosis of PCFCL[16]. Of note, Bcl-6 is also expressed by a subset of T lymphocytes (follicular T helper lymphocytes), but these cells are never arranged within clusters in cases of PCFCL.

In the vast majority of cases, staining for the protein product of *BCL-2* (Bcl-2) yields negative results within neoplastic follicles, representing a major difference from follicular lymphomas arising within lymph nodes[23]. Positivity for Bcl-2 by >75% neoplastic lymphocytes has been related to a higher rate of cutaneous recurrence[23a]. A useful, though somewhat counterintuitive, distinguishing immunohistochemical feature is the *lower* degree of proliferative activity within *malignant* follicles as detected by the anti-Ki-67 antibody (expressed by proliferating cells), in contrast to the *strong* Ki-67-positivity in *reactive* follicles[17]. In cases with large cell morphology (predominance of large cleaved cells), immunohistochemical staining for MUM-1 is either negative or is positive in a minority of neoplastic cells (in contrast to strong expression of MUM-1 by DLBCLLT; see below)[1,19]. The interchromosomal 14;18 translocation, typically found in *nodal* follicular lymphomas, is present in a minority of PCFCLs[23]. Therefore, the presence of the 14;18 translocation and/or expression of Bcl-2 should raise suspicion that the patient has a systemic lymphoma involving the skin. Analysis of the genes that encode the joining segment (J_H) and other regions of the immunoglobulin heavy chain (IGH) reveals the presence of a monoclonal rearrangement in the majority of patients (60%–70%). When gene expression in PCFCLs was analyzed via cDNA microarrays, a *germinal center cell signature pattern* was observed.

Analysis of morphologic, immunohistochemical, and molecular data suggests that follicular lymphomas originating in the lymph nodes and the skin, although characterized by a similar morphologic pattern, have different pathogenic mechanisms.

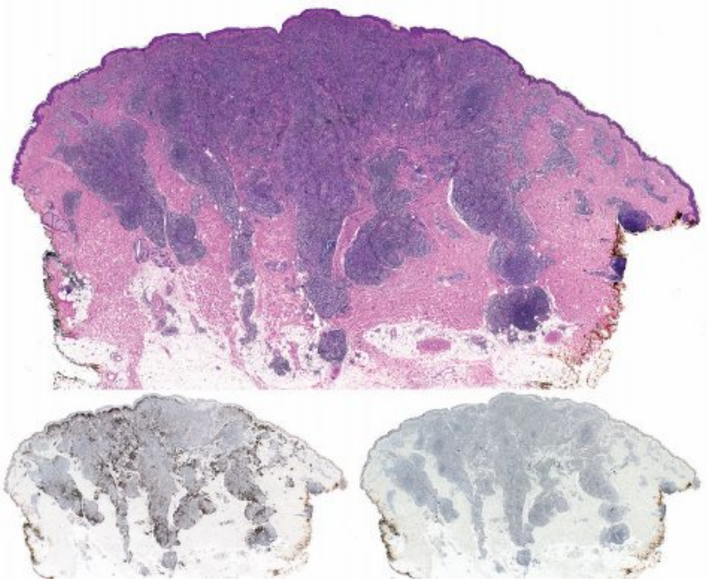

Fig. 119.8 Cutaneous marginal zone B cell lymphoproliferative disorder. Nodular lymphoid infiltrate within the entire dermis. Monotypic expression of kappa immunoglobulin light chain (left inset) with negativity for lambda light chain (right inset).

Primary Cutaneous Marginal Zone B Cell Lymphoproliferative Disorder

Histology of PCMZLD shows a patchy, nodular, or diffuse infiltrate involving the dermis and subcutaneous fat. The epidermis is spared. A characteristic pattern can be observed at scanning magnification (Fig. 119.8): nodular infiltrates (sometimes containing reactive germinal centers) are surrounded by a pale-staining population of small- to medium-sized cells with indented nuclei, inconspicuous nucleoli, and abundant pale cytoplasm – variously described as marginal zone cells, centrocyte-like cells, or monocytoid B cells (Fig. 119.9A)[4,5]. In addition, plasma cells (at the margins of the infiltrate), lymphoplasmacytoid cells, small lymphocytes, and occasional large blasts are observed. Eosinophils are also a common finding. In some patients, there may be a granulomatous reaction with epithelioid and giant cells. Cases with a predominance of lymphoplasmacytoid lymphocytes were once classified as cutaneous immunocytomas, but are now considered variants of PCMZLD. PAS-positive intranuclear inclusions (Dutcher bodies) are sometimes observed and represent a valuable clue to the diagnosis (Fig. 119.9B). Occasionally, the predominant cell type is a plasma cell (Fig. 119.9C), and although such cases used to be classified as primary cutaneous plasmacytomas, they are now also considered to be variants of PCMZLD[1]. Finally, rare cases are characterized by the predominance of large blastoid cells resembling plasmablasts (Fig. 119.9D)[24]. Solitary cutaneous nodular amyloidosis (cutaneous amyloidoma) harboring a small monoclonal population of plasma cells may represent a peculiar, rare variant of PCMZLD[25].

The centrocyte-like cells stain positively for CD20, CD79a, Fc receptor-like 4 (FCRL4/IRTA1)[26], and Bcl-2; they are negative for CD5, CD10, and Bcl-6. In the overwhelming majority of cases, intracytoplasmic monotypic expression of immunoglobulin light chains (either κ or λ, but not both) can be observed (see Fig. 119.8; Fig. 119.10). The monoclonal population of B lymphocytes is often characteristically arranged at the periphery of the cellular aggregates. Staining for proliferation markers also shows increased positivity at the periphery of the nodules (as well as in reactive germinal centers). IgG4 expression is observed in less than half of cases with plasmacytic differentiation but is not associated with systemic IgG4-related disease[27]. Monoclonal rearrangement of *IGH* can be detected in the majority of cases (60%–80%).

PCMZLDs express class-switched immunoglobulins, e.g. the same clone can switch from IgM to IgG or IgA[28]. Although the B lymphocyte changes antibody production from one class to another, the cell retains affinity for the same antigen. PCMZLD are also characterized

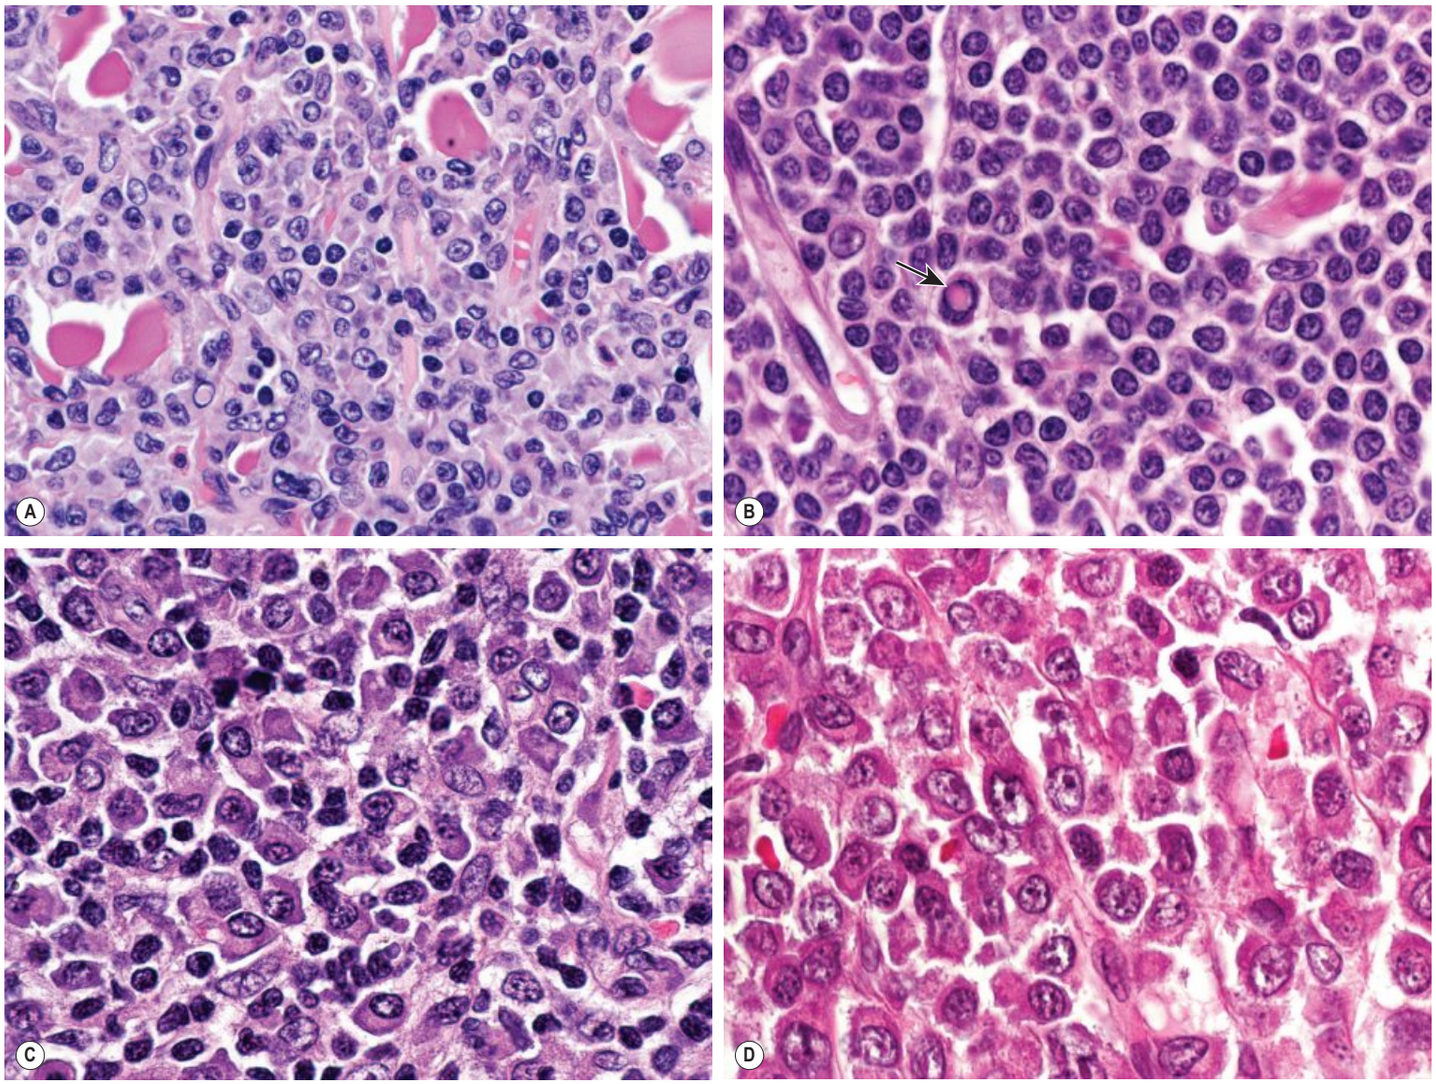

Fig. 119.9 Cutaneous marginal zone B cell lymphoproliferative disorder – spectrum of cell types. A Admixture of marginal zone cells, plasmacytoid cells, and plasma cells. **B** Predominance of lymphoplasmacytoid cells (formerly classified as cutaneous immunocytoma; note an intranuclear eosinophilic inclusion [Dutcher body, arrow]). **C** Predominance of plasma cells (formerly classified as cutaneous plasmacytoma). **D** Predominance of large blastoid cells similar to plasmablasts.

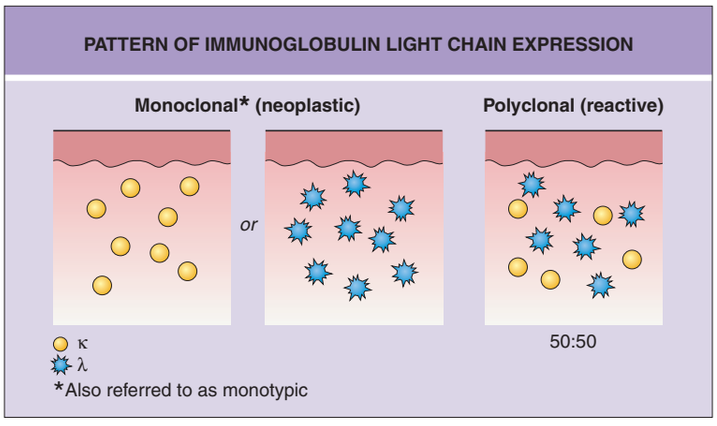

Fig. 119.10 Pattern of immunoglobulin light chain expression. Detection of monoclonal expression of immunoglobulin light chains (κ or λ) is a key diagnostic feature for primary cutaneous marginal zone B cell lymphoproliferative disorder. Monoclonality is defined as a >10/1 ratio.

by aberrant somatic hypermutations allowing binding to different antigens[29]. A minority of PCMZLD express IgM (non-switched cases), but this is associated with a higher frequency of extracutaneous dissemination.

A particular translocation, t(14;18)(q32;21), that involves *IGH* and *MALT1* has been detected in a subset of PCMZLD (~30%) as well as MALT lymphomas arising in organs other than the skin. In gene expression studies utilizing cDNA microarrays, PCMZLDs had a *plasma cell signature pattern*. Other genetic aberrations include trisomy 3 (with upregulation of *FOXP1*) and rarely an 11;18 or a 3;14 translocation[30]. However, in more than 50% of patients, no molecular abnormalities have been found.

Primary Cutaneous Diffuse Large B Cell Lymphoma, Leg Type

In DLBCLLT, a dense diffuse infiltrate is seen within the dermis and subcutis. The infiltrate usually involves the entire papillary dermis extending to the dermal–epidermal junction. Involvement of the epidermis by clusters of large atypical cells, simulating the Pautrier microabscesses found in cutaneous T cell lymphoma, can be observed in some cases (B cell epidermotropism), representing a potential diagnostic pitfall[4]. The neoplastic infiltrate consists predominantly of immunoblasts (large round cells with abundant cytoplasm and prominent nucleoli) and centroblasts (Fig. 119.11). Of note, cases of pCBCLs with a predominance of large cleaved cells (i.e. large centrocytes) are classified among the PCFCLs (see above)[1]. Reactive small lymphocytes are usually few in number, and mitoses are frequent. The common finding of immunoglobulin gene hypermutations is evidence that DLBCLLT is a large cell lymphoma, representing post germinal center lymphocytes that originated from lymphocytes of the germinal center.

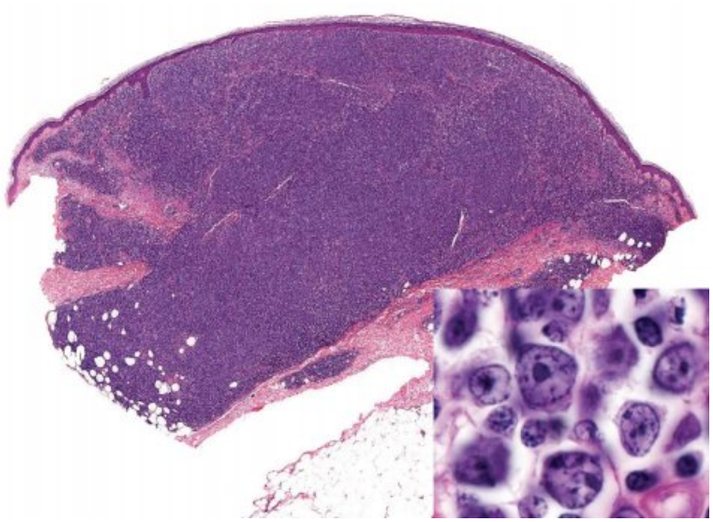

Fig. 119.11 Cutaneous diffuse large B cell lymphoma, leg type. Within the entire dermis, there is a dense, diffuse lymphoid infiltrate. Large cells with a round morphology (mainly immunoblasts) predominate (inset).

Neoplastic cells are positive for B cell markers (CD20, CD79a, PAX-5, IgM), but there can be (partial) loss of antigen expression. Bcl-2, MUM-1 (see above), FOX-P1, and MYC are expressed by neoplastic cells in most patients[1,19,31]. These markers are useful in the differential diagnosis of DLBCLLT from PCFCL, diffuse type; in the latter, Bcl-2, MUM-1, and FOX-P1 are usually either negative or expressed by a small minority of cells (Fig. 119.12). The tumors demonstrate monoclonal rearrangement of *IGH*. The interchromosomal 14;18 translocation is not present. An algorithmic approach to the diagnosis of cutaneous diffuse large B cell lymphomas is provided in Fig. 119.13. The differential expression of lymphoid markers in various types of diffuse large B cell lymphoma with cutaneous involvement is summarized in Table 119.3.

Rare cases of otherwise typical cutaneous DLBCLLT show expression of CD30 by neoplastic cells[19]. In nodal diffuse large B cell lymphomas, CD30 expression was associated with a better prognosis, but data on DLBCLLT are lacking. Hypermethylation of the genes that encode p15 and/or p16 (*CDKN2B*, *CDKN2A*), resulting in decreased expression of these proteins, has been observed in some patients. 9p21 deletions, possibly leading to loss-of-function of *CDKN2A*, are associated with a worse prognosis. A worse prognosis has also been noted in patients whose tumors have *MYD88* mutations.

In *nodal* diffuse large B cell lymphomas that have a rearrangement of *MYC* associated with additional rearrangements in *BCL-2* and/or *BCL-6* ("double-hit" or "triple-hit" lymphomas) have a worse prognosis. A poor prognosis is also associated with expression of the respective proteins as detected by immunohistochemistry ("double expression" or "triple expression" patterns). Data regarding primary cutaneous B cell lymphomas are still fragmentary, but it appears that *MYC* rearrangements are more common than in B cell lymphomas at extracutaneous sites, whereas double-hits are very rare and do not affect prognosis[32,33]. Expression of MYC, Bcl-2 and Bcl-6 is common in primary cutaneous lymphomas, but the prognostic value of "double expression", if any, is still unclear[32,33]. While the cut-off values for determining positivity of Bcl-2 and MYC expression within cells lack uniformity, currently accepted cut-off points are 50% for Bcl-2 and 40% for MYC.

Genetic data obtained by FISH or microarray chip technologies have confirmed that DLBCLLTs show clear molecular differences from PCFCL, diffuse type, confirming the need of classifying these cases separately[34]. The molecular profile of DLBCLLT is similar to that observed in diffuse large B cell lymphomas of the lymph nodes, with the *signature pattern of an activated B lymphocyte*[35].

Intravascular Diffuse Large B Cell Lymphoma

IVDLBCL is characterized by a proliferation of large atypical lymphocytes that fills dilated blood vessels within the dermis and subcutaneous tissues (Fig. 119.14). The malignant cells are large with scanty cytoplasm and often have prominent nucleoli. They are positive for B cell-associated markers as well as for Bcl-2, MUM-1, and FOX-P1. Staining with endothelial cell-related antibodies (e.g. CD31, CD34) highlights the characteristic intravascular location of the cells. Molecular analysis shows monoclonal rearrangement of *IGH*. The genetic profile is similar to that observed in diffuse large B cell lymphomas – activated B cell type.

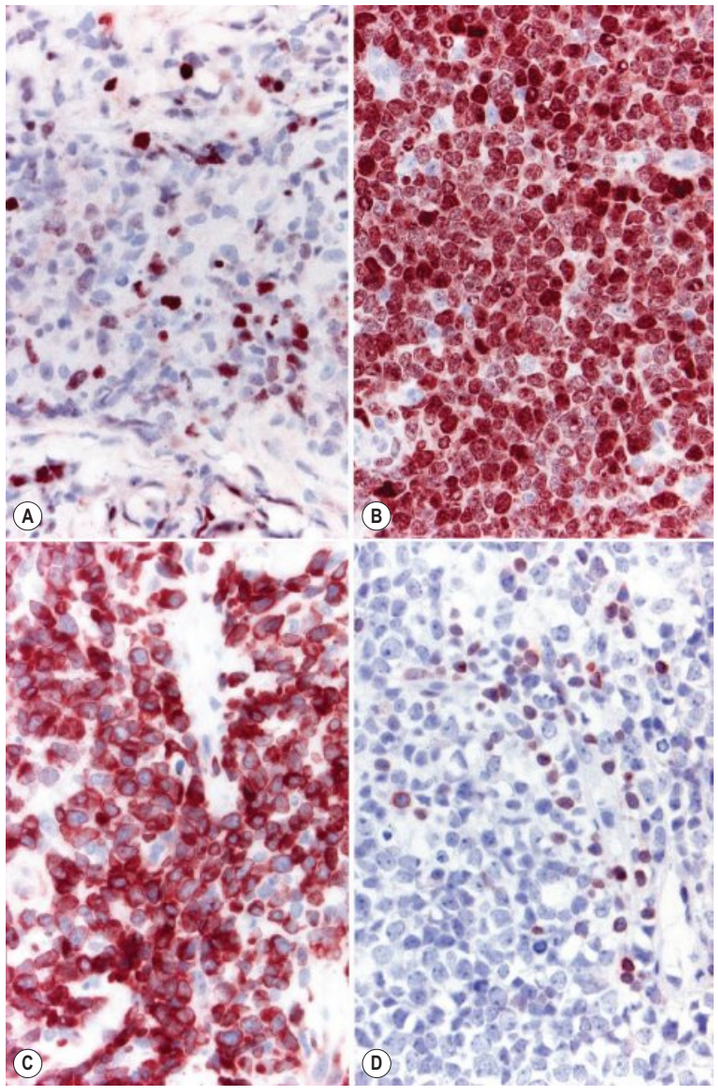

Fig. 119.12 Immunohistochemical staining with anti-Bcl-2 and anti-MUM-1 antibodies. Staining with anti-Bcl-2 antibody shows negativity (except for reactive small lymphocytes) in follicle center lymphoma, diffuse type (**A**) and positivity of most tumor cells in diffuse large B cell lymphoma, leg type (**B**). Anti-MUM-1 antibody stains virtually all the tumor cells in primary cutaneous diffuse large B cell lymphoma, leg type (**C**) while only a minority of cells are positive in primary cutaneous follicle center lymphoma, diffuse type (**D**).

Precursor B Lymphoblastic Lymphoma/Leukemia

Histologically, precursor B lymphoblastic lymphoma/leukemia shows a monomorphous proliferation of medium-sized cells with scanty cytoplasm and round or convoluted nuclei with fine chromatin (Fig. 119.15). A "starry sky" pattern is commonly seen at low power, due to the presence of macrophages with inclusion bodies ("tingible bodies"). Another characteristic feature is the arrangement of neoplastic cells in a "mosaic-stone" pattern. Mitoses and necrotic cells are abundant. It must be stressed that histologic features alone do not allow differentiation of lymphoblastic lymphomas of B cell phenotype from those of T cell lineage. Immunohistology demonstrates positive staining for TdT (terminal deoxynucleotidyl transferase; present on precursor

T and B cells), PAX-5, CD10, and the cytoplasmic μ-chain of immunoglobulins, and in most cases, CD20 and CD79a. CD20 is negative in the pre-pre-B cell variant, which is CD34$^+$. Molecular analyses usually show a monoclonal rearrangement of *IGH* and a polyclonal pattern for T cell receptor genes (*TCR*), but a lack of rearrangement of *IGH* or monoclonal rearrangement of both *TCR* and *IGH* may be observed.

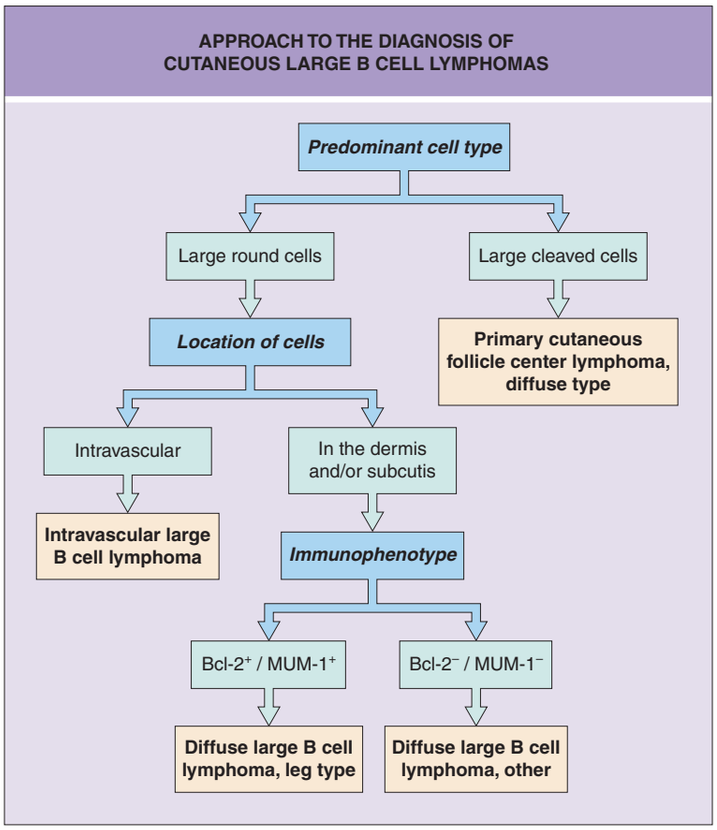

Fig. 119.13 Approach to the diagnosis of cutaneous large B cell lymphomas. In most patients with primary cutaneous diffuse large B cell lymphoma, leg type, the neoplastic cells strongly express MUM-1 and FOX-P1 (as well as Bcl-2), whereas in primary cutaneous follicle center lymphoma, diffuse type, these stains are usually either negative or expressed by a small minority of cells (see Fig. 119.12).

Other Cutaneous B Cell Lymphomas

EBV$^+$ mucocutaneous ulcer is characterized by the presence of atypical cells positive for CD30 and PAX5 within a polymorphous background, mimicking the features observed in Hodgkin lymphoma. EBV is detected within the atypical cells, but positivity is also observed in small lymphocytes, representing a clue for differentiation from true Hodgkin lymphoma (where EBV-positivity is limited to large, atypical cells)[36]. In addition, clinical features of the two entities are completely different.

Plasmablastic lymphoma is characterized by a proliferation of plasmablasts with large eccentric nuclei, abundant cytoplasm, and prominent nucleoli. While the tumor cells may appear lymphoid, they stain like plasma cells. They are positive for CD38, CD138 and MUM-1, but negative for CD20; they express monotypic immunoglobulin light chains. *In situ* hybridization for EBV (EBER-1) is positive in the vast majority of cases.

DIFFERENTIAL DIAGNOSIS

Although differential diagnoses of pCBCLs vary according to the type of lymphoma, in general they include inflammatory processes that may simulate malignant lymphomas clinically and/or histopathologically, referred to as cutaneous lymphoid hyperplasia, lymphocytoma cutis or "pseudolymphoma" (see Ch. 121). It must be emphasized that a definitive diagnosis of pCBCL can be reached only after careful examination of the clinical, histopathologic, immunophenotypic and molecular features; in some cases, only repeated examination of the patient and sequential biopsy specimens will allow the correct classification[4]. A schematic diagram with examples of the use of immunohistochemical stains and PCR in the differential diagnosis of pCBCLs is presented in Figure 119.16.

Patients for whom no definitive diagnosis can be established at the time of presentation should provisionally be classified as having "cutaneous atypical lymphoid proliferation of B cell lineage", and they should be re-examined at regular intervals[4]. A complete staging investigation does not belong in the diagnostic evaluation of these patients; that is, patients without a definitive diagnosis of CBCL should not be screened for extracutaneous disease until the diagnosis is established with certainty[4]. In contrast, once the diagnosis of CBCL has been established, complete staging is mandatory, as clinicopathologic features alone do not allow for the differentiation of primary from secondary cutaneous B cell lymphomas (see Table 119.2). A diagnostic algorithm for evaluation of patients at first presentation is provided in Figure 119.17.

In the following section, the major differential diagnoses of each of the main types of pCBCL are outlined separately, as they differ according to the lymphoma type.

IMMUNOHISTOCHEMICAL MARKER EXPRESSION IN PRIMARY AND SECONDARY CUTANEOUS LARGE B CELL LYMPHOMAS WITH OVERLAP IN ROUTINE HISTOPATHOLOGIC FINDINGS

	Immunohistochemical marker expression							
	Bcl-2	**Bcl-6**	**CD10**	**CD5**	**MUM-1**	**Cyclin D1**	**TdT**	**EBER-1**
Primary cutaneous lymphomas								
Follicle center lymphoma, diffuse	−	+	+/−	−	−	−	−	−
Marginal zone lymphoma, blastoid	+	−	−	−	−	−	−	−
Diffuse large B cell lymphoma, leg type	+	+/−	−	−	+	−	−	−
Systemic lymphomas with secondary skin involvement								
EBV$^+$ DLBCL	+/−	−/+	−/+	−	+	−	−	+
Nodal DLBCL	+	+/−	+/−	−/+	+/−	−	−	−
Mantle cell lymphoma, blastic	+	−/+	−	+	−/+	+	−	−
CLL/SLL → Richter syndrome	+/−	−	−	+	−	−	−	−
Burkitt lymphoma	−	+	+	−	−	−	−	+
B lymphoblastic lymphoma	+	−	+	−	−	−	+	−

+/−, majority of cases positive; −/+, majority of cases negative.

Table 119.3 Immunohistochemical marker expression in primary and secondary cutaneous large B cell lymphomas with overlap in routine histopathologic findings. As to be expected, there can be phenotypic overlap amongst these entities. All stain positively for CD20. The most helpful stains are shaded. CLL/SLL, B cell chronic lymphocytic leukemia/small lymphocytic lymphoma; DLBCL, diffuse large B cell lymphoma; EBV, Epstein–Barr virus.

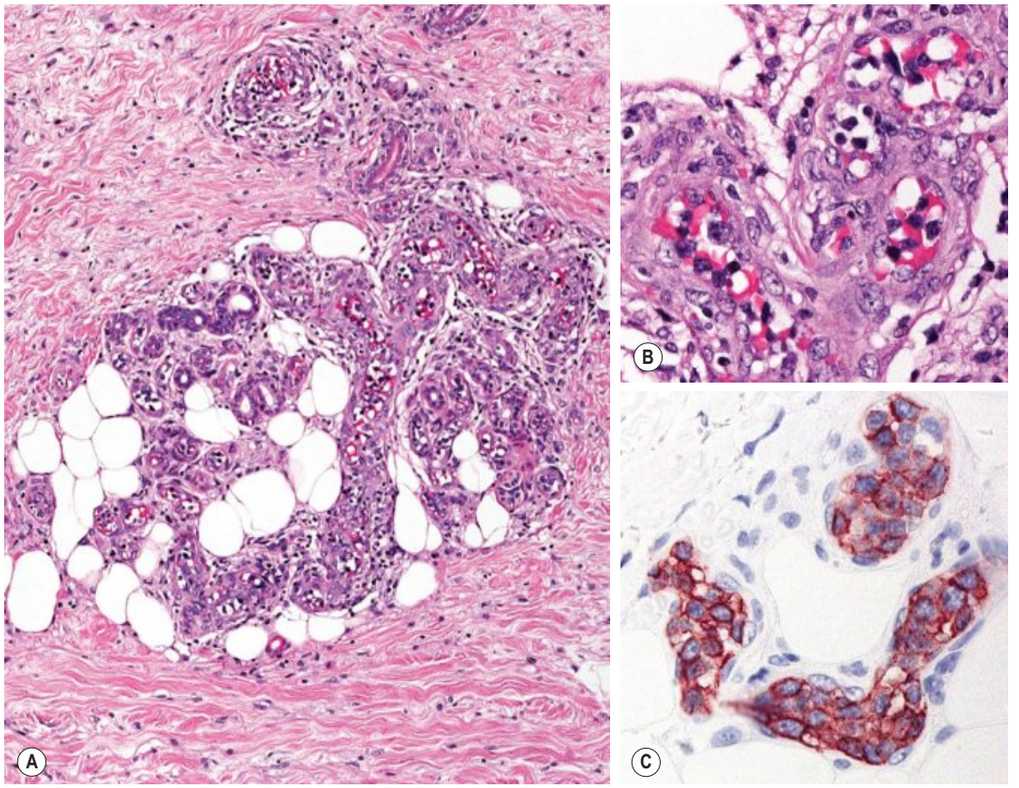

Fig. 119.14 Cutaneous diffuse intravascular large B cell lymphoma – histopathologic features. A Dermal cluster of several small blood vessels filled with large, atypical lymphocytes (**B**) which are positive for CD20 (**C**).

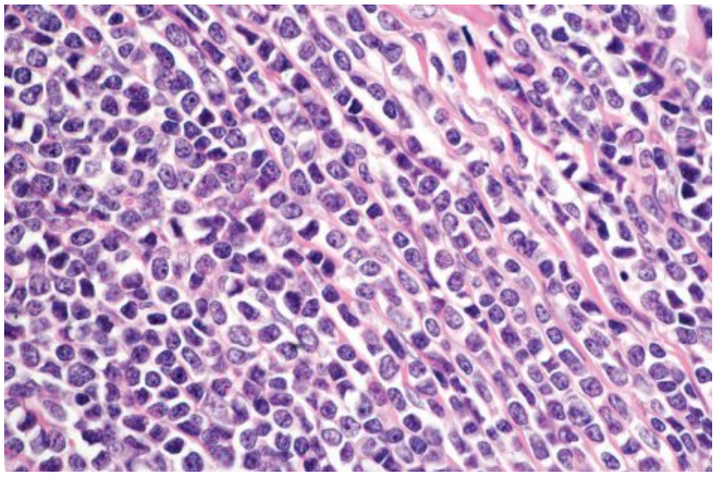

Fig. 119.15 Precursor B lymphoblastic lymphoma/leukemia. Medium-sized blasts with the characteristic "mosaic-stone" linear arrangement.

PCFCL with a follicular pattern of growth should be differentiated from B cell pseudolymphomas with prominent germinal centers, such as *Borrelia*-induced lymphocytoma cutis (cutaneous lymphoid hyperplasia)[17,37]. Lymphocytoma cutis can be triggered by a number of stimuli, including arthropod bites, vaccinations, tattoos and drugs, and it has a predilection for particular body sites such as the earlobes, nipples, and scrotum[37]. Clinically, lesions are usually solitary and relatively small. Although histologically a follicular pattern is almost always observed, germinal centers in lymphocytoma cutis are reactive, and they are accompanied by inflammatory infiltrates with small lymphocytes, plasma cells, and often eosinophils[4,37]. The germinal centers in *Borrelia*-induced lymphocytoma cutis are often devoid of a clear-cut mantle, but they are characterized by the presence of many tingible body macrophages, "clear" and "dark" areas, and a normal (high) proliferation rate[37].

Rare cases of cutaneous PCMZLD can have a prominent presence of reactive germinal centers, and they should be differentiated from the follicular type of PCFCL. In these cases, so-called follicular colonization by neoplastic marginal zone cells can indeed cause significant problems in histopathologic differential diagnosis, similar to what happens in B cell lymphomas of the MALT type. However, the overall architecture of the infiltrate, the presence of a population of monoclonal plasma cells belonging to the neoplastic clone, and the negativity of neoplastic cells for CD10 and Bcl-6 usually allow the diagnosis of cutaneous PCMZLD to be established.

As mentioned previously, secondary cutaneous involvement by primary extracutaneous follicular lymphomas has morphologic and phenotypic features similar or identical to those observed in primary cutaneous B cell lymphoma, except for the usual positivity of neoplastic cells for Bcl-2 in secondary cutaneous lesions. Consequently, the occurrence of a cutaneous follicular lymphoma with clear-cut positivity for Bcl-2 within neoplastic follicles should be considered as a hint (although exceptions can be encountered) for the diagnosis of secondary skin lesions of nodal lymphoma.

The differential diagnosis of **PCMZLD** consists primarily of reactive processes and other types of low-grade pCBCL. Benign, reactive processes do not have monotypic restriction of immunoglobulin light chain expression, in contrast to what is observed in the great majority of cases of PCMZLD. PCFCL, diffuse type, can be differentiated from PCMZLD by the architectural pattern and cytomorphology, with the former being characterized by a diffuse infiltrate of B lymphocytes with a predominance of centrocytes and centroblasts. Moreover, in contrast to PCMZLD, neoplastic cells in PCFCL express Bcl-6.

PCMZLD should also be distinguished from secondary cutaneous lesions of B cell chronic lymphocytic leukemia (B-CLL), a condition in which neoplastic B lymphocytes display positivity for CD20, CD23 and CD43, and usually for CD5. Helpful diagnostic features are: (1) the absence, in B-CLL, of plasma cells belonging to the neoplastic clone; and (2) the positivity for CD5 observed in most cases of cutaneous B-CLL, but practically never in PCMZLD. $CD20^+/CD5^+$ infiltrates are also seen in secondary skin involvement from mantle cell lymphoma, but in contrast to CLL, mantle cell lymphoma is usually positive for cyclin D1 and negative for CD23 (rare cases of mantle cell lymphoma that are negative for cyclin D1 are positive for SOX11).

PCMZLD with prominent plasma cell differentiation must be differentiated from reactive plasma cell proliferations and from inflammatory pseudotumors (plasma cell granulomas). In reactive conditions, plasma cells are not atypical, and they display a polyclonal pattern of immunoglobulin light chain expression. Besides inflammatory pseudotumors,

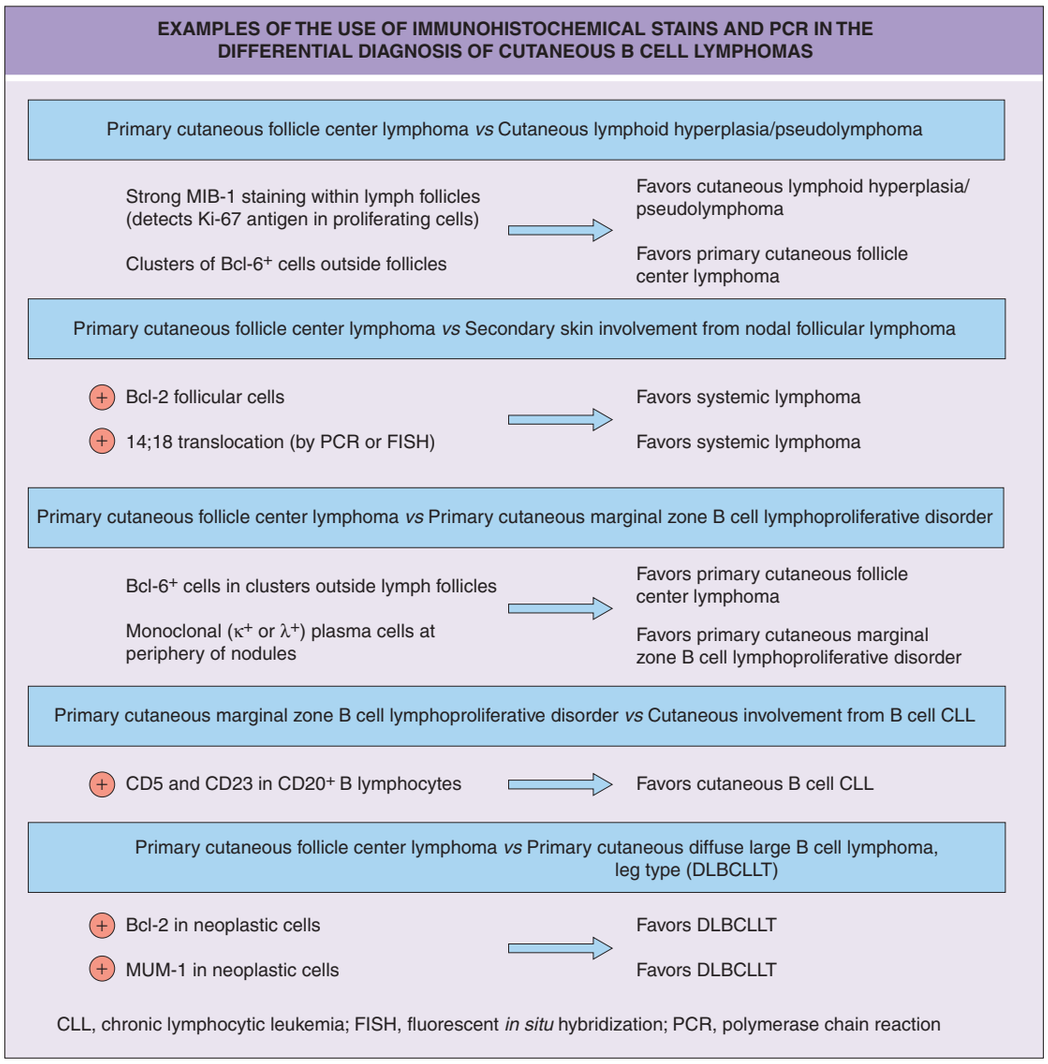

Fig. 119.16 Examples of the use of immunohistochemical stains and PCR in the differential diagnosis of cutaneous B cell lymphomas. This represents a simplification and is intended to assist dermatologists in their interpretation of pathology reports. $CD20^+/CD5^+$ infiltrates are also seen in secondary skin involvement from mantle cell lymphoma, but in contrast to CLL, mantle cell lymphoma is also positive for cyclin D1 and negative for CD23 (see Table 119.3).

reactive skin diseases with a predominance of plasma cells are very rare, with the exception of lesions arising on mucosal surfaces, spirochetal infections (e.g. syphilis, pinta, yaws, acrodermatitis chronica atrophicans), and cutaneous and systemic plasmacytosis. The latter disorder usually displays a polyclonal pattern of immunoglobulin light chain expression, but rarely monoclonality has been reported[38]. A silver stain (e.g. Warthin–Starry) or immunohistochemical staining for *Treponema pallidum* can help to highlight the microorganisms in cases of syphilis (see Fig. 0.33). The rare entity *pretibial lymphoplasmacytic plaque in children* is characterized by a polyclonal pattern of the plasma cells.

DLBCLLT must be differentiated from a number of entities, including cutaneous involvement from systemic lymphomas as well as specific infiltrates of acute myelogenous leukemia and non-lymphoid tumors (e.g. solid organ metastases; see Ch. 122). The clinicopathologic pattern together with phenotypic and molecular features allow correct classification of these lesions in most instances. In order to avoid diagnostic errors, detailed immunophenotyping is mandatory in all cases of cutaneous lymphoma, especially in those showing medium- to large-sized cell morphology.

The differential diagnosis of **IVDLBCL** is not a problem in typical cases. The large number of atypical cells within *blood vessels* is pathognomonic of this condition. Distinction between T and B cell types cannot be achieved on morphologic grounds alone. Rare cases of intralymphatic anaplastic large T cell lymphoma (ALCL) are characterized by a proliferation of neoplastic $CD30^+$ T cells within *lymphatic vessels*. This disorder represents a variant of ALCL and has similar phenotypic and prognostic features[39]. IVDLBCL should also be distinguished from reactive disorders characterized by an intravascular proliferation of atypical cells, in particular intralymphatic histiocytosis (IH) and benign intralymphatic proliferation of T cell lymphoid blasts (BIPTCLB). IH occurs in association with systemic disorders such as rheumatoid arthritis as well as metallic orthopedic implants. Within the dermis, *lymphatic vessels* that stain positively for podoplanin contain intraluminal collections of histiocytes ($CD68^+$, $CD20^-$, $CD3^-$). Of note, focal areas of IH can be an incidental finding. BIPTCLB is a rare entity observed in a wide range of cutaneous and extracutaneous disorders from pyogenic granuloma to appendicitis. As in IH, the *lymphatic vessels* are affected.

Cases of **precursor B lymphoblastic lymphoma/leukemia** should be differentiated from other cutaneous lymphomas/leukemias and from non-lymphoid tumors such as Ewing sarcoma, Merkel cell carcinoma, and small cell lung carcinoma. Positivity for TdT represents the most important immunohistochemical feature for the diagnosis of cutaneous lymphoblastic lymphoma. Histologic features of cutaneous lesions do not allow the differentiation of T cell from B cell lymphoblastic lymphomas, thus emphasizing the importance of complete immunophenotypic and genotypic analyses.

In immunosuppressed patients, the possibility of post-transplant lymphoproliferative disorder should be considered (Table 119.4).

TREATMENT

The most appropriate treatment modality for patients with a pCBCL is selected after exact classification of the lymphoma, analysis of results of staging investigations, and consideration of the overall condition of the patient[4]. Those patients with secondary cutaneous lesions of extracutaneous B cell lymphoma should be treated in a hemato-oncologic, not dermatologic, setting[4].

Before reviewing the major therapeutic strategies, it must be emphasized that many patients with low-grade pCBCL can be managed

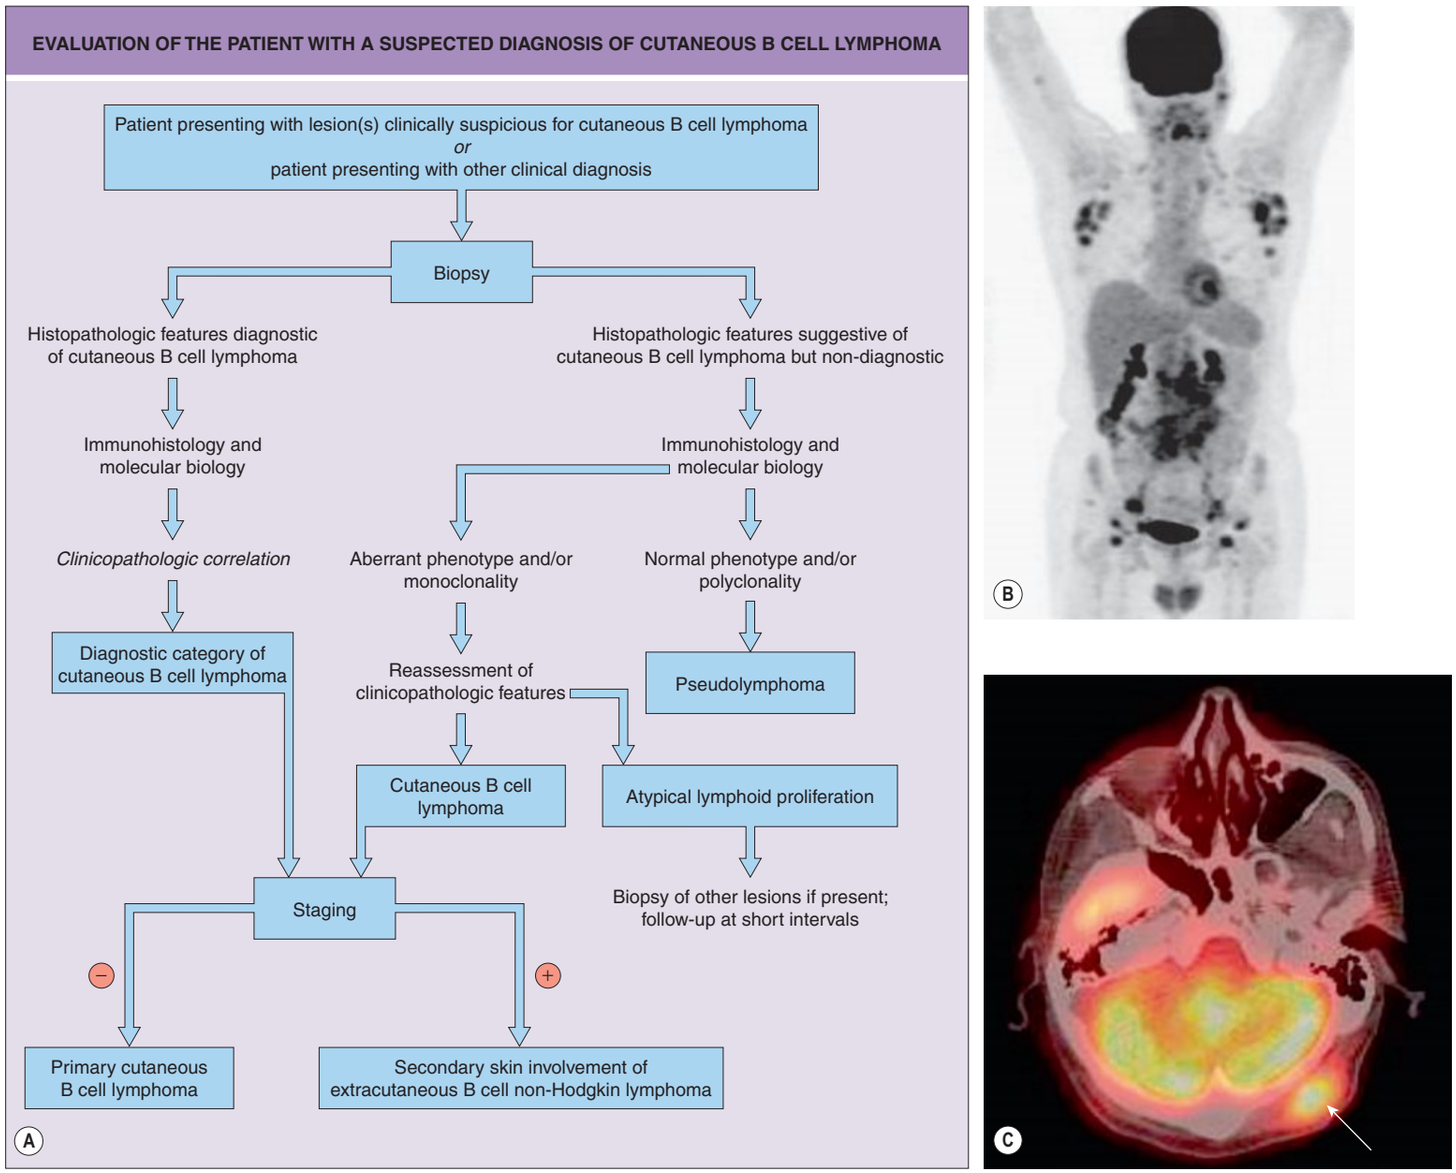

Fig. 119.17 Evaluation of the patient with a suspected diagnosis of cutaneous B cell lymphoma. A Algorithm outlining approach to the patient. **B, C** Positron emission tomography (PET) scans in a 66-year-old patient with stage IV B cell non-Hodgkin lymphoma. He had a 1-year history of a cutaneous nodule of the scalp that was originally diagnosed as an epidermoid inclusion cyst. Biopsy of the nodule showed a diffuse large B cell lymphoma ($CD10^+$, $CD20^+$, variably $Bcl\text{-}2^+$, $MUM\text{-}1^-$) and a PET-CT scan was performed for staging. There is evidence of widespread disease involving multiple lymph node basins in the dedicated (MIP) image (**B**) as well as a scalp lesion in a PET-CT fusion image (**C**; arrow). *B,C, Courtesy Dennis Cooper, MD.*

POST-TRANSPLANT LYMPHOPROLIFERATIVE DISORDERS
• Arise in the setting of immunosuppression
• Most commonly seen in solid organ transplant recipients, but can also affect other chronically immunosuppressed hosts (e.g. patient with rheumatoid arthritis receiving chronic methotrexate, HIV-positive patient)
• Patients most commonly present with extranodal disease, often involving the transplanted organ
• Other common sites of involvement include the GI tract and skin
• In the skin, polymorphic or monomorphic infiltrates are seen with the latter having similar clinicopathologic findings as conventional cutaneous B and NK/T cell lymphomas
• The abnormal lymphocytes are often EBV-positive, especially if B cells
• Initial therapeutic intervention is reduction of immunosuppression
• If persistent disease, appropriate treatment is administered depending on cell type

Table 119.4 Post-transplant lymphoproliferative disorders. EBV, Epstein–Barr virus; GI, gastrointestinal.

conservatively with a so-called watchful-waiting strategy, similar to what is often adopted for indolent B cell lymphomas and leukemias at extracutaneous sites[4,40]. Follow-up examinations in these patients should be performed at least every 6 months or at the onset of new lesions and/or new symptoms, in order to treat the patient as soon as it is necessary. Many patients managed conservatively with a watchful-waiting strategy experience a prolonged course and long survival, and they do not need aggressive treatment. For cosmesis and sometimes psychological benefit, intralesional triamcinolone can be injected into the papulonodules.

Most patients with pCBCLs that are low-grade (PCFCL, PCMZLD) and who have a solitary or few lesions can be treated by local radiotherapy, simple surgical excision, or surgical excision followed by radiotherapy of the surgical field[4,40]. It has been reported that recurrences are less frequently seen in patients treated by radiotherapy with wide margins (about 10–20 cm beyond clinically apparent lesions); this approach seems to be justified for so-called Crosti's lymphoma, a type of PCFCL arising on the back, in which erythematous nodules, papules, and patches surrounding the tumor represent specific infiltrates that can extend far beyond the main bulk of the lesion[41]. Radiotherapy with wide margins, however, does not seem to be justified for lesions other

than Crosti's lymphoma, as margins of about 3–5 cm usually suffice (depending on the size of the lesion). Surgical excision with narrow margins is a valuable therapeutic modality for patients with solitary well-circumscribed lesions and in the authors' opinion represents the treatment of choice for PCMZLD. In these patients, relapse rates do not seem to be higher than in patients treated with more time-intensive modalities such as local radiotherapy.

A few reports have appeared in which low-grade pCBCLs were treated with systemic antibiotics, achieving a complete resolution in at least a percentage of the patients[42]. This type of treatment is conceptually analogous to that adopted for *Helicobacter pylori*-associated MALT lymphomas of the stomach, which in their early stages can be cured by eradication of *H. pylori* infection. Complete response to antibiotic therapy has been observed in some patients with *Borrelia*-associated pCBCL. Although not yet corroborated by adequate data, antibiotic treatment of patients with pCBCLs should be considered before more aggressive therapeutic options are employed, particularly in European countries endemic for *Borrelia* infections. It is important to treat patients at the onset of the disease, because, in later stages, lesions may no longer be sensitive to systemic antibiotics. PCR analysis of *Borrelia* DNA is a rapid test that should be performed in all patients with pCBCL from European endemic areas, in order to identify those who would more likely benefit from early antibiotic treatment.

Another treatment modality for low-grade pCBCL is subcutaneous or intralesional interferon, particularly interferon-α-2a. Although some favorable results have been reported, it appears that treatment with interferon is associated with a complete response in about 50% of patients. Therapy with interferon (or intralesional triamcinolone) should be considered for patients presenting with multiple lesions at different body sites, such that local radiotherapy becomes difficult to administer.

Intralesional or systemic injection of anti-CD20 monoclonal antibody (rituximab) has been used to induce tumor reduction in patients with indolent pCBCLs[43,44]. Intralesional administration should be considered in patients presenting with a few, localized lesions. Therapy with intravenous rituximab represents a valid alternative to established treatments, especially in patients who present with disseminated skin lesions or relapse after radiotherapy. Rituximab can also be administered in combination with other treatment modalities for pCBCLs with more aggressive behavior (e.g. DLBCLLT). Additional monoclonal antibodies, bispecific T-cell engaging antibodies (e.g. mosunetuzumab), and small-molecule inhibitors (e.g. ibrutinib, lenalidomide) are also employed for aggressive B-cell lymphomas.

Patients with DLBCLLT and a limited number of patients with disseminated lesions of PCFCL, diffuse type, need more aggressive treatment modalities (e.g. systemic chemotherapy plus rituximab)[40,45]. The regimen used most frequently is cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) plus rituximab, and it represents the standard of care for DLBCLLT. In the absence of signs of transformation into high-grade lymphoma, aggressive treatment is not indicated in patients with PCMZLD. In the setting of significant comorbidities, rituximab alone or in combination with local radiotherapy may be administered. For relapsed DLBCLLT, CAR-T cell therapy is increasingly being used, especially when recurrence occurs within one year of primary therapy. In the setting of longer remissions, salvage chemotherapy followed by autologous HSCT is an option.

Systemic chemotherapy plus rituximab is the treatment of choice for patients with IVDLBCL, regardless of results of staging investigations. As with DLBCLLT, the addition of rituximab to anthracycline-based chemotherapy significantly improves outcome[45]. Finally, patients with precursor B lymphoblastic lymphoma/leukemia should be treated as B cell acute lymphoblastic leukemia by a hematologist.

PLASMA CELL DYSCRASIAS, INCLUDING MULTIPLE MYELOMA

A plasma cell dyscrasia represents a clonal proliferation of plasma cells and it can lead to a monoclonal gammopathy composed of intact immunoglobulins, isolated light chains (15% of patients) or, rarely, isolated heavy chains. The term plasma cell dyscrasia encompasses a number of entities, including monoclonal gammopathy of undetermined significance (MGUS; serum paraprotein <3 g/dl), smoldering/asymptomatic myeloma, and active/symptomatic myeloma, as well as light and heavy chain deposition diseases and systemic amyloidosis (AL). While proliferations of plasma cells within the skin are rare, an understanding of the spectrum and natural history of plasma cell dyscrasias is important for dermatologists given the number of cutaneous disorders associated with monoclonal gammopathies (Table 119.5; Fig. 119.18).

CUTANEOUS CONDITIONS ASSOCIATED WITH MONOCLONAL GAMMOPATHY
Proliferation of lymphoplasmacytic cells in the skin
• Extramedullary cutaneous plasmacytoma*
• Cutaneous Waldenström macroglobulinemia†
Deposition of the monoclonal protein in the skin, by definition
• Primary systemic amyloidosis (light chains)
• Cryoglobulinemic occlusive vasculopathy (type I cryoglobulins‡)
• Hyperkeratotic spicules (follicular > non-follicular)
• Crystal-storing histiocytosis
• Crystalglobulinemia
• IgM storage papules (cutaneous macroglobulinosis)†
• Subepidermal bullous dermatosis associated with IgM gammopathy†
Deposition of the monoclonal protein in the skin frequently observed
• Plasma cell dyscrasia-associated acquired cutis laxa, acral or generalized (amyloid and/or IgG)
• Plasma cell dyscrasia-associated reactive angioendotheliomatosis (type I cryoglobulins or amyloid)
Almost always associated with monoclonal gammopathy
• Scleromyxedema
• POEMS syndrome¶
• AESOP syndrome – *a*denopathy and *e*xtensive skin patch *o*verlying a *p*lasmacytoma; may coexist with POEMS syndrome¶
• TEMPI syndrome – *t*elangiectasias, *e*levated erythropoietin and erythrocytosis, *m*onoclonal gammopathy, *p*erinephric fluid collection, and *i*ntrapulmonary shunting
• Schnitzler syndrome†
• Necrobiotic xanthogranuloma
Frequently associated with monoclonal gammopathy
• Normolipemic plane xanthoma
• Scleredema (type 2)
• Angioedema secondary to acquired C1 esterase inhibitor deficiency
• Idiopathic systemic capillary leak syndrome (Clarkson syndrome)
Significant association with monoclonal gammopathy, primarily IgA (at least 15% of cases)
• Erythema elevatum diutinum
• Subcorneal pustular dermatosis (SPD) and SPD-type IgA pemphigus
• Pyoderma gangrenosum
• Neutrophilic papular xanthoma
Occasionally associated with monoclonal gammopathy
• Sweet syndrome
• Cutaneous small vessel vasculitis‡, including adult IgA vasculitis with monoclonal IgA gammopathy
• Xanthoma disseminatum
• Epidermolysis bullosa acquisita
• Paraneoplastic pemphigus
• Atypical scleroderma§
*In the current IC 2022 classification (see Table 119.1), primary cutaneous plasmacytoma is classified as primary cutaneous marginal zone B cell lymphoproliferative disorder.
†IgM monoclonal gammopathy is present by definition; in Schnitzler syndrome, IgG gammopathy has occasionally been observed; Waldenström macroglobulinemia is due to a lymphoplasmacytic lymphoma.
‡Cryoglobulinemic vasculitis can occur secondary to type II cryoglobulins.
¶Polyneuropathy (P), organomegaly (O), endocrinopathy (E), M-protein (M), skin changes (S; see Ch. 53 for list of skin changes); diagnosis requires monoclonal plasmaproliferative disorder & neuropathy + one other major criterion (sclerotic bone lesions, Castleman disease, increased serum VEGF levels) and one minor criterion (extravascular volume overload, papilledema, O, E, S, thrombocytosis/polycythemia).
§Possible association; sclerodermoid changes can also occur in the setting of primary systemic amyloidosis.

Table 119.5 Cutaneous conditions associated with monoclonal gammopathy. In some entities, there is a predominance of one type of immunoglobulin light chain, e.g. λ in scleromyxedema, κ in necrobiotic xanthogranuloma.

Fig. 119.18 Disorders associated with a monoclonal gammopathy. Subcorneal pustular dermatosis characterized by superficial vesiculopustules arising within a background of erythema; the patient had an IgA kappa monoclonal gammopathy. The clinical differential diagnosis includes IgA pemphigus. *Courtesy Karynne O. Duncan, MD.*

The diagnosis of symptomatic myeloma has recently been broadened from the need for disease-related CRAB (*c*alcium elevation, *r*enal insufficiency, *a*nemia and/or *b*one lesions [osteolytic > osteosclerotic]) to include patients with ≥60% bone marrow plasmacytosis, >1 lytic lesion on total body MRI (or PET-CT), or a ratio of involved : uninvolved free light chains of ≥100 : 1.

Of note, the level of circulating monoclonal protein associated with several of the skin disorders listed in Table 119.5 may be so low as to fall below the detection limit of a serum protein electrophoresis or an IgA paraprotein may not be detected because it falls within and is obscured by the β band. As a result, the more sensitive serum immunofixation electrophoresis (IFE) is required to detect an intact immunoglobulin (e.g. IgG, IgA) paraprotein.

In diagnosing patients with systemic amyloidosis whose cutaneous amyloid deposits are composed of light chains, the serum free light chain (SFLC) ratio is much more sensitive than even the serum IFE. In addition, because light chains are rapidly excreted into the urine, a urine IFE in addition to SFLC assay is necessary to exclude a light chain-producing plasma cell dyscrasia.

Histopathology

In specific skin lesions (see Table 119.5), diffuse infiltration of the dermis by atypical plasma cells or lymphoplasmacytoid cells is present, usually with several mitoses. Multinucleated plasma cells may be found. The infiltrating cells can be difficult to recognize as plasma cells, and CD45 and CD20 are negative in the vast majority of cases. Neoplastic plasma cells can be stained with CD38 and CD138, and they express monotypic immunoglobulins. Intracytoplasmic eosinophilic inclusions (Russell bodies) are often present; the cells are called Mott cells when these bodies form grape-like clusters. PAS-positive eosinophilic inclusions in the nucleus (Dutcher bodies) can also be observed. These are thought to be immunoglobulin or glycoprotein accumulations, and they can be found in other neoplastic conditions in which plasma cells are prevalent (e.g. plasma cell-rich PCMZLD; see Fig. 119.9B).

Differential Diagnosis

The differential diagnosis of PCMZLD with prominent plasma cell differentiation (formerly called cutaneous plasmacytoma) is discussed above. Cutaneous Waldenström macroglobulinemia has histologic features similar to PCMZLD with prominent lymphoplasmacytic differentiation (formerly called cutaneous immunocytoma)[46], except that direct immunofluorescence demonstrates monoclonal IgM within and around the infiltrating cells. Immunofixation electrophoresis of the serum detects the circulating monoclonal protein as IgM.

CUTANEOUS AND SYSTEMIC PLASMACYTOSIS

In cutaneous and systemic plasmacytosis, an entity most commonly seen in Asians, red–brown to violet–brown papules or nodules favor the back but can be widely disseminated[38]. Patients with the systemic form also have lymphadenopathy and occasionally have involvement of the lung, liver, spleen, or kidneys. The associated hypergammaglobulinemia is polyclonal as are the infiltrating plasma cells. Histologically, there are variably large aggregates of polyclonal plasma cells in the dermis, usually admixed with an inflammatory infiltrate and sometimes with reactive germinal centers[38]. The findings may overlap with those of plasma cell-rich Castleman disease.

INTRODUCTION

The term cutaneous T cell lymphoma (CTCL) describes a heterogeneous group of neoplasms of skin-homing T cells that show considerable variation in clinical presentation, histologic appearance, immunophenotype, and prognosis. CTCLs represent ~75%–80% of all primary cutaneous lymphomas, whereas primary cutaneous B cell lymphomas (CBCLs) account for ~20%–25%[1]. For many years, mycosis fungoides (MF) and Sézary syndrome (SS) were the only known types of CTCL. Over the past three decades, based on a combination of clinical, histologic and immunophenotypic criteria, new types of CTCL and CBCL have been defined and new classifications for the group of primary cutaneous lymphomas have been formulated[1–3,3a,3b]. A major advantage in the management of primary cutaneous lymphomas compared with lymphomas arising at other sites is that the former can be seen and can be biopsied easily, giving the dermatologist the unique opportunity to correlate the clinical appearance and clinical behavior with histologic, immunophenotypic, and genetic aspects of these conditions. Hence, the dermatologist can play a key role in the diagnosis, classification, and treatment of these diseases.

HISTORY

In 1806, a French physician, Jean Louis Alibert, was the first to describe a patient with MF. This case was designated *pian fungoïde* in his atlas, but in 1835 it was renamed *mycosis fungoïde* because of the resemblance of some skin tumors to mushrooms. In 1870, Bazin described the natural progression from a nonspecific premycotic phase to plaque lesions and finally to tumors, which probably represents one of the first descriptions of the "multistep model" in the development of a malignancy. In 1885, Vidal and Brocq used the term "mycosis fungoides d'emblée" for patients presenting with skin tumors not preceded by patches or plaques. It has now become clear that such cases mostly represent another type of CTCL. The erythrodermic form of MF was described in 1892 by Besnier and Hallopeau. These early descriptions of the major clinical forms of MF were followed by descriptions of Sézary syndrome by Sézary and Bouvrain in 1938, pagetoid reticulosis by Woringer and Kolopp in 1939, and lymphomatoid papulosis (LyP) by Macaulay in 1968.

Thus, in the early 1970s, MF and some related conditions were the only types of cutaneous lymphoma that had been rather well described. Reports on cutaneous lymphomas other than MF/SS, commonly designated in the past as malignant reticulosis or reticulum cell sarcoma, were few. Moreover, they were firmly believed to represent skin manifestations of a systemic lymphoma and treated as such.

The CTCL Concept

In 1968, Lutzner and Jordan described the ultrastructural features of the circulating atypical cells in SS. Characteristically, the nuclei of these cells had deep and narrow indentations, giving them a cerebriform appearance. Three years later, similar cells were found in the skin and lymph nodes of patients with MF. In 1975, based on the observation that the neoplastic cells in MF, SS, and related conditions not only had the same morphology but also a common T cell phenotype, the term "CTCL" was suggested for this group of diseases. Within a short time, this term gained wide acceptance, particularly in the US. The introduction of the CTCL concept can be considered as a landmark in the history of this group of diseases. However, a major disadvantage has been that in many subsequent studies, distinction was no longer made between MF, SS, and other T cell neoplasms, entities which may vary considerably in clinical presentation and clinical behavior.

The Concept of Primary Cutaneous Lymphomas

At about the same time that the CTCL concept was introduced, several European groups started to classify cutaneous lymphomas according to the criteria of the Kiel classification, a system used by hematopathologists for the categorization of nodal lymphomas. It was then determined that many types of CBCL and CTCL (other than classic MF and SS) can present in the skin without any evidence of extracutaneous disease at the time of diagnosis. It appeared that these primary cutaneous lymphomas often have a completely different clinical behavior and prognosis when compared to morphologically similar lymphomas arising within lymph nodes, and therefore require different types of treatment[2]. In addition, differences in the presence of specific chromosomal translocations and in the expression of oncogenes, viral sequences or antigens (e.g. EBV), and adhesion receptors involved in tissue-related lymphocyte homing were found.

Such differences underscored that primary cutaneous lymphomas represent a distinct group and may explain, at least in part, their different clinical behavior. For instance, the observation that the neoplastic T cells in most CTCLs express cutaneous lymphocyte antigen (CLA) and the CC-chemokine receptors 4 (CCR4) and 10 (CCR10) indicates that they are the neoplastic counterparts of normal skin-homing T cells, and this explains why these CTCLs present in the skin. Perhaps most importantly, it appeared that different types of CTCL and CBCL with different clinical behaviors and different therapeutic requirements may have an identical histologic appearance. This implies that histologic features should always be combined with clinical and immunophenotypic data before a definite diagnosis (classification) is made.

Such an approach resulted in the delineation of several new types of CTCL and CBCL, and it formed the basis of the European Organization for Research and Treatment of Cancer (EORTC) classification for primary cutaneous lymphomas[2].

EORTC, WHO, and WHO-EORTC Classification Schemes

The EORTC classification scheme was the first one that was specifically designed for the group of primary cutaneous lymphomas. It contained

WHO-EORTC CLASSIFICATION FOR CUTANEOUS T-CELL LYMPHOMAS – 2018 UPDATE		
WHO-EORTC classification	**Frequency (%)***	**5-year survival rate (%)***
Indolent clinical behavior		
Mycosis fungoides (MF)	52	88
Mycosis fungoides variants		
• Folliculotropic MF	7	75
• Pagetoid reticulosis	<1	100
• Granulomatous slack skin	<1	100
Primary cutaneous CD30-positive lymphoproliferative disorders		
• Primary cutaneous anaplastic large cell lymphoma (C-ALCL)	10	95
• Lymphomatoid papulosis (LyP)	16	99
Subcutaneous panniculitis-like T cell lymphoma (SPTCL)	1	87
Primary cutaneous CD4-positive small/medium T cell lymphoproliferative disorder†	8	100
Primary cutaneous acral CD8-positive T cell lymphoproliferative disorder§,†	<1	100
Aggressive clinical behaviour		
Sézary syndrome (SS)	3	36
Adult T-cell leukemia/lymphoma (ATLL)	<1	NDA
Extranodal NK/T-cell lymphoma, nasal type	1	16
Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T cell lymphoma†	<1	31
Primary cutaneous gamma/delta T cell lymphoma (PCGD-TCL)	<1	11
Primary cutaneous peripheral T cell lymphoma (PTCL), NOS	3	15

*Based on data included in Dutch and Austrian cutaneous lymphoma registries between 2002 and 2017[1].
†While listed as provisional entities in the 2018 WHO-EORTC classification, included as distinct entities in the 5th edition of the WHO classification of haematolymphoid tumours and the 2022 ICC classification of mature lymphoid neoplasms[3a,3b].
§In the 5th edition of the WHO classification reclassified as lymphoproliferative disorder rather than lymphoma[3a].

Table 120.1 WHO-EORTC classification for cutaneous T cell lymphomas – 2018 update[1]. NDA, no data available; NOS, not otherwise specified.

a limited number of well-defined types of CTCL and CBCL, and a distinction was made between cutaneous lymphomas with indolent, intermediate, or aggressive clinical behavior. By including well-defined and recognizable disease entities, this classification provided the clinician with detailed information on staging, preferred mode of treatment, clinical behavior and prognosis, serving as a useful guide for optimal management and treatment.

Collaboration between the EORTC and the World Health Organization (WHO) groups resulted in the publication of the WHO-EORTC consensus classification for primary cutaneous lymphomas in 2005 and its update in 2018[1]. In this 2018 update, the terminology and definitions of the different types of CTCL are identical to those in the 2016 revision of the WHO classification[3]. In the 2023 WHO classification (5th revision) as well as in the 2022 International Consensus Classification (ICC) of mature lymphoid neoplasms, only minor changes have been introduced, namely, primary cutaneous acral CD8-positive T cell lymphoma has been listed as a lymphoproliferative disorder rather than a lymphoma[3a,3b]. The frequency and survival of patients with the different types of CTCL recognized in the updated 2018 WHO-EORTC classification are presented in Table 120.1. Following a description of practical guidelines for diagnosis, classification, and staging, relevant features of the different types of CTCL included in this classification are presented.

PRACTICAL GUIDELINES FOR DIAGNOSIS, CLASSIFICATION AND STAGING OF CTCL

Diagnosis

The first step in the evaluation of a patient suspected of having CTCL is to decide if it represents a lymphoma or a benign condition. Skin biopsies – preferably deep punch biopsies 4–6 mm wide or an excisional or incisional biopsy from the most representative skin lesions – should be performed. In the US, broad shave (tangential) biopsies are also done for suspected patch/plaque stage MF.

Since prior treatment with topical corticosteroids or phototherapy (narrowband UVB, PUVA) may change the original histology profoundly, biopsies from untreated skin lesions are preferred. Even if an adequate biopsy specimen is obtained, a definite diagnosis is not always possible. First, several types of CTCL, such as MF, are often preceded for years by skin lesions that are neither clinically nor histologically diagnostic. The gradual progression from this prediagnostic phase to overt lymphoma explains why it has always been so difficult to reach a consensus on the minimal histologic criteria needed for an unequivocal diagnosis of MF[4]. In most cases, repeated biopsies, when appropriate, will ultimately result in the correct diagnosis.

Secondly, atypical T cell infiltrates are found not only in CTCL but also in reactive conditions, e.g. lymphomatoid drug eruptions (T cell pseudolymphomas). Therefore, a definite diagnosis should always be based on a combination of clinical, histologic and, in most cases, immunophenotypic criteria, and it may be supplemented with the results of gene rearrangement analysis.

Immunophenotyping

Immunohistochemical studies on paraffin sections using antibodies reactive with cell-surface or cytoplasmic molecules are extremely important in the diagnosis and classification of cutaneous lymphomas. By using a panel of such antibodies (see Ch. 0), distinction can be made between neoplasms of T cell, B cell, NK cell, and myeloid or monocytic origin. Within the group of CTCLs, such studies have contributed to the delineation of new subtypes and provided important diagnostic and prognostic criteria.

With respect to the diagnosis of CTCL, demonstration of an aberrant phenotype, i.e. loss of one or more T cell-associated antigens, such as CD2, CD3, CD4 or CD5, by the neoplastic T cells, can be considered as an important additional criterion in establishing a definite diagnosis of CTCL[4]. However, loss of CD7 expression, which may be caused by chronic T cell stimulation and is commonly observed in benign dermatoses, is a less reliable marker.

T Cell Receptor Gene Rearrangement Analysis

T cell receptor (TCR) gene rearrangement analysis, utilizing a standardized assay (e.g. BIOMED-2), may provide useful information for the diagnosis and staging of malignant lymphomas[5]. However, caution is warranted in interpreting the results of such analyses. Clonal T cell populations have been detected not only in skin lesions, lymph nodes, and peripheral blood of patients with CTCL and in cases of chronic dermatitis preceding MF ("clonal dermatitis"), but also in skin lesions of patients with apparently benign conditions, such as pityriasis lichenoides et varioliformis acuta, lichen planus, lichen sclerosus, and some pseudolymphomas[5].

Demonstration of clonal T cell populations can therefore not be used as an absolute criterion of malignancy, but should always be considered in conjunction with clinical and histologic features, which together remain the "gold standard". If the clinical and histologic findings are not consistent, and an aberrant phenotype is not detected, a definite diagnosis of CTCL should not be made.

High-throughput sequencing (HTS) of TCR genes, most commonly the TCRβ gene, was more recently introduced as a novel technique. It provides detailed information on the number of distinct T cell clones present within a sample as well as their relative frequency[6]. HTS-TCR is a much more sensitive technique for the early diagnosis of CTCL and allows tracking of specific T cell clones over time and following treatment. In addition, HTS-TCR can be performed on multiple tissues, e.g. skin and peripheral blood. Studies suggest that a tumor clone frequency >25% in lesional skin of early stage MF is associated with reduced survival[7].

DIFFERENTIAL DIAGNOSIS OF COMMON HISTOLOGIC PATTERNS IN CUTANEOUS T CELL LYMPHOMA		
Histologic category	**Differential diagnosis**	**Diagnostic criteria/clues**
Epidermotropic CTCL (simulating or consistent with plaque stage MF)	Mycosis fungoides (MF)	• Characteristic patches and plaques • Most atypical cells within the epidermis (basal layer)
	Pagetoid reticulosis	• Solitary plaque, commonly on distal extremities • Neoplastic cells confined mostly to an often acanthotic epidermis • Often $CD8^+$ phenotype; CD30 expression common
	Lymphomatoid papulosis (LyP), type B or type D	• Recurrent, self-healing papular eruption • Sometimes extension of infiltrate into lower dermis • In some cases, admixture with large atypical cells as in type A LyP (mixed type A and B) • LyP type B is $CD4^+$; type D is $CD8^+$
	Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T cell lymphoma	• Infiltrated plaques, but often eruptive nodules and tumors with ulceration • Intraepidermal accumulation of medium-sized pleomorphic T cells or small blast cells; no typical cerebriform appearance • Phenotype: $CD8^+$, TIA-1^+, granzyme B^+, $CD45RA^+$, $CD7^{-/+}$
	Sézary syndrome	• Often more monotonous infiltrate histologically • Erythroderma • Peripheral blood involvement • Same T cell clone in the skin and blood
	Adult T cell leukemia/lymphoma	• Often clinically and histologically identical to MF • Check HTLV-1 status in patients from endemic areas
CTCL with diffuse pleomorphic infiltrates ($CD30^-$) (simulation or consistent with tumor stage MF; few $CD30^+$ tumor cells may be present)	Tumor stage MF	• Concurrent patches and plaques • Variable numbers of small, medium-sized, and/or large cerebriform T cells and/or blast cells • Variable admixture with inflammatory cells
	Primary cutaneous peripheral T cell lymphoma, NOS	• Histologically, often indistinguishable from MF with large cell transformation • No prior or concurrent patches and plaques
	Primary cutaneous CD4-positive small/medium T cell lymphoproliferative disorder (and/or nodular pseudo-T cell lymphoma [see text])	• Presents as solitary plaque or tumor (2–3 cm) • No prior or concurrent patches and plaques • Scattered medium-sized to large pleomorphic T cells (<30% of cells; express PD-1) • Many admixed $CD8^+$ T cells, B cells, and histiocytes • No aberrant phenotype (i.e. no "marker loss") • Clonal T cell population in most cases
CD30-positive CTCL (see Fig. 120.11)	Lymphomatoid papulosis, type A/C	• Recurrent self-healing papules and nodules • Histologic spectrum (from typical LyP to identical to C-ALCL)
	Primary cutaneous anaplastic large cell lymphoma (C-ALCL)	• Generally, solitary or localized nodules or tumors • No evidence of prior or concurrent MF or another type of CTCL • No extracutaneous disease (staging negative) • Histologic spectrum (from typical C-ALCL to similar to LyP) • Phenotype: CLA^+, EMA^-, ALK^-; common loss of pan-T cell markers
	Systemic ALCL with secondary skin involvement	• Prior or concurrent extracutaneous involvement (exception: involvement of one regional lymph node basin which has same prognosis as C-ALCL) • Often generalized skin lesions • Phenotype: CLA^-, EMA^+, ALK^+ (mainly in pediatric subgroup)
	MF with large cell transformation	• Histologically, an admixture with typical cerebriform cells, but sometimes indistinguishable from C-ALCL • Prior or concurrent patches and plaques
CTCL with subcutaneous involvement	Subcutaneous panniculitis-like T cell lymphoma	• Infiltrates confined to subcutis • Characteristic rimming of individual fat cells by neoplastic T cells • Deeply seated nodules and plaques, mainly involving the legs and trunk • Characteristic $CD3^+$, $CD4^-$, $CD8^+$, $CD56^-$, $\beta F1^+$ T cell phenotype
	Other types of CTCL	• Subcutaneous infiltrates represent extension from dermal infiltrates • For specific features: see text

Table 120.2 Differential diagnosis of common histologic patterns in cutaneous T cell lymphoma (CTCL). ALK, anaplastic lymphoma kinase; βF1, positivity reflects α/β T cell origin; CLA, cutaneous lymphocyte antigen; C-ALCL, cutaneous anaplastic large cell lymphoma; EMA, epithelial membrane antigen; PD-1, programmed death-1 (CD279); TIA, T cell restricted intracellular antigen.

Classification

Once a diagnosis of CTCL has been made, the type of CTCL should be determined. As noted previously, the histologic diagnosis is not the final diagnosis, which means that CTCL cannot be classified on the basis of histologic criteria alone. For instance, in the case of a skin biopsy showing a dermal infiltrate which is composed predominantly of CD30-positive large anaplastic or pleomorphic T cells, the *histologic diagnosis* will be (CD30-positive) anaplastic large cell lymphoma (ALCL). However, depending upon the clinical presentation, the *definite diagnosis* may be: a primary cutaneous ALCL; cutaneous involvement of a systemic ALCL; large cell transformation of MF with expression of CD30; or LyP (in cases of recurrent self-healing papules). Obviously, each of these conditions requires a different approach in terms of staging and treatment.

In Table 120.2, the differential diagnosis of four histologic categories has been elaborated. This histologic subdivision into epidermotropic CTCL, CTCL with diffuse pleomorphic infiltrates, CD30-positive CTCL, and subcutaneous CTCL is neither complete nor meant as an alternative classification. It is only presented as an illustration of how histology should be combined with clinical and immunophenotypic data to arrive at a definite diagnosis.

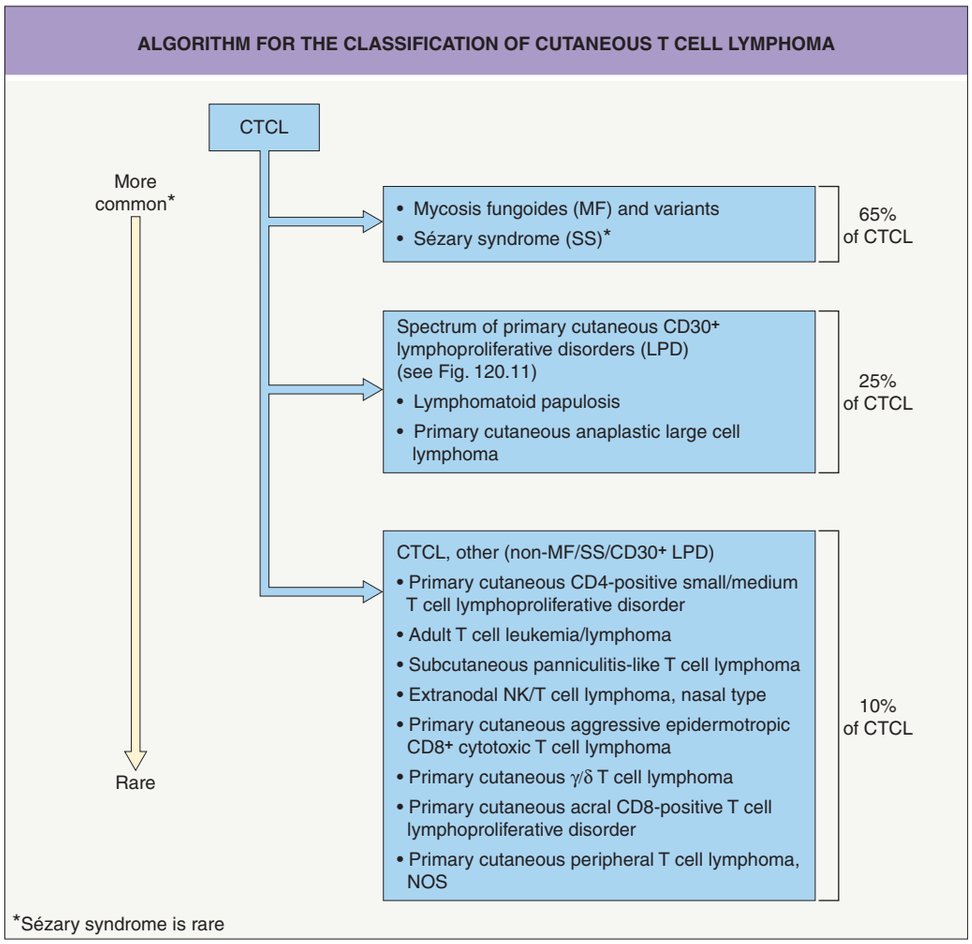

Fig. 120.1 Algorithm for the classification of cutaneous T cell lymphoma (CTCL). NOS, not otherwise specified. See also Table 120.1. *Adapted from Willemze R, Beljaards RC, Meijer CJLM. Classification of primary cutaneous T-cell lymphoma. Histopathology 1994;24:405–15.*

Practical Guidelines

For those not regularly involved in the diagnosis and classification of CTCL and perhaps confused by the many different types of CTCL, a stepwise approach, as presented in Fig. 120.1, may serve as a practical guide.

Step one: Based on a combination of clinical, histologic, and immunophenotypic criteria, distinction is first made between classic MF, MF variants, and SS on the one hand *and* CTCL other than these conditions on the other. The rationale for this first step is that dermatologists are familiar with the former set of conditions, which comprise ~65% of CTCLs, and these lymphomas require a different clinical approach in terms of staging and therapy compared to the other forms of CTCL.

Step two: The second category to be considered is the group of *primary* cutaneous CD30-positive lymphoproliferative disorders. It implies that evaluation of skin biopsies from patients with (suspected) CTCL should always include CD30 immunostaining. This group includes cases of cutaneous ALCL (C-ALCL) and LyP, which together represent the second most common group of CTCL (see Table 120.1). Patients within this spectrum of disease generally have an excellent prognosis, and most individuals can be managed easily by dermatologists.

Step three: With the first two steps, ~90% of CTCL will be classified correctly. The remaining group (10% of patients) contains rare types of CTCL, including those that usually have an indolent clinical behavior (subcutaneous panniculitis-like T cell lymphoma, primary cutaneous CD4-positive small/medium T cell lymphoproliferative disorder, and primary cutaneous acral CD8-positive T cell lymphoproliferative disorder) as well as ones with an aggressive clinical behavior (extranodal NK/T cell lymphoma, nasal type, primary cutaneous gamma/delta T cell lymphoma, and primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T cell lymphoma) (see Table 120.1). The term primary cutaneous peripheral T cell lymphoma (PTCL), not otherwise specified (NOS) is employed for the remaining cases that do not fit into any of the aforementioned entities. It should be emphasized that because of overlapping clinicopathologic features and highly aberrant phenotypes, distinction between different types of aggressive CTCL is sometimes very difficult.

Staging

Apart from CTCL, a term preferably used only for *primary* CTCL, systemic T cell lymphomas frequently present or relapse in the skin. Adequate staging procedures are required to differentiate between CTCL and these systemic lymphomas secondarily involving the skin. The extent of staging procedures is dependent on the type of (suspected) CTCL, and in the case of classic MF, on the clinical stage of the disease[8]. In cases of early patch/plaque stage MF, pagetoid reticulosis, unequivocal cases of LyP, and probably typical cases of primary cutaneous CD4-positive small/medium T cell lymphoproliferative disorder and primary cutaneous acral CD8-positive T cell lymphoproliferative disorder, staging procedures are generally not mandatory. In cases of suspected SS, adequate staging with special emphasis on assessment of peripheral blood involvement by cytology, immunophenotyping (flow cytometry), and TCR gene rearrangement analysis is essential. In all other types of CTCL, routine hematologic staging, including complete and differential blood cell counts, a serum chemistry panel, computed tomographic (CT) scans and/or positron emission tomography (PET) of the chest and abdomen, and in most cases bone marrow sampling, are required[9].

MYCOSIS FUNGOIDES

Definition

Mycosis fungoides (MF) represents the most common type of CTCL and accounts for ~50% of all primary cutaneous lymphomas (see Table 120.1). The term MF should be restricted to the classic "Alibert–Bazin" type characterized by the typical evolution of patches, plaques, and tumors, or for clinicopathologic variants showing a similar clinical course.

Epidemiology

MF has an incidence of about 0.4 per 100 000 inhabitants per year in the US[10]. MF typically affects older adults (median age at diagnosis: 55–60 years), but it may occur in children and adolescents as well. Men are affected more often than women, with a male-to-female ratio of 1.6–2.0 : 1.

Pathogenesis

The etiology and the pathogenetic mechanisms involved in the development and stepwise progression of MF are largely unknown. Genetic, environmental, and immunologic factors have all been considered.

Genetic factors

Lymphomagenesis is considered to be a multifactorial process, in which a stepwise accumulation of genetic abnormalities may result in clonal proliferation, malignant transformation, and ultimately, progressive and widely disseminated disease. Although the successive clinical steps of tumor progression were described more than a century ago, the molecular events underlying the different steps of tumor progression have not been fully identified. In gene expression studies of early stage MF, an overexpression of the transcription factor TOX and PDCD1 (PD-1) was observed and noted to be a useful diagnostic marker[11]. Advanced stages of MF usually have complex karyotypes with somatic copy-number variants constituting the vast majority of all driver mutations[12].

In tumor stage MF, integrated whole-genome sequencing and RNA sequencing have shown rearrangements in multiple genes involved in transcriptional regulation and signal transduction. Deletions of *HNRNPK* and *SOCS1*, which encode signaling inhibitors of the JAK-STAT pathway, were the most frequent genetic alterations in MF after deletion of *CDKN2A*[13]. Deletion or inactivation of *CDKN2A* has been associated with a shorter survival in patients with tumor stage MF while deletion of *HNRNPK* and *SOCS1* may contribute to constitutive activation of STAT3.

Staphylococcus aureus and its toxins can also activate STAT3 signaling and increase expression of the interleukin-2 receptor (IL-2R) in tumor cells and nonmalignant T cells, thereby stimulating proliferation of tumor cells in CTCL[14]. Aggressive antibiotic treatment can effectively eradicate this stimulus, normalize the tumor microenvironment, inhibit STAT3 signaling and cellular proliferation within lesional skin, and provide significant clinical improvement in MF and Sézary syndrome[14]. *Staphylococcus aureus* α-toxin also blocks $CD8^+$ T cell-mediated killing of malignant T cells, allowing immune evasion and continued proliferation[15].

Environmental factors

Persistent antigenic stimulation has been demonstrated to play a crucial role in the development of various malignant lymphomas, including *m*ucosa-*a*ssociated *l*ymphoid *t*issue (MALT) lymphomas (*Helicobacter pylori* infection), CBCL (*Borrelia burgdorferi* infection), and enteropathy-type T cell lymphoma (celiac disease). In MF, persistent antigenic stimulation has also been proposed as an initial event, but the nature of the antigen(s) involved is unknown. Large case–control studies have suggested a relationship with industrial or environmental exposures, but their role in the development of MF remains controversial[16]. Whereas the etiologic roles of human T cell leukemia virus 1 (human T cell lymphotropic virus 1; HTLV-1) in adult T cell leukemia/lymphoma and EBV in nasal NK/T cell lymphoma have been firmly established, conclusive evidence for a primary etiologic role of these and other viruses in MF is lacking.

Immunologic factors

$CD8^+$ cytotoxic T cells (CTL) are thought to play a crucial role in the antitumor response in MF. A relationship between high percentages of $CD8^+$ CTL in the dermal infiltrates and improved survival has been described[17]. These $CD8^+$ T cells exert their antitumor effect both by a direct cytotoxic effect and by the production of cytokines, particularly interferon (IFN)-γ. They can mediate tumor cell lysis via exocytosis of cytotoxic granules containing perforin, granzymes, and T cell-restricted intracellular antigen (TIA-1), and by expression of Fas ligand (FasL), which interacts with Fas (CD95; APO-1) on the neoplastic T cells. Both pathways ultimately lead to activation of caspase 3 and tumor cell death. Loss of Fas expression or function by the neoplastic T cells is one of the many mechanisms by which tumor cells can escape from an effective antitumor response[18].

In most patients, the neoplastic T cells in SS and tumor stage MF are derived from $CD4^+$ T cells with a Th2 cytokine profile (production of IL-4, IL-5, and IL-10), whereas the cytotoxic T cells are the main producers of IFN-γ, which plays an important role in augmenting T cell- and NK cell-mediated killing. In accordance with this concept, a gradual shift from a predominantly type 1 cytokine profile in MF patches and plaques to a predominantly type 2 cytokine profile in MF tumors has been suggested. Increased levels of Th2 cytokines may impair the Th1 cell-mediated antitumor response and contribute to the immunosuppression seen in patients with advanced MF[19].

Clinical Features

Characteristically, patients with classic MF progress from patch stage to plaque stage and finally to tumor stage disease, and they have a protracted clinical course over years or even decades. Before a definite diagnosis is made, patients generally have many years of nonspecific eczematous or psoriasiform skin lesions and non-diagnostic biopsies. The median duration from onset of skin lesions to the diagnosis of MF is 4–6 years, but it may vary from several months to more than five decades[20].

Early patch stage MF is characterized by the presence of variably sized erythematous, finely scaling lesions, which may be mildly pruritic (Fig. 120.2A). These early lesions may show variable degrees of atrophy, and a poikilodermatous variant consisting of patches with mottled hyper- and hypopigmentation, atrophy, and telangiectasia has been described (formerly called poikiloderma vasculare atrophicans). Generalized hypopigmented lesions may be observed in patients with

Fig. 120.2 Mycosis fungoides, limited patch/plaque stage disease (stage 1A). A Patches on the buttocks involving less than 10% of the skin surface. **B** Few atypical T cells in the basal layer of the epidermis. Immunohistochemical staining for CD3 more clearly demonstrates many atypical lymphocytes in a characteristic linear configuration along the epidermal basal layer (inset).

darkly pigmented skin (Fig. 120.3), and this is also a common presentation of juvenile-onset MF.

The initial skin lesions have a predilection for the buttocks and other covered sites of the trunk and limbs. With progression, more infiltrated reddish-brown, scaling plaques develop, which gradually enlarge and may have an annular, polycyclic, or typical horseshoe-shaped configuration (Fig. 120.4A). It should be stressed that many patients never progress beyond the plaque stage of the disease. However, a minority of patients may develop nodules or tumors. These patients with tumor stage MF characteristically show a combination of patches, plaques, and tumors (Fig. 120.5A); the latter often show ulceration.

If only skin tumors are present without preceding or concurrent patches or plaques, a diagnosis of MF is highly unlikely and another type of CTCL should be considered. The risk of developing extracutaneous disease correlates with the extent and type of skin lesions. It is exceedingly rare in patients with limited patch/plaque stage disease, relatively uncommon in patients with generalized plaques, and most likely in patients with skin tumors or erythroderma[20]. Initially extracutaneous dissemination most often involves the regional lymph nodes draining areas of extensive skin involvement. Visceral involvement may develop subsequently and can involve any organ. The bone marrow is rarely involved.

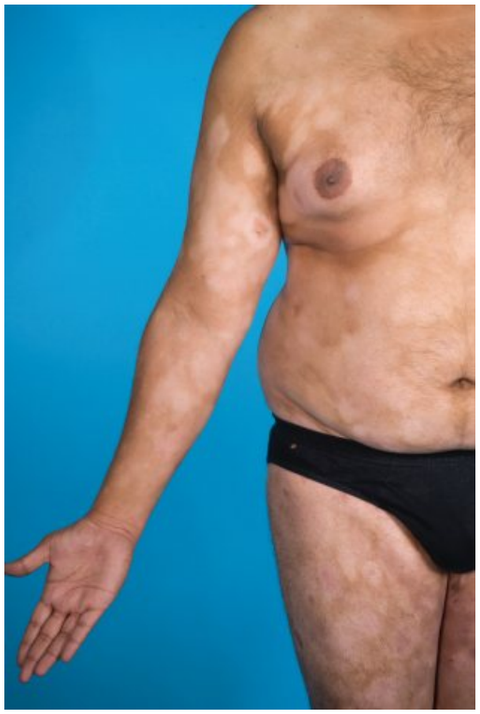

Fig. 120.3 Hypopigmented mycosis fungoides (stage 1B). Generalized hypopigmented lesions as well as pink to pink–brown plaques.

Pathology

Early *patch* lesions in MF show superficial band-like or lichenoid infiltrates, consisting primarily of lymphocytes. Atypical cells, with small to medium-sized, highly convoluted (cerebriform) and sometimes hyperchromatic nuclei, are few in number and are mostly confined to the epidermis (epidermotropism). These lymphocytes characteristically colonize the basal layer of the epidermis as single cells surrounded by vacuolated halos, often in a linear configuration[4] (Fig. 120.2B).

In *plaques*, epidermotropism is generally more pronounced (Fig. 120.4B). The presence of intraepidermal nests of atypical cells (referred to as Pautrier microabscesses, although the initial description was by Darier) is a highly characteristic feature, but is observed in only a minority of cases. The epidermis may show acanthosis and elongated rete ridges, but spongiosis is generally mild or absent. The dermal infiltrates are also more pronounced, and they may contain a higher number of atypical cells with cerebriform nuclei and occasional blast cells, as well as admixed eosinophils and plasma cells. Rarely, a predominantly interstitial infiltrate that may resemble morphea is observed (interstitial MF).

With progression to *tumor* stage MF, the dermal infiltrates can involve the entire dermis and extend into the subcutaneous tissue. Epidermotropism may no longer be present. The tumor cells increase in number and size, showing variable proportions of small, medium-sized, or large cells with cerebriform nuclei, blast cells with prominent nuclei, and intermediate forms (Fig. 120.5B). *Large cell transformation*, defined by the presence of CD30-negative or CD30-positive large cells exceeding 25% of the infiltrate or forming microscopic nodules, may occur and is generally associated with a poor prognosis. However, within this group, CD30-positive patients have a much better prognosis than CD30-negative patients[21].

Immunophenotype

The neoplastic cells in MF have a mature $CD3^+$, $CD4^+$, $CD45RO^+$, $CD8^-$ memory T cell phenotype. In a minority of patients with otherwise classic MF, a $CD3^+$, $CD4^-$, $CD8^+$ mature T cell phenotype or more rarely a γ/δ T cell phenotype ($\beta F1^-$, $TCR\gamma/\delta^+$, $CD3^+$, $CD4^-$, $CD8^+$) may be seen[22,23]. These patients have the same clinical behavior and prognosis as $CD4^+$ cases and should not be considered separately. Demonstration of an aberrant phenotype (e.g. loss of pan-T cell antigens such as CD2, CD3, and CD5) is an important adjunct in the diagnosis of MF, but is uncommon in the early stages of MF. A $CD8^+$ T cell phenotype is more common in pediatric MF and in some variants of MF including hypopigmented, hyperpigmented, or poikilodermatous MF.

Differential Diagnosis

Regarding the differential diagnosis of MF, three categories should be considered. The first category contains a diverse group of benign

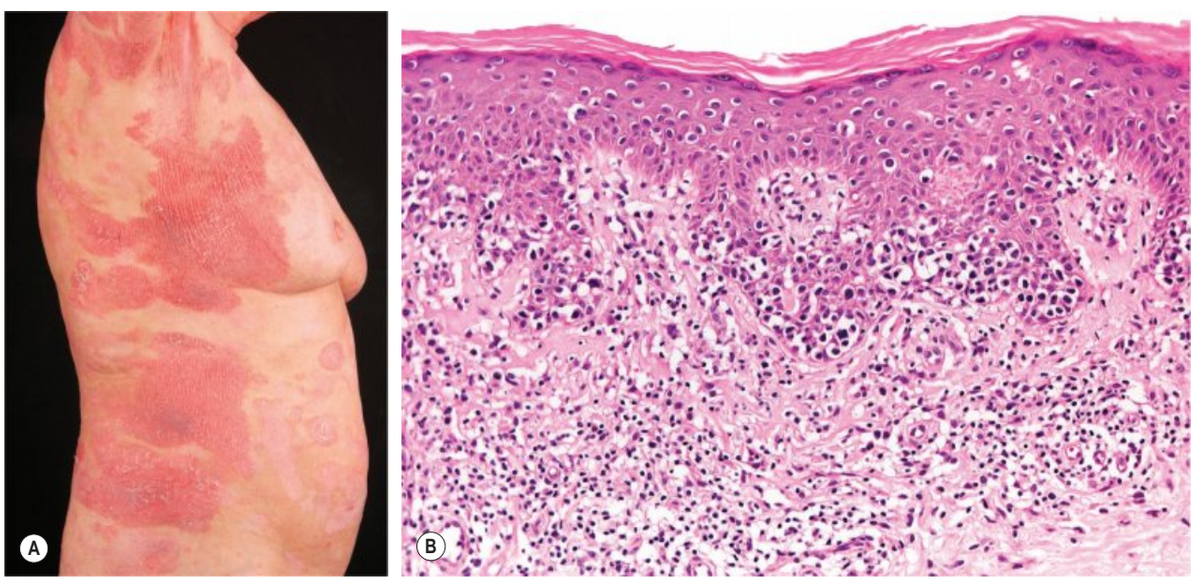

Fig. 120.4 Mycosis fungoides, generalized patch/plaque stage disease (stage 1B). A Extensive patches and plaques with scale involving more than 10% of the skin surface. **B** Epidermotropism with the formation of small nests of atypical cells (Pautrier microabscesses). The majority of the dermal infiltrate is composed of small reactive lymphocytes. *A, Courtesy Lorenzo Cerroni, MD.*

dermatoses, which early MF may resemble clinically, and it includes several types of eczema, psoriasis, superficial fungal infections, and drug reactions. These specific diagnoses can generally be excluded by histologic and other standard dermatologic examinations. This category may also include patients with *large plaque parapsoriasis* (parapsoriasis en plaque) who show slightly scaly, sometimes atrophic, erythematous patches or plaques, which are commonly located on the trunk and buttocks (see Ch. 9). Whereas large plaque parapsoriasis cannot be distinguished clinically from early patch or plaque stage MF, the histologic features are often not consistent with MF. Long-term follow-up studies have documented progression of large plaque parapsoriasis to overt MF in ~10% of cases. However, one prevailing opinion is that large plaque parapsoriasis should be considered a form of MF, rather than a potential precursor of MF, but the authors feel there is no consensus. There is more consensus that small plaque parapsoriasis does not represent MF.

A second category includes several benign conditions with histologic features highly suggestive of MF. Examples of these are lymphomatoid contact dermatitis, lymphomatoid drug reactions, and actinic reticuloid. Apart from subtle histologic differences (e.g. the predominance of atypical T cells in the dermal infiltrates rather than in the epidermis), careful evaluation of the clinical features, which are generally not consistent with MF, often results in a correct diagnosis.

The third category includes other types of (epidermotropic) CTCL, which may resemble MF histologically. Diagnostic features of these entities are presented in Table 120.2.

Staging Systems and Staging Procedures

Staging patients with MF and SS is important, since it determines management and treatment and has prognostic significance. In 2007, a revised clinical staging system for MF and SS was proposed, which is based on the TNM (tumor–node–metastasis) classification system and takes into account the type and extent of skin lesions (T1–4) as well as the presence or absence of nodal (N0–3), visceral (M0–1), and peripheral blood involvement (B0–2)[8] (Table 120.3 & 120.4).

Evaluation of patients suspected of having MF should include a thorough physical examination with special attention to the type and extent of skin lesions and the presence of palpable lymph nodes, as well as skin biopsies, complete blood counts, and serum chemistries. Enlarged lymph nodes should be biopsied. Histologically, distinction can be made between lymph nodes showing dermatopathic lymphadenopathy without involvement by MF (N1), dermatopathic lymphadenopathy with early MF involvement (N2), and lymph nodes showing effacement of the normal lymph node architecture by neoplastic T cells (N3). The prognostic significance of such a subdivision has been well established.

No further examinations are recommended for patients with stage IA–B disease. CT or PET-CT scans of the chest and abdomen are recommended in patients in whom extracutaneous disease is suspected, but they are less useful in patients with limited patches and/or plaques without lymphadenopathy. Examination of other organs, including the bone marrow, should only be performed if clinically indicated.

TNMB CLASSIFICATION OF MYCOSIS FUNGOIDES AND SÉZARY SYNDROME	
T (skin)	
T_1	Limited patch/plaque (involving <10% of total skin surface)
T_2	Generalized patch/plaque (involving ≥10% of total skin surface)
T_3	Tumor(s)
T_4	Erythroderma
N (lymph node)	
N_0	No enlarged lymph nodes
N_1	Enlarged lymph nodes, histologically uninvolved
N_2	Enlarged lymph nodes, histologically involved (nodal architecture uneffaced)
N_3	Enlarged lymph nodes, histologically involved (nodal architecture [partially] effaced)
Nx	Clinically abnormal lymph nodes; no histologic confirmation
M (viscera)	
M_0	No visceral involvement
M_1	Visceral involvement
B (blood)	
B_0	Absence of significant blood involvement: <5% of peripheral blood lymphocytes are atypical (Sézary) cells
B_1	Low blood tumor burden: >5% of peripheral blood lymphocytes are atypical (Sézary) cells, but does not meet the criteria for B_2 (B_{1a}: clone negative; B_{1b}: clone positive)
B_2	High blood tumor burden: clone positive *plus* either ≥1000/mcl Sézary cells – *or* – CD4/CD8 ratio >10, $CD4^+CD7^-$ cells ≥40%, or $CD4^+CD26^-$ cells ≥30%)

Table 120.3 TNMB classification of mycosis fungoides and Sézary syndrome.

Treatment

The choice of an initial treatment in MF depends on the stage of the disease and the general condition and age of the patient[24,25]. Given the chronic and recurrent nature of MF, treatment should be aimed at improving symptoms while limiting toxicity. Following the traditional "stage-based" approach, skin-directed therapies are preferred in the

CLINICAL STAGING SYSTEM FOR MYCOSIS FUNGOIDES AND SÉZARY SYNDROME				
Clinical stage				
IA	T_1	N_0	M_0	$B_{0–1}$
IB	T_2	N_0	M_0	$B_{0–1}$
IIA	$T_{1–2}$	$N_{1–2}$	M_0	$B_{0–1}$
IIB	T_3	$N_{0–1}$	M_0	$B_{0–1}$
III	T_4	$N_{0–2}$	M_0	$B_{0–1}$
IVA_1	$T_{1–4}$	$N_{0–2}$	M_0	B_2
IVA_2	$T_{1–4}$	N_3	M_0	$B_{0–2}$
IVB	$T_{1–4}$	$N_{0–3}$	M_1	$B_{0–2}$

Table 120.4 Clinical staging system for mycosis fungoides and Sézary syndrome. The shaded boxes highlight the required features for the three subdivisions of stage IV disease.

early stages of MF (stages IA–IIA) and even in patients with limited tumor stage MF (IIB) (Table 120.5). These skin-directed therapies include topical or intralesional corticosteroids, topical cytotoxic agents (e.g. mechlorethamine [nitrogen mustard]), phototherapy, and radiotherapy. In patients with stage IA disease even expectant management with active surveillance can be considered. The efficacy of skin-directed therapies in MF is explained by the preferential localization of the neoplastic skin-homing T cells to the epidermis and superficial dermis. Systemic multi-agent chemotherapy is not useful in these early stages, since it does not improve survival and is associated with considerable morbidity.

In patients with refractory or progressive skin disease, skin-directed therapies can be combined with IFN-α or systemic retinoids. Alternatively, novel agents such as denileukin diftitox, mogamulizumab, or *h*istone *deac*etylase *i*nhibitors (HDACi) such as vorinostat and romidepsin can be used, before systemic chemotherapy is considered. HDACi and denileukin diftitox have been approved by the FDA for patients with relapsed and refractory CTCL, but they have not been registered for CTCL in Europe. While denileukin diftitox was withdrawn from the market in 2014, a revised version is currently under investigation. In general, systemic chemotherapy is only indicated in advanced stages when there is nodal or visceral involvement or in patients with rapidly progressive tumors unresponsive to less aggressive therapies.

TREATMENT OF MYCOSIS FUNGOIDES
Premycotic phase
• Topical or intralesional corticosteroids; narrowband UVB*
• If former not effective, PUVA*
Stage IA–IIA (patches/plaques)
• PUVA*; HN2 (see Ch. 129)
• Narrowband UVB* (if only patches)
• Topical corticosteroids, topical retinoids†, or topical imiquimod (if only limited patches/thin plaques as second-line therapy)
• Local radiotherapy (if single lesion)
• TSEB (if generalized thick plaques)
Stage IIB (skin tumors)
• PUVA or HN2 + local radiotherapy (if only a few tumors)
• TSEB (followed by skin-directed therapies)
• Relapse: PUVA + IFN-α; PUVA + retinoids (acitretin; oral bexarotene‡); second-line therapy: HDACi (romidepsin, vorinostat)‡
• Add local radiotherapy (if persistent tumors); consider second course of TSEB (10–20 Gy)
Stage III (erythroderma)
• ECP; if not effective, add IFN-α and/or systemic retinoids
• Low-dose methotrexate
• Add skin-directed therapies (PUVA; HN2; local radiotherapy), if necessary
• Second-line therapy: oral bexarotene‡; HDACi‡; low-dose alemtuzumab
Stage IV (nodal, visceral involvement)
• Brentuximab vedotin
• Gemcitabine
• Liposomal doxorubicin
• Pralatrexate
• Multi-agent chemotherapy (e.g. CHOP) (becoming historical)
• Mogamulizumab¶,§
• Add skin-directed therapies (PUVA; HN2), if necessary
• Allogeneic hematopoietic stem cell transplantation (utilizing reduced-intensity conditioning regimens)
*Address UV-shielded areas (e.g. upper inner thighs) via positioning.
†Bexarotene 1% gel (FDA approved for CTCL), tazarotene 0.1% gel, alitretinoin 0.1% gel.
‡Efficacy compared to traditional treatments yet to be determined.
¶Most effective in patients with blood involvement (B2).
§Do not administer if considering allogeneic hematopoietic stem cell transplantation as can worsen graft versus host disease.

Table 120.5 Treatment of mycosis fungoides. Topical bis-chloronitrosourea (BCNU; carmustine) is rarely used nowadays. Anti-PD-1 antibodies have been used to treat Sézary syndrome in the setting of PD-1 positivity and anti-staphylococcal antibiotics may lead to improvement. Use of dupilumab has been reported to lead to worsening of disease. CHOP, cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin® (vincristine) and prednisone; ECP, extracorporeal photopheresis; HDACi, histone deacetylase inhibitors; HN2, topical mechlorethamine (nitrogen mustard); IFN, interferon; TSEB, total skin electron beam.

Skin-directed therapies

Topical corticosteroids

In many MF patients with only patches and thin plaques, application of topical corticosteroids is effective in controlling disease activity. In patients with limited patch/plaque stage disease (mainly patches), complete remissions in up to 60% of patients have been reported. In more advanced stages, they continue to be an important adjuvant therapy.

Topical chemotherapy

Topical application of mechlorethamine has proven to be an effective treatment for early stage MF. Mechlorethamine, either dissolved in water or compounded in an ointment- or gel-based preparation (see Ch. 129), results in complete remissions in approximately 60%–80% of patients with stage IA–B disease. Side effects include skin irritation, allergic contact dermatitis, and an increased risk for the development of skin cancer related to long-term use.

Radiotherapy

Total skin electron beam irradiation (TSEB) with an energy of 4–6 MeV is a highly effective treatment in patients with skin-limited MF (see Ch. 139). The total dose is traditionally 36 Gy administered in fractions of 1.5–2 Gy over an 8- to 10-week period. Recently, lower total doses (10–12 Gy) have been employed, with the advantages of a shorter duration of treatment, fewer side effects, and opportunity for re-treatment. TSEB is most effective in patients with stage IA–B disease, with complete response rates of >80%. However, in most centers, such patients are treated with phototherapy or topical chemotherapy. TSEB is particularly useful in patients with tumor stage MF, where complete response rates of ~40% have been reported. Side effects are generally mild and include erythema, scaling, and temporary loss of hair, nails, and sweat gland function.

Local radiotherapy with X-ray or preferably electron beam may be considered for single tumors in patients with plaque stage disease, either in combination with other modalities (e.g. PUVA) as an alternative to TSEB, or for new tumors following TSEB. A dose of ≥8 Gy suffices. In patients with unilesional MF, local radiotherapy may be curative.

Phototherapy

Several types of phototherapy can be used in the treatment of MF, in particular PUVA therapy and narrowband UVB therapy (Ch. 134). Extracorporeal photopheresis (ECP) may be effective in patients with erythrodermic MF (see the section on Sézary syndrome).

PUVA treatment has become a standard therapy for the early stages of MF. In patients with stages IA–IIA, complete response rates of 80%–90% have been reported. In many centers, maintenance PUVA therapy (every 2 to 4 weeks) is given to prolong remission. Although sustained complete remissions have been reported, most patients will relapse after cessation of PUVA therapy or during maintenance treatment. Recurrent or persistent lesions particularly favor UV-shielded areas, such as the inner thighs and

the gluteal cleft. In tumor stage MF, PUVA therapy alone is unlikely to result in complete responses, but favorable results may be achieved when combined with systemic retinoids, IFN-α, or radiotherapy.

In patients with only patches, *narrowband UVB* therapy (311 nm) represents first-line therapy.

Systemic therapies (other than chemotherapy)

Interferons

The most commonly prescribed biological response modifier has been interferon-alpha (IFN-α). In most centers, IFN-α is administered subcutaneously in doses of 3 to 9 million units three times a week. Side effects include flu-like symptoms, hair loss, nausea, depression, and bone marrow suppression and although they are generally mild and reversible, dose reductions are commonplace. The overall response rate of IFN-α, when used as a single agent, is ~50%, with 17% representing complete remissions. The combination of PUVA and IFN-α appears to produce higher response rates than PUVA alone, and this combination may also be considered in patients with early tumor stage disease, when PUVA therapy alone is insufficient.

Retinoids

When used as a single agent, the overall and complete response rates of several first- and second-generation oral retinoids (isotretinoin, acitretin) and a novel RXR-selective retinoid (bexarotene) are roughly similar to those of IFN-α. A combination of retinoids (including bexarotene) plus PUVA (RePUVA) produces response rates similar to those of PUVA alone, although patients treated with RePUVA require fewer treatments and a lower cumulative UVA dose. In many centers, bexarotene has replaced the earlier-generation retinoids (see Table 126.4), but comparative studies have never been performed. In patients with patches or thin plaques, topical retinoids (bexarotene 1% gel [FDA approved for CTCL], tazarotene 0.1% gel, alitretinoin 0.1% gel) may be considered, but skin irritation is a limiting factor.

Denileukin diftitox

Denileukin diftitox is a fusion protein, in which diphtheria toxin is linked to IL-2. It binds to the high-affinity IL-2 receptor expressed by the neoplastic T cells in MF, and internalization of the toxin results in inhibition of protein synthesis and cell death. Overall and complete clinical response rates are ~30% and 10%, respectively. Denileukin diftitox can have substantial side effects, including capillary leak syndrome, fever, and fluid retention. A revised version is currently under investigation (see above).

Histone deacetylase inhibitors

HDACi, such as vorinostat and romidepsin, represent a novel class of drugs used in cancer therapy. Inhibition of the enzyme HDAC affects the expression of many genes (and their protein products) that are involved in cellular proliferation, differentiation, migration, and apoptosis. Studies of both vorinostat and romidepsin report overall response rates of ~35% in patients with MF and SS, but complete responses are rare. The most common side effects are fatigue, gastrointestinal symptoms, and reversible thrombocytopenia. It remains to be determined which patients are most likely to benefit from this therapy.

Mogamulizumab

Discussed in SS treatment section.

Systemic chemotherapy

In patients with advanced and refractory disease, gemcitabine or liposomal doxorubicin may be considered, but responses are generally short-lived. More recently, high response rates have been reported with brentuximab vedotin (an anti-CD30 monoclonal antibody coupled to the anti-tubulin agent monomethyl auristatin E) in patients with advanced, CD30-expressing MF/SS[26]. Systemic multi-agent chemotherapy should only be used in patients with unequivocal lymph node or visceral involvement, or in patients with progressive skin tumors that have failed to respond to other therapies. In many centers, the standard treatment in such cases was the administration of six cycles of CHOP (*c*yclophosphamide, *h*ydroxydaunomycin [doxorubicin], *O*ncovin® [vincristine] and *p*rednisone). However, with this and other combination regimens, high response rates can be achieved for extracutaneous involvement, but as with single-agent chemotherapy, the responses are generally short-lived. Moreover, concurrent patches and plaques are often less responsive, and may require additional treatment with PUVA or mechlorethamine.

In young patients with refractory, progressive MF and SS, an allogeneic hematopoietic stem cell transplantation (HSCT) may be considered. Using reduced-intensity conditioning regimens, durable responses have been reported, but the optimal conditioning regimen and optimal timing for the transplant are still a matter of debate[27]. Prior to transplantation, patients may benefit from tumor debulking via TSEB or brentuximab vedotin[24]. Results with autologous HSCT in MF and SS have been disappointing, suggesting the need for a graft-versus-tumor response.

Prognosis

The prognosis of patients with MF is dependent on the stage, and in particular the type and extent of skin lesions and the presence of extracutaneous disease[20]. Patients with limited patch/plaque stage MF have a similar long-term life expectancy as an age-, sex-, and race-matched control population. The disease-related 10-year survival is 96% for stage IA, 77%–83% for stage IB, 42% for stage IIB, but only 20% for stage IV[20]. Patients usually die of systemic involvement or infections.

VARIANTS OF MYCOSIS FUNGOIDES

Apart from the classic Alibert–Bazin type of MF, many clinical and/or histologic variants have been reported. Clinical variants, such as bullous and hyper- or hypopigmented MF, have clinical behavior similar to that of classic MF, and they are therefore not considered separately. In contrast, folliculotropic MF, pagetoid reticulosis, and granulomatous slack skin have distinctive clinicopathologic features, clinical behavior and/or prognosis, and therefore they have been included as distinct variants or subtypes of MF in the WHO-EORTC classification scheme.

Folliculotropic MF

Synonyms: ■ Adnexotropic (folliculotropic and syringotropic) MF ■ Folliculocentric MF ■ Pilotropic MF ■ MF-associated follicular mucinosis

Definition

Folliculotropic MF is a distinct variant of MF characterized by the presence of folliculotropic infiltrates, often with sparing of the epidermis and preferential involvement of the head and neck region. Most cases show mucinous degeneration of the hair follicles (follicular mucinosis; Ch. 46) and are traditionally designated as MF-associated follicular mucinosis. Similar cases, but without follicular mucinosis, have been reported as pilotropic MF. Compared with classic MF, folliculotropic MF was previously said to have a worse prognosis. However, when more recent studies defined subgroups of early and advanced folliculotropic MF, the prognosis was similar to early and advanced stage classic MF[28,29].

Epidemiology

This variant is found in ~10%–20% of MF patients. It occurs mostly in adults, but may occasionally affect children and adolescents. Men are affected more often than women.

Clinical features

Patients may present with (grouped) follicular papules, acneiform lesions, indurated plaques, and sometimes tumors, which preferentially involve and are most pronounced in the head and neck area (see Fig. 36.15C). Infiltrated plaques in the eyebrow region with concurrent alopecia are a common and highly characteristic finding (Fig. 120.6A). Some patients may have keratosis pilaris-like lesions located primarily on the trunk and extremities and they are often associated with alopecia. Rarely, patients present with either a solitary cutaneous lesion (solitary or unilesional folliculotropic MF) or erythroderma. Sometimes a prominent feature is eruptive small cysts and comedones (comedonal MF; see Fig. 36.15D). Pruritus is often more severe than in classic MF and may represent a reliable parameter of disease activity. Secondary bacterial infections are frequently observed.

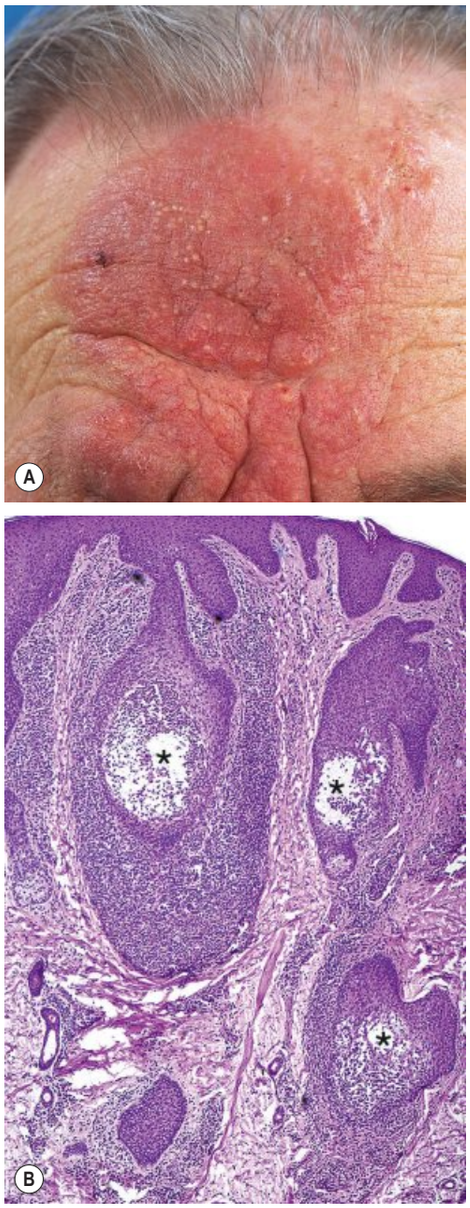

Fig. 120.6 Folliculotropic mycosis fungoides. A Infiltrated plaques on the forehead and eyebrow with concurrent hair loss. **B** Characteristic perifollicular infiltrates with extensive follicular mucinosis (asterisks). Note absence of epidermotropism.

Pathology

There are perifollicular infiltrates, with variable infiltration of the follicular epithelium by small, medium-sized, or sometimes large T cells with cerebriform and hyperchromatic nuclei[30]. Infiltration of the interfollicular epidermis, characteristic of early stage classic MF, is uncommon; i.e. folliculotropism rather than epidermotropism is seen (Fig. 120.6B). Although mucinous degeneration of the follicular epithelium (follicular mucinosis), which can be visualized by Alcian blue or colloidal iron staining is often present, cases without follicular mucinosis have been described. Infiltration of the follicular epithelium may be accompanied by infiltration of the eccrine sweat glands (syringotropism), a combination that is often referred to as adnexotropic MF.

In early stage lesions such as patches with follicular prominence and acneiform or keratosis pilaris-like lesions, the perifollicular infiltrates are generally sparse and contain variable numbers of small reactive T cells, histiocytes, and occasional eosinophils, in addition to atypical T cells. The perifollicular infiltrates in plaques or tumors are more dense and more diffuse and may contain an increasing number of blast cells. There is often a considerable admixture with eosinophils, and especially if there is secondary bacterial infection, plasma cells. If the hair follicle epithelium is destroyed, a granulomatous reaction can be observed. Large cell transformation has been reported in >20% of folliculotropic MF cases and is more common than in classic MF[28]. As a result, an admixture of CD30-positive blast cells with $CD3^+$, $CD4^+$, $CD8^-$ neoplastic T cells (most common phenotype as in classic MF) is often observed.

Differential diagnosis

The distinctive clinical and histologic features should facilitate an early and correct diagnosis. However, because of the preferential involvement of the head and neck area, the absence of patches and plaques on the trunk and buttocks, and particularly because of the absence of epidermotropic atypical T cells, the diagnosis of MF or CTCL is often not considered and is misinterpreted as seborrheic dermatitis or atopic dermatitis. Clinicopathologic correlation is also required to differentiate folliculotropic MF from other types of CTCL. The relationship between folliculotropic MF and the so-called benign or idiopathic form of follicular mucinosis (alopecia mucinosa) resembles the relationship between classic MF and "parapsoriasis". In the case of persistent generalized lesions of the idiopathic form, patients should be monitored regularly, since progression into overt folliculotropic MF has been reported. The unilesional form of follicular mucinosis occurs more often in children and does not progress to MF.

Treatment

Recognition of indolent and aggressive subgroups of folliculotropic MF is important as it supports a stepwise, stage-adapted therapeutic approach, similar to early and advanced stage classic MF[31]. Patients with early stage disease may do quite well with non-aggressive skin-directed therapies, such as topical corticosteroids, PUVA, or topical mechlorethamine. In patients with unresponsive disease, treatment options include PUVA plus local radiotherapy, IFN-α or retinoids, systemic retinoids alone, or TSEB. For those rare patients with a solitary plaque or tumor, local radiotherapy is the preferred mode of treatment.

Pagetoid Reticulosis

Synonyms: ■ Woringer–Kolopp disease ■ Unilesional MF

Definition

This is a rare variant of MF, characterized by the presence of localized patches or plaques with an intraepidermal proliferation of neoplastic T cells. The term pagetoid reticulosis should only be used for the localized type (Woringer–Kolopp type) and not for the disseminated type (Ketron–Goodman type). Nowadays, patients with generalized disease would most likely be classified as having primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T cell lymphoma, primary cutaneous gamma/delta T cell lymphoma, or tumor stage MF[1].

Epidemiology

Pagetoid reticulosis is extremely rare, and it accounts for fewer than 1% of CTCL cases. It mostly affects adults.

Clinical features

Patients present with a solitary, slowly progressive psoriasiform or hyperkeratotic patch or plaque. It usually develops on an extremity, in particular the hand or foot (Fig. 120.7A). In contrast to classic MF, extracutaneous dissemination or disease-related deaths have not been reported.

Pathology

The typical histologic picture consists of a hyperplastic epidermis with marked infiltration by large atypical pagetoid cells, arranged singly or in nests or clusters (Fig. 120.7B). The atypical cells have medium-sized or large, sometimes hyperchromatic and cerebriform nuclei and abundant, vacuolated cytoplasm. The superficial dermis may have an infiltrate of mostly small lymphocytes, but rarely contains neoplastic T cells.

Immunophenotype

The neoplastic T cells may show either a $CD3^+$, $CD4^+$, $CD8^-$ or a $CD3^+$, $CD4^-$, $CD8^+$ phenotype. CD30 is often expressed[32].

Differential diagnosis

Pagetoid reticulosis should be differentiated from other types of epidermotropic CTCL, such as MF, LyP type B, LyP type D, and primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T cell lymphoma (see Table 120.2). Useful criteria for pagetoid reticulosis include the characteristic clinical presentation and the often strictly epidermal localization of the neoplastic T cells.

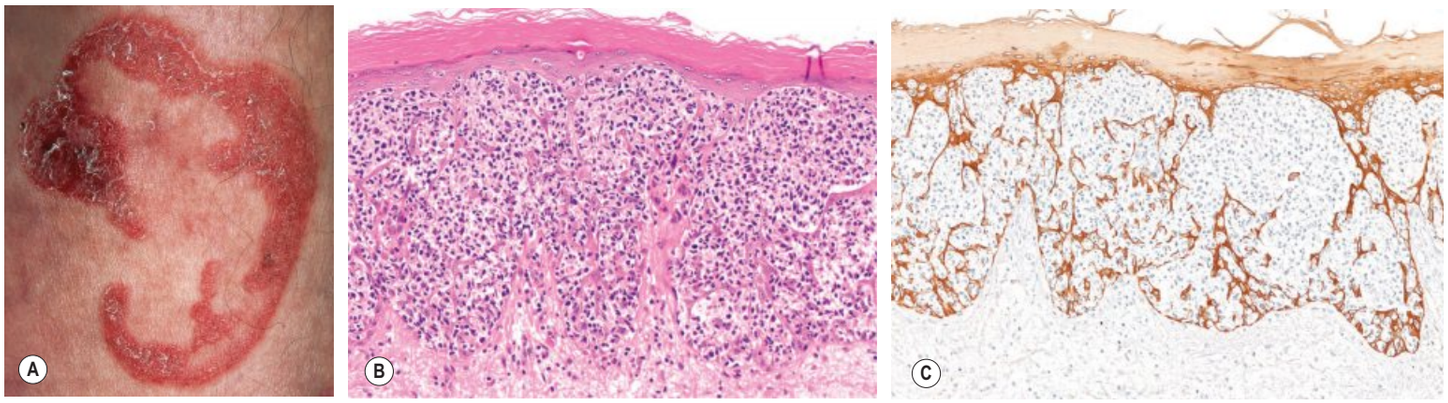

Fig. 120.7 Pagetoid reticulosis. A Solitary plaque on the left upper leg. **B** Purely intraepidermal proliferation of atypical T cells. **C** Immunohistochemical staining for keratin shows almost complete replacement of the epidermis by atypical T cells.

Treatment

The preferred mode of treatment is radiotherapy or surgical excision.

Granulomatous Slack Skin

Definition

This is an extraordinarily rare type of CTCL characterized by the slow development of folds of lax skin and a granulomatous infiltrate with clonal T cells.

Epidemiology

It is an extremely rare type of CTCL, with ~60 cases reported. It typically affects adolescents and adults, and mostly occurs in men.

Clinical features

This condition is characterized by circumscribed areas of pendulous lax skin with a predilection for the axilla and groin (Fig. 120.8A). In approximately one-third of the reported patients, an association with Hodgkin lymphoma was observed. Most patients have an indolent clinical course.

Pathology

Fully developed lesions show dense granulomatous dermal infiltrates that contain atypical T cells with cerebriform nuclei, macrophages, and often many multinucleated giant cells; destruction of elastic tissue and elastophagocytosis by the multinucleated cells is also seen (Fig. 120.8B). Phagocytized lymphocytes are usually present within the cytoplasm of some of the multinucleated histiocytic giant cells. The epidermis may be infiltrated by small atypical T cells with cerebriform nuclei, as in classic MF. The atypical T cells have a $CD3^+$, $CD4^+$, $CD8^-$ phenotype. A large study noted overlapping histologic features between granulomatous slack skin and granulomatous MF[33].

Treatment

Radiotherapy may be effective, but experience is still limited. Rapid recurrences after surgical excision have been reported.

Fig. 120.8 Granulomatous slack skin. A Pendulous fold of atrophic lax skin in the right inguinal area. **B** Multinucleated giant cells with intracellular leukocytes, surrounded by a dense leukocytic infiltrate. Inset: Elastic tissue stain showing a multinucleated giant cell containing an elastic fiber (elastophagocytosis).

SÉZARY SYNDROME

Definition

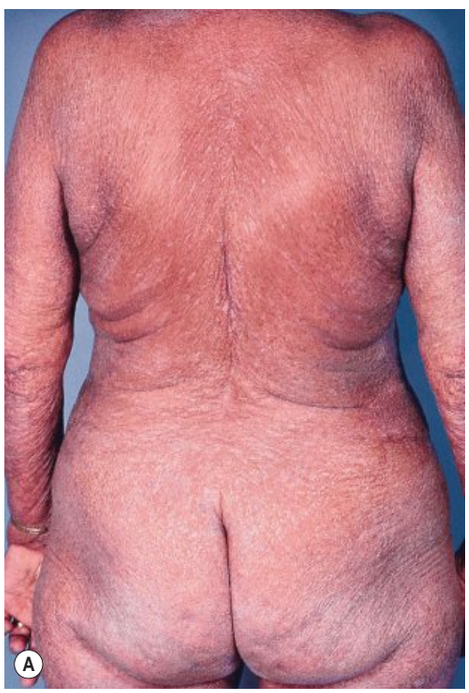
Sézary syndrome (SS) is defined historically by the triad of erythroderma, generalized lymphadenopathy, and the presence of neoplastic T cells (Sézary cells) in the skin, lymph nodes, and peripheral blood (see Table 120.4). Criteria for the diagnosis of SS include demonstration of a T cell clone in the peripheral blood (preferably the same T cell clone as in the skin), in combination with either an absolute Sézary cell count ≥1000 cells/mcl or immunophenotypic abnormalities including an expanded $CD4^+$ T cell population resulting in a CD4/CD8 ratio >10, $CD4^+CD7^-$ cells ≥40%, or $CD4^+CD26^-$ cells ≥30%[1]. While SS is often designated as a leukemic phase or variant of MF, more recent studies have revealed major genomic and phenotypic differences between these two entities, suggesting that SS and MF should be considered as separate lymphomas arising from distinct functional T cell subsets[34,35].

Epidemiology

SS is a rare disease accounting for <5% of all CTCL (see Table 120.1). It occurs exclusively in adults.

Clinical Features

SS is characterized by erythroderma, which may be associated with marked exfoliation, edema, and lichenification; it is intensely pruritic (Fig. 120.9A). Lymphadenopathy, alopecia, onychodystrophy, and palmoplantar hyperkeratosis are common findings. The overt clinical picture may be preceded by a non-diagnostic dermatitis. The prognosis is generally poor, with an overall 5-year survival of ~35%. Most patients die of opportunistic infections due to immunosuppression.



Pathology

The histologic features in SS may be similar to those in MF. However, the cellular infiltrates in SS are more often monotonous, and epidermotropism may be absent. In up to one-third of skin biopsies from patients with otherwise classic SS, the histologic findings may be nonspecific. Involved lymph nodes characteristically show a dense, monotonous infiltrate of Sézary cells with effacement of the normal lymph node architecture. The bone marrow may be involved, but the infiltrates are often sparse and mainly interstitial. The neoplastic T cells have a $CD3^+$, $CD4^+$, $CD8^-$ phenotype, characteristically lack CD7 and CD26 expression, and express programmed death-1 (PD-1; CD279) in almost all cases[5,36] (Fig. 120.9B).

Pathogenesis

The pathogenesis of SS is unknown. Conclusive evidence of an etiologic role for HTLV-1 is lacking. Previous studies suggested that the neoplastic $CD4^+$ T cells in SS patients were derived from central memory T cells and the neoplastic cells in MF from effector memory T cells. However, more recent studies found that Sézary cells may also be derived from other T cell subsets[35,36]. In addition, tumor cell populations in individual SS patients had a high degree of single-cell heterogeneity, and these distinct subpopulations of malignant T cells may differ in their sensitivity to treatments[37].

Studies of genetic alterations in SS have shown extensive genetic instability and complex structural and numerical alterations. Chromosomal aberrations include *deletions* involving chromosomes 10q22–25 (harbors *PTEN*) and 17p12–13 (includes *TP53*) and *gains* involving chromosomes 8q22–24 (includes *MYC*), 10p11.2, and 17q22–25[34,38]. Gene expression studies found increased expression of *PLS3* (T-plastin), *TWIST1*, *DNM3*, *EPH4* and *CD158k/KIR3DL2*, which might serve as diagnostic markers[5,36]. With next generation sequencing, alterations in genes that play a role in T cell activation, NF-κB and JAK-STAT signaling, apoptosis control, chromatin remodeling, and DNA damage response were identified[12].

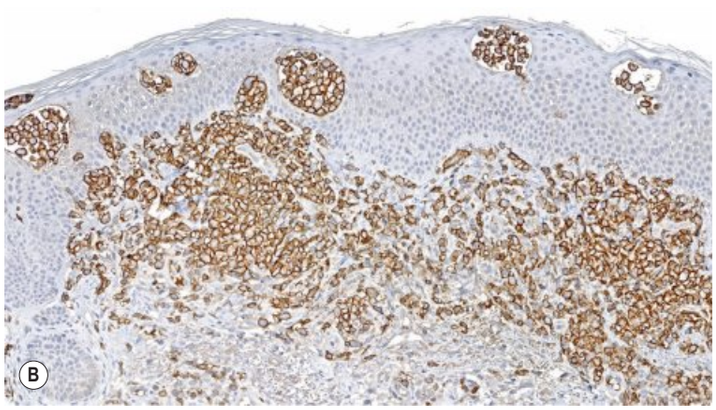


Fig. 120.9 Sézary syndrome. A Erythroderma with diffuse scaling. **B** Strong expression of PD-1 by neoplastic T cells within the dermal infiltrate and Pautrier microabscesses.

Differential Diagnosis

Differentiation between SS and non-neoplastic forms of erythroderma may be extremely difficult. The differential diagnosis includes erythroderma secondary to psoriasis, atopic dermatitis, or other forms of dermatitis, pityriasis rubra pilaris, and drug reactions as well as idiopathic erythroderma (see Ch. 10). Demonstration of an identical T cell clone in skin and peripheral blood is an important diagnostic criterion favoring SS. New biomarkers supporting a diagnosis of SS include PD-1 (CD279), TOX, and KIRDL2 (CD158k)[4,36]. Demonstration of a predominant $CD3^+$, $CD4^-$, $CD8^+$ T cell population in the skin and peripheral blood is highly suggestive of actinic reticuloid (see Ch. 87).

Treatment

Being a systemic disease (leukemia) by definition, systemic treatment is required. Skin-directed therapies like PUVA or potent topical corticosteroids may be used as adjuvant therapy. Extracorporeal photopheresis (ECP), either alone or in combination with other treatment modalities, has been suggested as the treatment of choice in SS and erythrodermic MF, with overall response rates of 30%–80%, and complete response rates of 14%–25%[24,25]. This great variation in response rates may reflect differences in patient selection and/or concurrent therapies. The suggested superiority of ECP over traditional low-dose chemotherapy regimens has not yet been substantiated by randomized controlled trials. Beneficial effects have also been reported with IFN-α (either alone or in combination with PUVA therapy) as well as prolonged treatment with methotrexate, but complete responses are uncommon.

Low-dose alemtuzumab (10 mg SC thrice weekly for 12 weeks), single-agent chemotherapy (gemcitabine, liposomal doxorubicin), or multi-agent chemotherapy (CHOP or CHOP-like regimens) have been recommended as second-line treatments for SS, but responses are generally short-lived[25]. Allogeneic HSCT may have curative potential, even in patients with advanced disease (see MF treatment). The monoclonal antibody mogamulizumab targets the CC chemokine receptor 4 (CCR4), which is consistently expressed on malignant T cells in MF/SS as well as on Th2, Th17, and regulatory T cells, resulting in their destruction via antibody-dependent cellular cytotoxicity. While mogamulizumab has shown significant clinical efficacy in both MF and SS, it is most effective in patients with blood involvement[39]. Patients may develop a mogamulizumab-associated rash (MAR) that often favors the head and neck and may mimic MF[39a]. Clinical presentation is variable and may include folliculotropic MF-like scalp lesions with alopecia, photodistributed dermatitis, a morbilliform eruption, and erythroderma. Histologically, psoriasiform, spongiotic, lichenoid, and/or granulomatous patterns can be seen. Demonstration of an inverted or normalized CD4:CD8 ratio of intraepidermal T cells and an absence of clonal T cells may be useful criteria for differentiating MAR from recurrent MF/SS. Treatment options include high potency topical corticosteroids, systemic corticosteroids, and/or methotrexate; increasing the dosing interval or discontinuation of mogamulizumab may be considered[39b].

ADULT T CELL LEUKEMIA/LYMPHOMA

Definition

Adult T cell leukemia/lymphoma (ATLL) is a type of T cell neoplasm etiologically associated with HTLV-1. Skin lesions are generally a manifestation of widely disseminated disease. However, a slowly progressive form that sometimes has only cutaneous lesions has been described (smoldering variant)[40].

Epidemiology

ATLL is endemic in areas with a high prevalence of HTLV-1 in the population, such as southwestern Japan, the Caribbean Islands, and parts of Central Africa. In addition, a high prevalence is seen in Jewish individuals whose ancestors were from Mashhad, Iran. However, only a minority of seropositive patients eventually develop ATLL. The disease occurs in adults, and men are affected more frequently than women. Vertical transmission is more common than horizontal transmission.

Clinical Features

Most patients present with acute ATLL characterized by the presence of leukemia, lymphadenopathy, organomegaly, hypercalcemia, and frequently skin lesions (Fig. 120.10); it has a poor prognosis. Chronic and smoldering variants often present with patches, plaques, and papular skin lesions, which may closely resemble MF, and circulating neoplastic T cells are few or absent. Such cases have a more protracted clinical course, but progression to a high-grade malignant disseminated form of the disease may occur.

Pathology

Skin lesions demonstrate a superficial or more diffuse infiltration of small, medium-sized, or large pleomorphic T cells, which often display marked epidermotropism. The histologic picture may be indistinguishable from MF. Skin lesions in the smoldering type may have sparse dermal infiltrates with only slightly atypical cells. The neoplastic T cells express a $CD3^+$, $CD4^+$, $CD8^-$, $CD25^+$ phenotype, and – as in SS – strongly express PD-1.

Differential Diagnosis

Differentiation between chronic or smoldering variants of ATLL and MF may be extremely difficult, particularly in endemic areas. In such cases, a definite diagnosis of ATLL requires demonstration of clonally integrated HTLV-1. Some patients have a preceding history of HTLV-1-associated infective dermatitis (see Ch. 13).

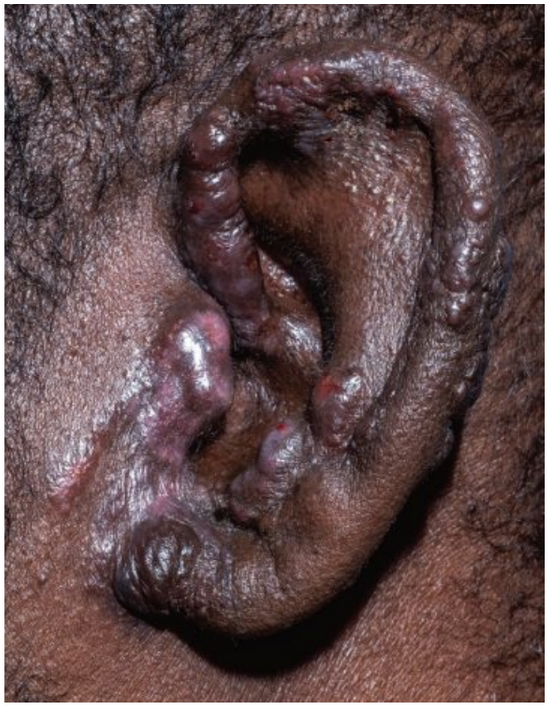

Fig. 120.10 Adult T cell leukemia/lymphoma (ATLL). Multiple papulonodules, a few of which are eroded, of the external ear. *Courtesy Edward Cowen, MD.*

Treatment

ATLL may be treated with a combination of zidovudine and IFN-α, but in most cases, systemic chemotherapy is required[41]. In Japan, mogamulizumab (anti-CCR4) is approved for treating ATLL. For chronic and smoldering disease mainly affecting the skin, skin-directed therapies as in MF are preferred.

PRIMARY CUTANEOUS CD30-POSITIVE LYMPHOPROLIFERATIVE DISORDERS

Primary cutaneous CD30-positive lymphoproliferative disorders represent the second most common group of CTCL, accounting for ~25% of CTCL (see Table 120.1). This group includes primary cutaneous anaplastic large cell lymphoma (C-ALCL), lymphomatoid papulosis (LyP), and borderline cases. C-ALCL and LyP have overlapping clinical, histologic, and immunophenotypic features and form a spectrum of disease (Fig. 120.11). Thus, histologic criteria alone are often insufficient to distinguish between the two ends of the spectrum. In the end, the clinical appearance and course are used as decisive criteria for the definite diagnosis and choice of treatment. The term "borderline case" refers to patients in whom, despite careful clinicopathologic correlation, a definite distinction between C-ALCL and LyP cannot be made. Longitudinal clinical evaluation will generally disclose whether the patient has C-ALCL or LyP[42].

Guidelines for the diagnosis and treatment of primary cutaneous CD30-positive lymphoproliferations are provided in Fig. 120.11.

Primary Cutaneous Anaplastic Large Cell Lymphoma

Definition

Primary cutaneous anaplastic large cell lymphoma (C-ALCL) is composed of large cells with an anaplastic, pleomorphic, or immunoblastic cytomorphology and expression of the CD30 antigen by the majority (>75%) of tumor cells. Patients should not have clinical evidence of or a history of MF. In such individuals, a diagnosis of tumor stage MF with large cell transformation is more likely.

Epidemiology

These lymphomas account for ~10% of all CTCLs (see Table 120.1). They predominantly affect adults and are rare in children or adolescents. The male-to-female ratio is approximately 2:1.

Clinical features

Most patients present with solitary or localized nodules or tumors (sometimes papules) that often develop ulceration (Fig. 120.12A). Multifocal lesions are seen in about 15% of patients. The skin lesions may show partial or complete spontaneous regression, as in LyP. These lymphomas frequently relapse in the skin. Extracutaneous dissemination occurs in 10%–15% of patients, and it mainly involves the regional lymph nodes. The prognosis is usually favorable, with a 10-year disease-related survival exceeding 85%[43,44]. However, patients who present with extensive skin lesions on the leg have a reduced survival rate[43].

Pathology

Histologically, these lymphomas show diffuse non-epidermotropic infiltrates with cohesive sheets of large CD30-positive tumor cells (Fig. 120.12B). In most cases, the tumor cells have the characteristic morphology of anaplastic cells, with round, oval or irregularly shaped nuclei, prominent (eosinophilic) nucleoli, and abundant cytoplasm. Less commonly (20%–25%), tumor cells have a pleomorphic, immunoblastic, or Reed–Sternberg cell-like appearance. The mitotic index is generally high. Reactive lymphocytes are often present at the periphery of the tumor.

Ulcerating lesions may show LyP-like histology with an abundant inflammatory infiltrate of reactive T cells, histiocytes, eosinophils, neutrophils, and relatively few CD30-positive cells. In such cases, epidermal hyperplasia may be prominent at the edge of the ulceration.

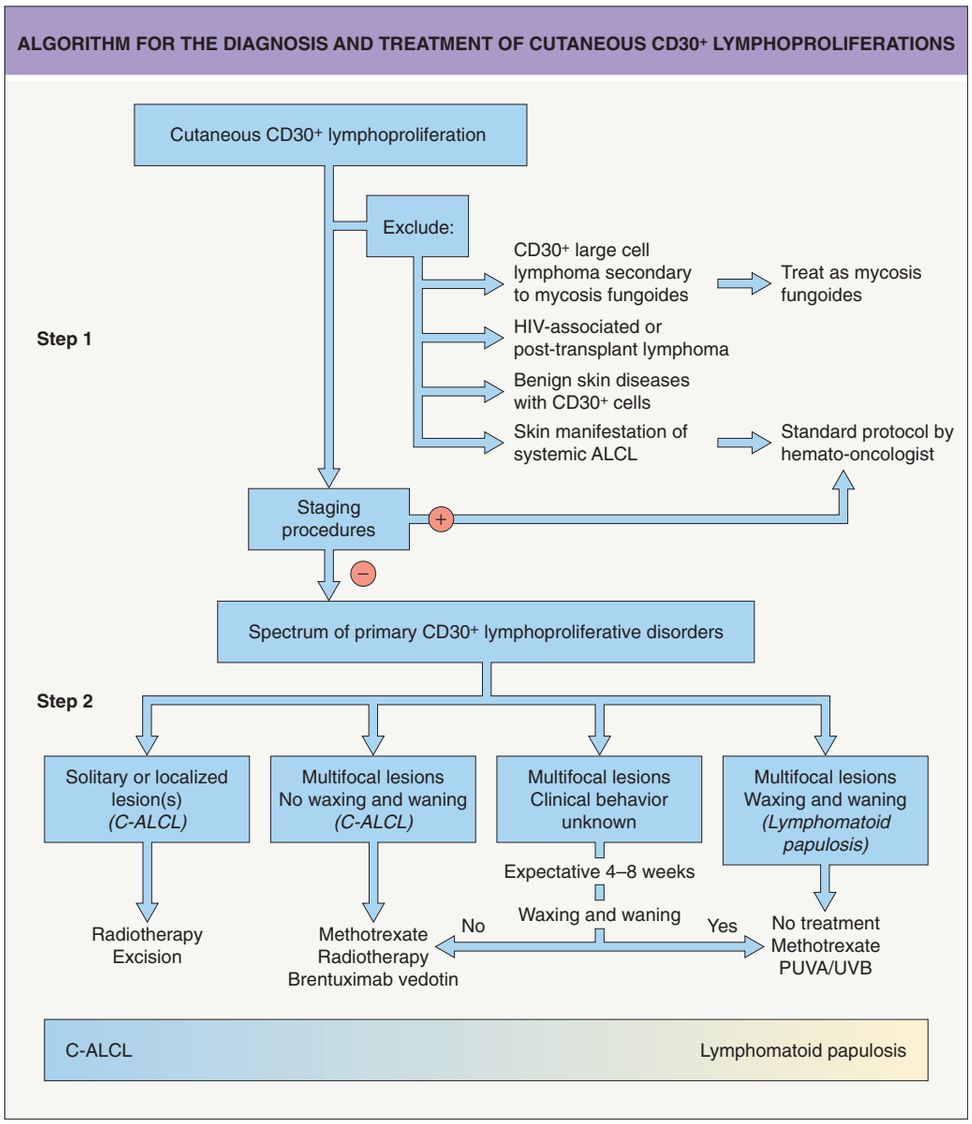

Fig. 120.11 Algorithm for the diagnosis and treatment of primary cutaneous CD30-positive lymphoproliferations. Cases previously designated as regressing atypical histiocytosis, as well as rare cases of primary cutaneous Hodgkin lymphoma with an indolent clinical course, also belong to this spectrum. Of note, there are reports of ALCL developing in patients with breast implants. C-ALCL, cutaneous anaplastic large cell lymphoma. *From reference* 42.

Intralymphatic complexes of tumor cells are common, and purely intralymphatic cases of C-ALCL have been observed[45].

Immunophenotype

The neoplastic cells often express a CD4+ T cell phenotype with variable loss of CD2, CD5, and/or CD3. Some cases (<5%) have a CD8+ T cell phenotype. *CD30 must be expressed by the majority of neoplastic cells*. Expression of cytotoxic proteins (granzyme B, TIA-1, perforin) is noted in ~70% of cases, while MUM1/IRF4 (multiple myeloma oncogene 1/interferon regulatory factor 4) is expressed in almost all cases[45]. Unlike systemic ALCL, most C-ALCLs express CLA (cutaneous lymphocyte antigen), but do not express EMA (epithelial membrane antigen) or ALK (anaplastic lymphoma kinase); the latter is indicative of a t(2;5) chromosomal translocation.

Genetic features

The t(2;5) *translocation*, which is found predominantly in systemic ALCL in children, is not present in the vast majority of C-ALCLs. However, unusual cases of ALK+ C-ALCL have been reported, both in children and in adults, including cases with: (1) strong nuclear and cytoplasmic staining characteristic of the t(2;5) chromosomal translocation; or (2) expression of cytoplasmic ALK protein, indicative of a variant translocation[46,47]. While many of these patients had an excellent prognosis, rapid progression to systemic ALCL has been reported. *Rearrangements* of the *DUSP22-IRF4* locus on chromosome 6p25.3 are found in ~25% of C-ALCLs and in a small subset of LyP, but do not have prognostic significance[48].

Rearrangements of *TP63* on chromosome 3q28 are associated with poor survival in ALK-negative systemic ALCL, but are not or only rarely found in C-ALCL. A novel recurrent *NPM1-TYK2 gene fusion*, resulting in constitutive STAT signaling, has been described in both C-ALCL and LyP. In addition, *TYK2* breaks were found in 15% of primary cutaneous CD30+ T cell lymphoproliferative disorders[49].

Frequent *chromosomal aberrations*, found in almost half of the patients with C-ALCL, are gains of 7q31 and losses on 6q16–21 and 13q34[50]. In contrast to tumor stage MF and PTCL, NOS, loss of 9p21.3 is rarely observed in C-ALCL. Gene expression profiling has demonstrated high expression of skin-homing chemokine receptor genes *CCR10* and *CCR8* in C-ALCL, which may explain its affinity for the skin and low incidence of dissemination to extracutaneous sites[50].

Treatment

Radiotherapy or surgical excision is first-line therapy in patients presenting with a solitary or a few localized nodules or tumors[25,51]. However, if a solitary lesion disappears spontaneously, no further therapy is required. Patients presenting with multifocal skin lesions can be treated with radiotherapy (if there are only a few lesions) or low-dose methotrexate as in LyP. Brentuximab vedotin has shown high response rates in patients with primary cutaneous CD30-positive lymphoproliferations and is used to treat multifocal skin lesions refractory to conventional therapies as well as extracutaneous disease[25,26]. Multiagent chemotherapy is only indicated for extracutaneous disease beyond locoregional lymph nodes and those rare patients with rapidly progressive skin disease unresponsive to brentuximab vedotin.

Lymphomatoid Papulosis

Definition

Lymphomatoid papulosis (LyP) is defined as a chronic, recurrent, self-healing papulonecrotic or papulonodular skin disease with histologic

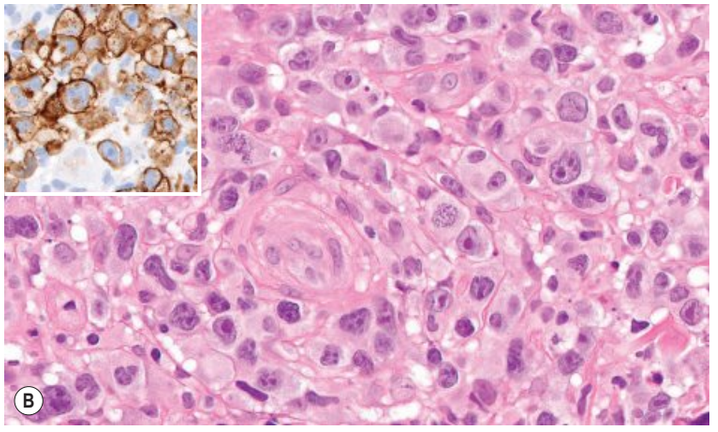

Fig. 120.12 Primary cutaneous anaplastic large cell lymphoma. **A** Characteristic clinical presentation with a solitary tumor. **B** Detail of dermal infiltrate showing cohesive clusters of large (CD30-positive [inset]) anaplastic cells with pronounced eosinophilic nucleoli and abundant cytoplasm.

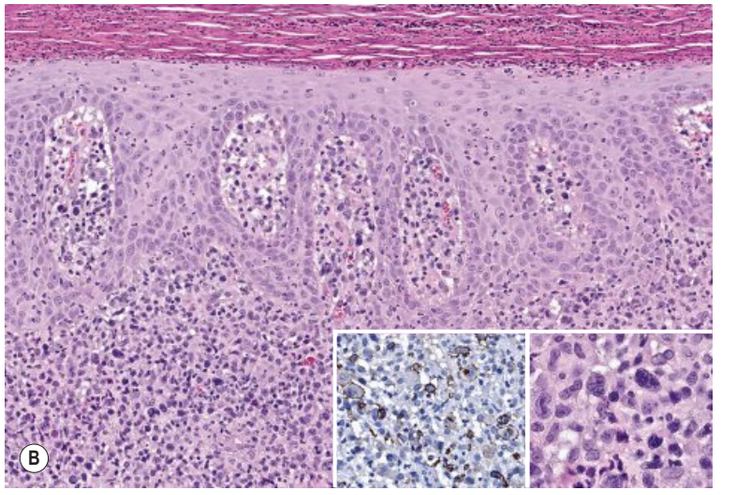

Fig. 120.13 Lymphomatoid papulosis (LyP). **A** Clinical presentation with papulonecrotic skin lesions at different stages of evolution. **B** Dense dermal infiltrate with scattered large anaplastic cells that have prominent nucleoli and abundant cytoplasm (right inset). Note the sprinkling of neutrophils within the epidermis. Immunohistochemical stain of type A LyP demonstrates scattered large $CD30^+$ cells (left inset).

features suggestive of a (CD30-positive) malignant lymphoma. Since the introduction of the term LyP in 1968 by Macaulay, there has been continued discussion as to whether LyP is a malignant, premalignant, or benign condition. Because of the overlapping clinical and histologic features between LyP and C-ALCL, including the presence of an aberrant T cell phenotype, the presence of clonally rearranged TCR genes in 60%–70% of the patients, and the presence of identical T cell clones in LyP lesions and associated lymphoma lesions, LyP is best regarded as a low-grade variant of CTCL.

Pathogenesis

The initiating event in LyP is unknown. Several authors have suggested a viral etiology. However, studies searching for an etiologic role for HTLV-1, EBV, and other herpes viruses, including herpes simplex virus types 1 and type 2 and human herpesvirus-6, have been consistently negative. The mechanisms involved in the spontaneous disappearance of skin lesions, or in the tumor progression observed in some patients with LyP, have not yet been identified. It has been suggested that interactions between CD30 and its ligand (CD30L) may contribute to apoptosis of the neoplastic T cells and the subsequent regression of the skin lesions, but the exact mechanism is as yet unknown[45,49].

Epidemiology

LyP accounts for ~15% of all CTCL (see Table 120.1). It may occur at any age. The youngest patient reported to date was 8 months old, and the oldest was 92 years of age. In large series, the average age of onset is 45 years[52]. The male-to-female ratio is approximately 1.5:1.

Clinical features

The typical skin lesions in LyP are red–brown papules and nodules that may develop central hemorrhage, necrosis, and crusting; they subsequently disappear spontaneously within 3 to 12 weeks. Characteristically, skin lesions in different stages of evolution coexist (Fig. 120.13A). The papulonodules may leave transient hypopigmented or hyperpigmented macules and occasionally, superficial atrophic (varioliform) scars, or they may disappear without ulceration or sequelae. The number of lesions varies from several to more than one hundred. Lesions may be localized, sometimes clustered within rather well-defined areas, or generalized. The predominant sites of involvement are the trunk and limbs, and very rarely, concurrent intraoral lesions are present. The eruption is generally asymptomatic.

The duration of the disease ranges from several months to more than 40 years. In up to 20% of patients, LyP may be preceded by, associated with, or followed by another type of cutaneous or systemic lymphoma, generally MF or C-ALCL[52]. However, the prognosis is usually excellent. In a study of 504 patients with LyP, only 14 patients (3%) developed a systemic lymphoma, and only five patients (1%) died of systemic disease over a median follow-up period of 120 months[52]. Risk factors for the development of a systemic lymphoma are unknown.

Pathology

The histologic picture of LyP is extremely variable, which in part correlates with the age of the sampled skin lesion (Fig. 120.13B). In addition, several histologic types of LyP have been described (Table 120.6), with LyP type A being the classic and most common type of LyP (>75%)[42]. It should be noted that different types of LyP may occur in different but

LYMPHOMATOID PAPULOSIS (LyP) – HISTOLOGIC SUBTYPES AND THEIR DIFFERENTIAL DIAGNOSES		
LyP type	**Characteristic histologic features**	**Primary differential diagnosis**
Type A	Wedge-shaped infiltrate with scattered or small clusters of large, atypical, sometimes multinucleated or Reed–Sternberg-like, $CD30^+$ T cells The T cells are within an extensive inflammatory infiltrate composed of small lymphocytes, histiocytes, neutrophils, and/or eosinophils Neutrophils may be scattered within the epidermis	C-ALCL Tumor stage MF Hodgkin lymphoma
Type B	Epidermotropic, with a superficial perivascular to band-like and sometimes wedge-shaped infiltrate of small to medium-sized, atypical $CD4^+$, $CD30^+$ T cells	Patch/plaque stage MF
Type C	Diffuse infiltrates or large clusters of large $CD30^+$ T cells, with relatively few admixed inflammatory cells	C-ALCL Transformed MF ($CD30^+$)
Type D	Marked epidermotropism of atypical, small to medium-sized, $CD8^+$, $CD30^+$ pleomorphic T cells Necrotic keratinocytes may be present	Primary cutaneous aggressive epidermotropic $CD8^+$ cytotoxic T cell lymphoma Pityriasis lichenoides et varioliformis acuta
Type E	Prominent angioinvasion and angiodestruction by medium-sized $CD8^+$, $CD30^+$ pleomorphic T cells Vascular occlusion and/or thrombi; hemorrhage, extensive necrosis, and ulceration	Extranodal NK/T cell lymphoma
Type F	Perifollicular infiltrates with variable degree of folliculotropism of atypical $CD30^+$ T cells	Folliculotropic MF
DUSP-IRF4 type*	Extensive epidermotropism by weakly $CD30^+$ small to medium-sized T cells with cerebriform nuclei Strongly $CD30^+$ medium-sized to large blast cells in the dermis	Transformed MF C-ALCL
*Chromosomal rearrangements involving the *DUSP-IRF4* locus on 6p25.3; localized skin lesions in older individuals.		

Table 120.6 Lymphomatoid papulosis (LyP) – histologic subtypes and their differential diagnoses. C-ALCL, cutaneous anaplastic large cell lymphoma; MF, mycosis fungoides. *Adapted from Kempf W. A new era for cutaneous CD30-positive T-cell lymphoproliferative disorders. Semin Diagn Pathol 2017;34:22–35.*

concurrent lesions, and that a single LyP lesion may show histologic features of different subtypes of LyP. Knowledge of the variable histologic presentations of LyP is more important for pathologists than for clinicians as the subtype has no therapeutic or prognostic implications.

Differential diagnosis

LyP is often diagnosed clinically as more common entities. Small recurrent LyP lesions on the trunk are frequently misinterpreted as folliculitis or arthropod bites for years, and notably, $CD30^+$ cells can be observed in many benign conditions, including various viral infections, arthropod bite reactions, scabies, atopic dermatitis, and drug reactions[45]. On the other hand, because of the presence of multifocal skin lesions with the histologic features of CD30-positive CTCL, LyP patients are regularly treated unnecessarily with multi-agent chemotherapy by physicians not familiar with this condition. Obviously, when the clinical features are taken into account, differentiation between LyP and the malignant lymphomas it may resemble histologically is not difficult.

Because of the clinical similarities between LyP and pityriasis lichenoides, a relationship between the two conditions was initially suggested. More recently, clonal T cell populations have been demonstrated in skin biopsies of both conditions. However, pityriasis lichenoides occurs more often in younger patients, is often relatively short-lived, does not develop nodular lesions, and rarely, if ever, progresses to a lymphoma. Histologically, the diseases are usually easily distinguished, and CD30-positive blast cells are generally not seen in pityriasis lichenoides, but in rare cases differentiation may be challenging[45] (see Ch. 9).

Treatment

The treatment of patients with LyP is unsatisfactory[51]. Topical or systemic corticosteroids and antibiotics are not effective. Aggressive treatment modalities such as systemic chemotherapy or TSEB irradiation may produce complete remissions, but after discontinuation of therapy, the LyP lesions generally reappear within weeks or months, and the disease follows its natural course. Since a curative therapy is not available and none of the available treatment modalities affects the natural course of the disease, the short-term benefits of active treatment should be balanced carefully against potential side effects[42,51].

In patients with relatively few non-scarring lesions, expectant management is reasonable. When there are cosmetically disturbing lesions (e.g. scarring or many papulonodules), low-dose oral methotrexate (5–20 mg/week) is the most effective therapy for reducing the number of skin lesions. PUVA therapy is also effective, but is less attractive if maintenance treatment is required. When larger skin tumors develop in the course of LyP, they can be observed for a period of 4 to 12 weeks for the possibility of spontaneous remission. If spontaneous resolution does not occur, such lesions can be excised or treated with radiotherapy. Because of the potential risk for developing a systemic lymphoma, long-term follow-up is required in all patients with LyP.

COMPARISON OF SUBCUTANEOUS PANNICULITIS-LIKE T CELL LYMPHOMA AND PRIMARY CUTANEOUS GAMMA/DELTA T CELL LYMPHOMA WITH SUBCUTANEOUS INVOLVEMENT		
	SPTCL	**PCGD-TCL with subcutaneous involvement**
Phenotype	α/β T cell phenotype	γ/δ T cell phenotype
T cell receptor	$\beta F1^+$, $TCR\gamma/\delta1^-$	$\beta F1^-$, $TCR\gamma/\delta1^+$
T cell phenotype	$CD3^+$, $CD4^-$, $CD8^+$	$CD3^+$, $CD4^-$, $CD8^-$
Coexpression of CD56	Absent	Common
Architecture	Subcutaneous	Subcutaneous and epidermal/dermal
Clinical features	Nodules and plaques Rarely ulceration	Nodules and plaques Ulceration common
Hemophagocytic lymphohistiocytosis (HLH)*	Uncommon	Common
Survival (5-year)	>80%	<10%
Treatment	Systemic corticosteroids	Systemic chemotherapy
*Presence significantly decreases 5-year survival rate.		

Table 120.7 Comparison of subcutaneous panniculitis-like T cell lymphoma (SPTCL) and primary cutaneous gamma/delta T cell lymphoma (PCGD-TCL) with subcutaneous involvement[53]. Hemophagocytic lymphohistiocytosis has also been referred to as hemophagocytic syndrome. βF1, positivity reflects α/β T cell origin; TCR, T cell receptor.

SUBCUTANEOUS PANNICULITIS-LIKE T CELL LYMPHOMA

Definition

Subcutaneous panniculitis-like T cell lymphoma (SPTCL) is a cytotoxic T cell lymphoma composed of α/β TCR-positive T cells that preferentially infiltrate subcutaneous tissue[1,3]. In past classifications, cases with subcutaneous involvement and a γ/δ T cell phenotype were included in this group. However, patients with a γ/δ T cell phenotype have different clinicopathologic features and usually a much more aggressive clinical course compared to those with an α/β T cell phenotype. Therefore, the

former were reclassified as having primary cutaneous gamma/delta T cell lymphoma (PCGD-TCL) (Table 120.7).

Epidemiology

SPTCL is a rare condition, accounting for <1% of all CTCL. It may occur in adults as well as in young children, and both sexes are equally affected.

Clinical Features

Patients generally present with a solitary or multiple nodules or deeply seated plaques with a diameter varying from 1 to 20 cm. The skin lesions involve primarily the extremities and the trunk and less commonly the face; when the nodules and plaques resolve, they may be replaced by areas of lipoatrophy (Fig. 120.14A). Ulceration is uncommon. Systemic symptoms such as fever, fatigue, and weight loss may be present in over half of the patients. Laboratory abnormalities including cytopenias and elevated liver function tests are common, but a frank hemophagocytic lymphohistiocytosis (HLH) is observed in only ~15% of patients[53]. Dissemination to extracutaneous sites is rare and while hepatosplenomegaly may be seen, it is generally not due to lymphomatous involvement.

SPTCL may be preceded for years or decades by a seemingly benign panniculitis. Up to 20% of patients have an associated autoimmune disease, most commonly systemic lupus erythematosus. Recent studies have suggested overlapping features between SPTCL and lupus profundus[54]. SPTCL has a favorable prognosis with a 5-year overall survival of ~80%[53]. However, the presence of HLH is associated with a more unfavorable prognosis.

Pathology

Subcutaneous infiltrates simulating a lobular panniculitis are seen in SPTCL. Small, medium-sized, or sometimes large pleomorphic T cells with hyperchromatic nuclei are present and are often admixed with many macrophages. The overlying epidermis and dermis are typically uninvolved. Rimming of individual fat cells by neoplastic T cells is a helpful, although not entirely specific, diagnostic feature (Fig. 120.14B). Necrosis, karyorrhexis, and cytophagocytosis are common findings. In contrast to lupus panniculitis, clusters of B cells, plasma cells, and plasmacytoid dendritic cells are not present.

Immunophenotype

These lymphomas have a TCRα/β$^+$, CD3$^+$, CD4$^-$, CD8$^+$ T cell phenotype, with expression of cytotoxic proteins. The neoplastic T cells express βF1, but are negative for TCRγ/δ and CD56, facilitating differentiation from PCGD-TCL with subcutaneous involvement and panniculitis-like lesions (see Table 120.7). CD30 is rarely, if ever, expressed.

Genetic Features

Recently, germline mutations in *HAVCR2* that lead to loss-of-function of TIM3 (T cell immunoglobulin mucin 3) were reported in 60%–85% of SPTCL patients[55]. TIM3 deficiency can lead to activation of macrophages and T cells, and patients can develop HLH.

Treatment

While doxorubicin-based chemotherapy has traditionally been used, more conservative immunosuppressive regimens (e.g. prednisone, cyclosporine, methotrexate) are often effective and should be considered as first-line therapy in patients with SPTCL without associated HLH. In patients presenting with a solitary lesion, local radiotherapy may be effective[25,53]. Ruxolitinib has been reported to successfully treat HLH in patients with germline mutations in *HAVCR2*.

EXTRANODAL NK/T CELL LYMPHOMA, NASAL TYPE

Extranodal NK/T cell lymphoma, nasal type is an EBV-positive lymphoma with an NK cell, or more rarely a cytotoxic T cell, phenotype and aggressive clinical behavior. It occurs more commonly in Asia and Central and South America and is very rare in Western countries[1,3]. The skin is the second most common site of involvement after the nasal cavity/nasopharynx, and some patients have only cutaneous lesions[56].

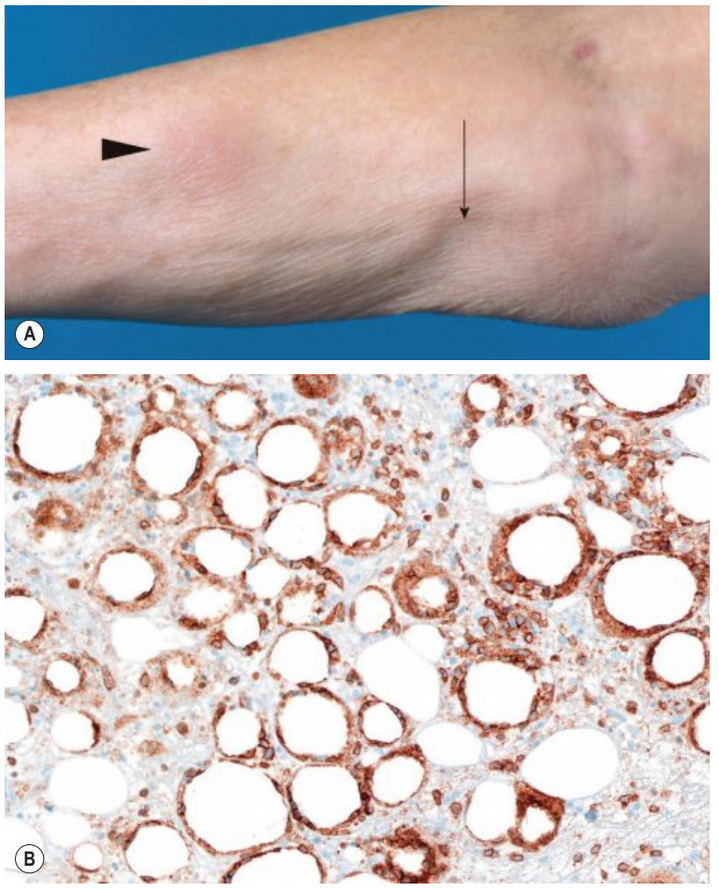

Fig. 120.14 Subcutaneous panniculitis-like T cell lymphoma (SPTCL). A Pink nodular skin lesions (arrowhead) as well as an area of lipoatrophy (arrow) at the site of a resolved nodule. **B** Subcutaneous infiltration with rimming of CD8-positive neoplastic T cells around adipocytes.

This lymphoma affects primarily adults, with a predominance of men. The typical presentation is multiple plaques or tumors on the trunk and extremities or, in the case of nasal NK/T cell lymphoma, a midfacial destructive tumor (Fig. 120.15). Of note, the latter was previously referred to as lethal midline granuloma. Ulceration is common.

Histologically, there are dense infiltrates involving the dermis and often the subcutis. Prominent angiocentricity and angiodestruction are often accompanied by extensive necrosis. Cell size ranges from small to large, but most cases consist of medium-sized cells with irregular or oval nuclei, moderately dense chromatin, and pale cytoplasm. In some cases, a heavy inflammatory infiltrate of small lymphocytes, histiocytes, plasma cells, and eosinophils can be seen. The TCR usually has a germline configuration, but can be clonally rearranged in the rare T cell-derived cases. The neoplastic cells express CD2, CD56, cytoplasmic CD3ε, and cytotoxic proteins (TIA-1, granzyme B, perforin), but they lack surface CD3. Detection of EBV by *in situ* hybridization and expression of cytotoxic proteins is required for diagnosis.

These lymphomas have an aggressive clinical behavior and are often resistant to chemotherapy. Combined modality treatment including L-asparaginase (the SMILE regimen) is the preferred mode of treatment[57]. In rare cases with small solitary lesions, radiotherapy alone can be considered[25,58].

Hydroa Vacciniforme-Like Lymphoproliferative Disorder

The updated WHO-EORTC classification contains a new section entitled chronic active EBV infection. It includes hydroa vacciniforme-like lymphoproliferative disorder (HV-like LPD) and hypersensitivity reactions to mosquito bites[1,3]. HV-like LPD is used as an encompassing term for cases previously referred to as HV, intermediate forms, and HV-like T cell lymphoma; however, there is some controversy regarding the relationship between the two ends of this spectrum[59].

Fig. 120.15 Extranodal NK/T cell lymphoma, nasal type. A Ulcerated plaques and papulonodules. **B** Ulceration of the hard palate. *Courtesy Luis Requena, MD.*

These disorders occur primarily in children and adolescents from Asia or in indigenous populations from Latin America. Clinically, classic HV presents with a papulovesicular eruption in sun-exposed sites, in particular the face, earlobes, and dorsal hands (see Fig. 87.9). There is often seasonal activity, but no systemic symptoms. In more severe cases, there is involvement of both sun-exposed and non-sun-exposed areas as well as facial swelling (see Fig. 87.10). Extensive ulceration is common and systemic symptoms such as fever, wasting, lymphadenopathy, and hepatosplenomegaly may be present. The clinical course is variable and patients may have recurrent skin lesions for many years before progression to systemic lymphoma.

PRIMARY CUTANEOUS AGGRESSIVE EPIDERMOTROPIC CD8-POSITIVE CYTOTOXIC T CELL LYMPHOMA

These tumors are characterized by a proliferation of epidermotropic CD8-positive cytotoxic T cells and an aggressive clinical behavior[60,61]. Differentiation from other types of CTCL expressing a CD8-positive cytotoxic T cell phenotype, including primary cutaneous acral CD8-positive T cell lymphoproliferative disorder, pagetoid reticulosis, and rare cases of MF, LyP, and C-ALCL, is based on the clinical presentation and clinical behavior. In the latter conditions, no differences in clinical presentation or prognosis are observed between $CD4^+$ and $CD8^+$ cases.

Clinically, these lymphomas are characterized by the presence of localized or disseminated eruptive papules, nodules, and tumors with central ulceration and necrosis *or* by superficial, hyperkeratotic patches and plaques (Fig. 120.16). They may disseminate to other visceral sites (lung, testis, central nervous system, oral mucosa), but lymph nodes are often spared. The median survival is 12 months, but some patients have a prodromal phase of chronic patches prior to the development of aggressive ulcerative lesions[62].

Histologically, these lymphomas show strongly epidermotropic, band-like to diffuse infiltrates of small, medium-sized, or large pleomorphic T cells with a $CD3^+$, $CD4^-$, $CD8^+$, $CD7^{-/+}$, $CD45RA^+$, granzyme B^+, perforin$^+$, TIA-1^+ phenotype[57,61]. The epidermis may be acanthotic or atrophic, and there may be necrotic keratinocytes, ulceration and variable spongiosis, sometimes with blister formation. Invasion and destruction of cutaneous adnexal structures are commonly seen. Angiocentricity and angioinvasion may be present.

These lymphomas run an aggressive clinical course and their response to systemic chemotherapy is often short-lived. Allogeneic HSCT should be considered in selected patients[62].

Fig. 120.16 Primary cutaneous aggressive epidermotropic CD8-positive cytotoxic T cell lymphoma. Generalized skin tumors with central ulceration. Previously, such cases were designated as disseminated pagetoid reticulosis (Ketron–Goodman type).

PRIMARY CUTANEOUS ACRAL CD8-POSITIVE T CELL LYMPHOPROLIFERATIVE DISORDER

In the 2018 updated WHO-EORTC classification, primary cutaneous acral CD8-positive T cell lymphoma was included as a provisional entity characterized by a diffuse infiltrate of clonal atypical medium-sized $CD8^+$ cytotoxic T cells. Although the histologic features suggest an aggressive lymphoma, there is usually a solitary skin lesion in an acral location that has an indolent clinical behavior[1,3,63]. As a result, in the 5th edition of the WHO Classification of Haematolymphoid Tumours, this condition has been reclassified as primary cutaneous acral CD8-positive T cell lymphoproliferative disorder[3a].

Patients typically present with a solitary, slowly enlarging papule or nodule. The most common site is the ear, but papulonodules can develop in other acral sites including the nose and the foot[63,64].

Histologically, there is a diffuse proliferation of monomorphic medium-sized atypical T cells throughout the dermis, often extending into the subcutaneous fat. The epidermis is generally spared and separated from the dermal infiltrate by a clear grenz zone. The atypical cells have a $CD3^+$, $CD4^-$, $CD8^+$, $CD30^-$ T cell phenotype with variable loss of T cell antigens (CD2, CD5, CD7). They are also positive for TIA-1, but unlike other types of $CD8^+$ CTCL, are negative for other cytotoxic proteins (granzyme B, perforin). Positive CD68 staining often has a Golgi dot-like pattern. In almost all cases, the proliferation rate as assessed by Ki-67 is very low (<10%).

The prognosis is excellent and in typical cases staging is not recommended. Surgical excision and radiotherapy represent treatment options. Cutaneous relapses may occur, but dissemination to extracutaneous sites is exceptional[65].

PRIMARY CUTANEOUS GAMMA/DELTA T CELL LYMPHOMA

Primary cutaneous gamma/delta T cell lymphoma (PCGD-TCL) is a lymphoma composed of a clonal proliferation of mature, activated gamma/delta T cells with a cytotoxic phenotype. This group includes cases previously known as SPTCL with a gamma/delta T cell phenotype. PCGD-TCL should be differentiated from SPTCL, other types of aggressive cytotoxic cutaneous T/NK cell lymphomas, and tumor stage MF, but this may prove extremely difficult and requires integration of clinical, histologic, phenotypic, and molecular genetic data (see Tables 120.2 and 120.7). It should be noted that TCRγ/δ expression is not only found in PCGD-TCL, but has also been reported in other types of CTCL, including rare cases of otherwise classic MF and LyP[22,23].

PCGD-TCL generally presents with disseminated plaques and/or ulceronecrotic nodules or tumors, particularly on the extremities, but other sites may be affected[53,66] (Fig. 120.17). Involvement of mucosal and other extranodal sites is frequently observed, but involvement of lymph nodes, spleen, or bone marrow is uncommon. In patients with panniculitis-like tumors, HLH may occur.

Histologically, three major patterns of involvement can be seen: epidermotropic, dermal, and/or subcutaneous. The epidermal pattern can vary from mild epidermotropism to a marked pagetoid reticulosis-like infiltrate. Rimming of fat cells may be observed when there is subcutaneous involvement, similar to SPTCL. Angiocentricity and angiodestruction are commonly seen. The neoplastic cells are generally medium to large in size with coarsely clumped chromatin, and they have a $TCR\gamma/\delta^+$, $TCR\alpha/\beta$ $(\beta F1)^-$, $CD3^+$, $CD2^+$, $CD4^-$, $CD5^-$, $CD7^{+/-}$, $CD8^-$, $CD56^+$ phenotype with strong expression of cytotoxic proteins.

Most patients have aggressive, often rapidly fatal disease, which is resistant to multi-agent chemotherapy. Patients with subcutaneous fat involvement may have a worse prognosis in comparison to patients with epidermal or dermal disease only[66]. There are, however, reports of patients with an indolent clinical course[67].

PRIMARY CUTANEOUS CD4-POSITIVE SMALL/MEDIUM T CELL LYMPHOPROLIFERATIVE DISORDER

In the 2005 WHO-EORTC classification, primary cutaneous CD4-positive small/medium T cell *lymphoma* was included as a provisional entity characterized by a solitary skin lesion (without prior or concurrent patches or plaques typical of MF) and a predominance of small to medium-sized $CD4^+$ pleomorphic T cells histologically. These cases also had the same benign clinical course as well as clinical, histopathologic, and immunophenotypic features as the entity previously referred to as *nodular cutaneous pseudo-T cell lymphoma*. Therefore, it is highly uncertain if these lesions represent a frank malignancy[68,69]. As a result, in the 2018 WHO-EORTC classification, the term "primary cutaneous CD4-positive small/medium T cell *lymphoproliferative disorder*" rather than lymphoma was assigned[1,3].

Characteristically, patients present with a solitary plaque or tumor, generally on the face, the neck, or the upper trunk[68,69]. Histologically, lesions show dense, diffuse, or nodular infiltrates within the dermis with a tendency to infiltrate the subcutis. Epidermotropism may be present focally. There is a predominance of small/medium-sized $CD3^+$, $CD4^+$, $CD8^-$, $CD30^-$ pleomorphic T cells. A small proportion (<30%) of large pleomorphic cells may be present. A variable proportion of atypical $CD4^+$ T cells, either scattered or forming small clusters, consistently express follicular helper T cell markers – programmed death-1 (PD-1; CD279), ICOS, BCL6, and CXCL13[69,70]. The proliferation rate as assessed by Ki-67 is generally low. Almost all cases show a considerable admixture with reactive $CD8^+$ T cells, $CD20^+$ B cells, plasma cells, and histiocytes, including multinucleated giant cells.

Patients have an excellent prognosis and in typical cases staging procedures are not required. Skin lesions that don't resolve spontaneously after skin biopsy should be treated. First-line therapies are intralesional corticosteroids and surgical excision; only by exception is radiotherapy used[68,69].

Rare patients who present with generalized skin lesions, large and rapidly growing tumors, >30% large pleomorphic T cells, and/or a high proliferative fraction do not belong in this category[71]. Such cases usually have a more aggressive clinical course and should be classified as primary cutaneous peripheral T cell lymphoma, NOS (see below).

PRIMARY CUTANEOUS PERIPHERAL T CELL LYMPHOMA, NOS

The designation "primary cutaneous peripheral T cell lymphoma (PTCL), NOS (not otherwise specified)" is used for CTCLs that do not fit into any of the better-defined subtypes outlined in Table 120.1. It is therefore a diagnosis of exclusion. Clinically, these patients present with solitary or localized, but more frequently generalized, nodules or tumors[72] (Fig. 120.18).

Fig. 120.17 Primary cutaneous gamma/delta T cell lymphoma. Multiple plaques and nodules of the upper inner arm, several of which are ulcerated. *Courtesy Jake Wang, MD.*

Fig. 120.18 Primary cutaneous peripheral T cell lymphoma, NOS. Rapidly growing nodules and tumors. Note: the skin lesions in the left upper corner do not represent patches, but rather deep plaques present for 2 weeks.

Histologically, there are nodular or diffuse infiltrates with variable numbers of medium-sized to large pleomorphic or immunoblast-like T cells. Epidermotropism is generally mild or absent. Most cases have an aberrant $CD4^+$ T cell phenotype with variable loss of pan-T cell antigens. CD30 staining is negative or restricted to a few scattered tumor cells. Rare cases may show coexpression of CD56.

Patients should be treated with systemic chemotherapy, but the prognosis is generally poor, with a 5-year survival of <20%[72]. Enrollment in clinical trials, including with JAK1-specifiic inhibitors, should also be considered.

BENIGN LYMPHOCYTIC INFILTRATES

Lymphocytic Infiltrate of Jessner

Synonyms: ■ Lymphocytic infiltrate of Jessner–Kanof ■ Benign lymphocytic infiltrate of the skin ■ Jessner lymphocytic infiltrate of the skin ■ Jessner lymphocytic infiltration of the skin ■ Jessner–Kanof lymphocytic infiltration of the skin

Key features

- Erythematous papules, plaques, and less commonly nodules
- Most common on the head, neck, and back
- Dermal infiltrate of lymphocytes without epidermal involvement

History

Lymphocytic infiltrate of Jessner (LIJ) was initially described in 1953 by Jessner and Kanof[1] as circinate papules on the face, surrounding a central area of clearing.

Epidemiology

This entity occurs primarily in middle-aged adults. There is no sex predilection.

Pathogenesis

Benign lymphocytic infiltrate of the skin remains a controversial entity[2]. Several authors believe it is a variant of cutaneous lupus erythematosus (primarily LE tumidus), an opinion shared by the authors of this chapter. Rare cases of drug-induced disease (e.g. angiotensin-converting enzyme [ACE] inhibitors, glatiramer acetate, targeted immunomodulators ["biologics"]) have been described[3,4] as have familial cases[5].

Clinical features

Cutaneous lesions appear primarily on the head, neck, and back as one or several asymptomatic, erythematous papules, plaques, and less commonly nodules, with an absence of secondary epidermal changes such as scale (Fig. 121.1). Annular plaques with central clearing are commonly observed and individual lesions last several weeks to months. There are no associated systemic manifestations. Although spontaneous resolution occurs, recurrences are common.

Pathology

The epidermis is unremarkable, with little evidence of interface dermatitis. There is a superficial and deep, primarily perivascular, lymphocytic infiltrate that may surround hair follicles (Fig. 121.2). A mild increase in dermal mucin may be seen. Because some cases may be misinterpreted morphologically as a cutaneous lymphoproliferative disorder, detailed immunophenotypic studies and clinicopathological correlation are required[6]. By immunohistochemistry, a mixed T cell infiltrate with a predominance of $CD8^+$ lymphocytes is observed, admixed with variably large clusters of $CD123^+$ plasmacytoid dendritic cells. The distribution of plasmacytoid dendritic cells is identical to that seen in LE tumidus, further supporting a close relationship[7].

Differential diagnosis

The differential diagnosis includes the plaque form of polymorphic light eruption, LE tumidus, cutaneous lymphoid hyperplasia (pseudolymphoma), reticular erythematous mucinosis, and cutaneous lymphoma (Fig. 121.3). Subacute cutaneous LE and discoid LE are distinguished by the presence

Fig. 121.1 Lymphocytic infiltrate of Jessner. A Annular erythematous plaque on the cheek. **B** On the central back, pink papules and plaques due to confluence of papules (inset). On palpation, the lesions feel infiltrated. *B, Courtesy Lorenzo Cerroni, MD.*

of secondary changes, including scale, central hypopigmentation, and follicular plugging, along with interface changes histologically. Because in LE tumidus interface changes are sparse, if present at all, distinction from LIJ is impossible when there is increase in dermal mucin. Reticular erythematous mucinosis, which is considered by some as synonymous with LE tumidus, has abundant dermal mucin.

Polymorphic light eruption is associated with sun exposure and usually has a self-limited clinical course. Histologically, papillary dermal edema is often seen and usually there are no clusters of $CD123^+$ plasmacytoid dendritic cells. For some patients, phototesting may provide additional helpful information (see Fig. 121.3).

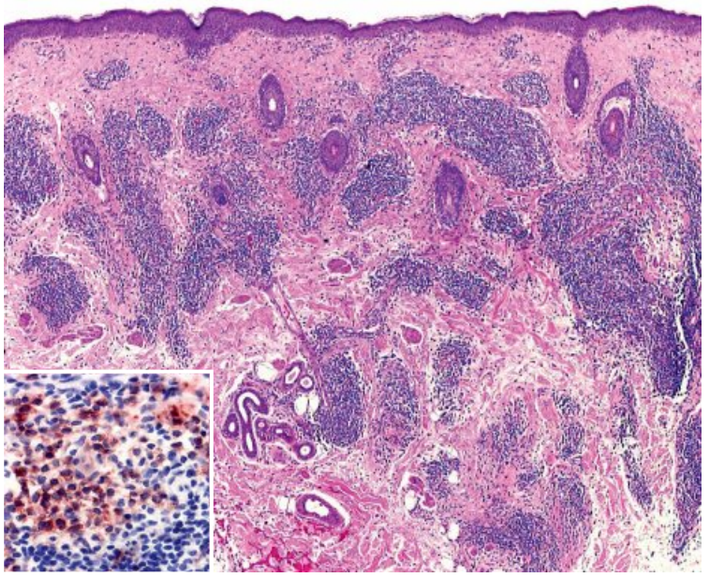

Fig. 121.2 Lymphocytic infiltrate of Jessner. A superficial and deep perivascular infiltrate without an interface component is characteristic. $CD123^+$ plasmacytoid dendritic cells are present within the infiltrate (inset).

Cutaneous lymphomas can have significant clinical and histopathologic overlap with LIJ. If the dermal lymphocytic infiltrate is extensive, immunophenotypic analyses allow distinction between the two entities (see Chs. 119 & 120). Although individual lesions of borderline lepromatous leprosy may resemble LIJ, these patients have a greater number of widespread lesions and bacilli are detected within the dermis by special stains (see Table 75.2).

Treatment

The cutaneous manifestations of LIJ may resolve spontaneously within months to years, without scarring. Oral antibiotics and topical or intralesional corticosteroids have been used with limited success. Up to 50% of patients may improve with hydroxychloroquine. In general, the disorder is resistant to radiation therapy. A crossover study of oral thalidomide (100 mg/day) versus placebo in 25 patients resulted in a clinical response of 76% for thalidomide and 16% for placebo. In isolated case reports, improvement following pulsed dye (595 nm) laser treatment or chemotherapy (for an unrelated malignancy) has been described[8].

Cutaneous Lymphoid Hyperplasia (Pseudolymphoma of the Skin)

Synonyms: ■ Lymphocytoma cutis ■ Lymphadenosis benigna cutis (LABC) ■ Spiegler–Fendt sarcoid ■ Miliary lymphocytoma

Key features

- Often an isolated, firm, erythematous to violaceous nodule or plaque that measures 1–3 cm in diameter
- Most common on the face and upper trunk
- Mixed dermal infiltrate of lymphocytes, plasma cells, and eosinophils; reactive germinal centers
- Polyclonal inflammatory infiltrate

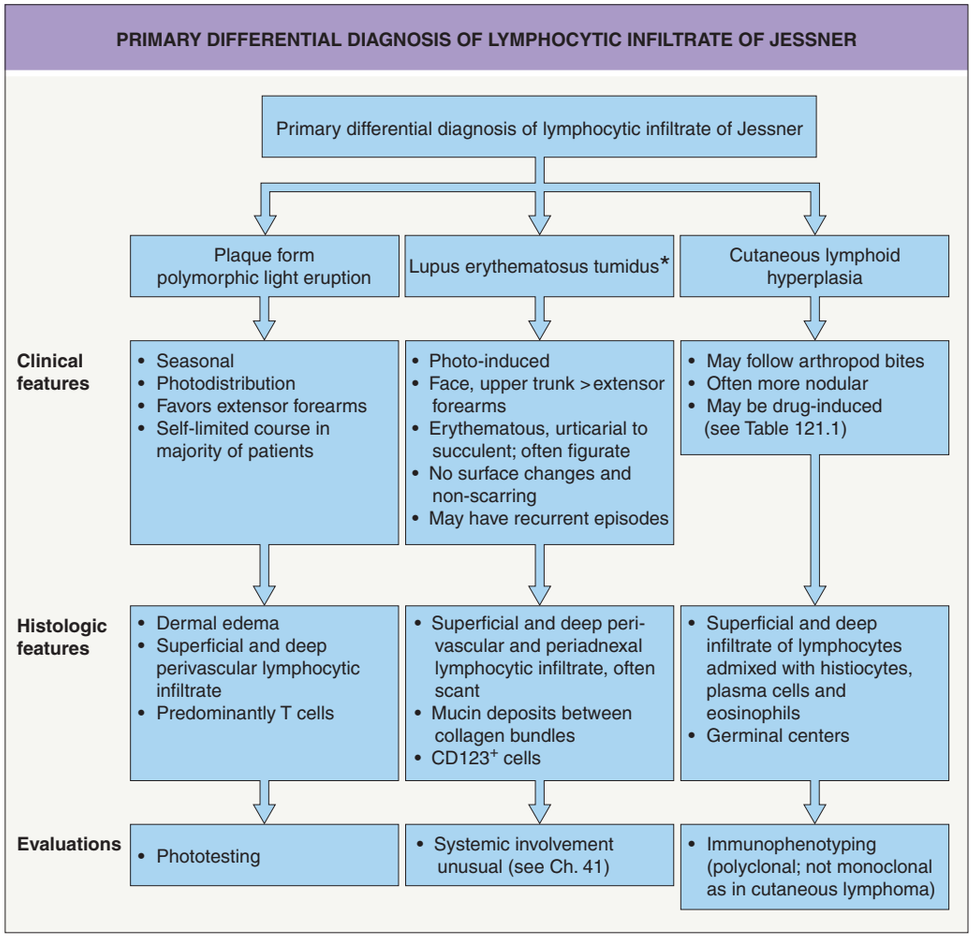

Fig. 121.3 Primary differential diagnosis of lymphocytic infiltrate of Jessner. Reticular erythematous mucinosis (REM) can also be considered in the differential diagnosis; histologically, abundant dermal mucin is observed. *Several authors consider lymphocytic infiltrate of Jessner, LE tumidus, and REM to be similar entities along a clinical spectrum. The differential diagnosis also includes cutaneous T and B cell lymphomas.

History

Cutaneous lymphoid hyperplasia (pseudolymphoma) was first reported by Spiegler in 1894. He described patients who presented with clinical features of a malignant neoplasm but experienced a benign clinical course. Although a characteristic feature is the resemblance to cutaneous lymphoma, there is a spectrum of clinical and histologic findings, reflecting its heterogeneous nature[9].

Epidemiology

Precise data regarding incidence, prevalence, and geographic distribution are lacking. Both children and adults can be affected.

Pathogenesis

Cutaneous lymphoid hyperplasia (CLH) does not represent a single disease, but rather reflects an exaggerated local immunologic reaction to a stimulus, often unrecognized. The possibility of a hapten-driven immunologic response to cells damaged by a direct toxic effect of stimuli has been suggested[10]. Inciting agents include arthropod bites (including ticks and mites), tattoos, metal implants, contact allergens, vaccinations, and medications (Table 121.1)[9–12]. In addition, several infections such as herpes zoster and in Europe Lyme borreliosis have been associated with CLH[9,13,14].

MEDICATIONS ASSOCIATED WITH CUTANEOUS LYMPHOID HYPERPLASIA (PSEUDOLYMPHOMA)	
Anticonvulsants	*Carbamazepine, phenobarbital, phenytoin, ethosuximide, lamotrigine, valproic acid*, ethotoin, *gabapentin*
Antiarrhythmics	*Mexiletine*, procainamide
Antibiotics	*Trimethoprim–sulfamethoxazole, cefixime*, cefuroxime*, nitrofurantoin*, clarithromycin*, vancomycin, rifampin, levofloxacin*
Antidepressants	*Amitriptyline*, desipramine, *fluoxetine*, clompramine, lithium, *sertraline*
Antihistamines	*Cimetidine, ranitidine*, nizatidine, doxepin
Antihypertensives (including diuretics)	*Atenolol*, *captopril*, lisinopril, *diltiazem*, *amlodipine*, *furosemide*, amiloride, losartan, valsartan, clonidine patch, metoprolol
Antineoplastic agents	*Imatinib*, fluorouracil, *gemcitabine*, oxaliplatin, tamoxifen, leucovorin, *ipilimumab, nivolumab*
Antipsychotics	*Chlorpromazine*, perphenazine, thioridazine
Lipid-lowering agents	Gemfibrozil, lovastatin
Nonsteroidal anti-inflammatory drugs (NSAIDs)	*Aspirin*, *ibuprofen*, *naproxen*, *diclofenac*, indomethacin, ketoprofen, sulindac, diflunisal, oxaprozin, nabumetone
Rheumatologic agents	*Allopurinol*, *dapsone*, *sulfasalazine*, methotrexate, gold, D-penicillamine
Sedatives	Benzodiazepines
Steroid hormones	Estrogen, progesterone
Stimulants	Methylphenidate
Targeted immunomodulators ("biologics")	Adalimumab, etanercept, infliximab, secukinumab, tocilizumab
Vaccines*	Hepatitis A, hepatitis B, influenza, quadrivalent HPV, tetanus, varicella–zoster, SARS-CoV-2, early summer meningoencephalitis, GM-CSF-producing tumor cell vaccine, hyposensitization injections
Miscellaneous	Aldesleukin (interleukin-2), bromocriptine, cyclosporine, glatiramer acetate, interferon-alpha, zoledronic acid; black cohosh
*Often aluminum-adsorbed or aluminum-containing.	

Table 121.1 Medications associated with cutaneous lymphoid hyperplasia (pseudolymphoma). For patients with the drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) who have atypical lymphocytes in the blood and skin, the term pseudolymphoma is sometimes applied; however, although this is a separate entity (see Ch. 21), there is overlap. The drugs in *italics* have also been reported to cause DRESS/DIHS. GM-CSF, granulocyte-macrophage colony-stimulating factor; HPV, human papilloma virus. *Adapted from references 9, 10, and 13.*

Clinical features

CLH usually presents as a single, 1–3 cm, firm, erythematous to violaceous plaque or nodule located on the head, neck, or upper extremities (Fig. 121.4A). That said, presentations can vary from multiple clustered papules to larger panniculitis-like nodules (Fig. 121.4B)[9]. The vast majority of lesions lack surface changes such as scale.

Pathology

The histopathological features are variable and the pattern may resemble either a low-grade B cell lymphoma (follicle center lymphoma, marginal zone lymphoma) or a T cell lymphoma, in particular mycosis fungoides, lymphomatoid papulosis (LyP), cutaneous anaplastic large cell lymphoma (cALCL), or subcutaneous panniculitis-like T cell lymphoma[9,13].

In CLH with *B cell predominance*, there is typically a superficial and deep nodular or diffuse infiltrate of lymphocytes, admixed with histiocytes and occasional plasma cells and eosinophils. In florid cases, germinal centers with prominent tingible-body macrophages may be observed (Fig. 121.5). Distinction from follicle center lymphoma can be made on routine histologic sections or with the addition of immunohistochemical stains (Table 121.2). Clonality, based upon IgH gene rearrangements or restricted κ or λ expression, is usually not seen

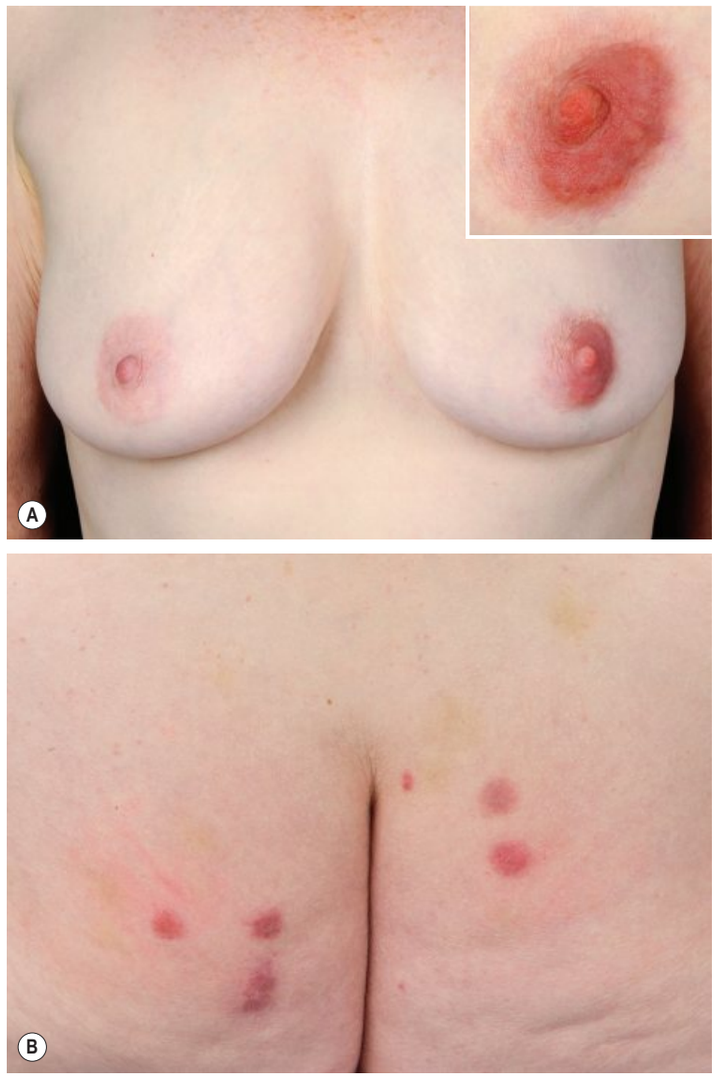

Fig. 121.4 Cutaneous lymphoid hyperplasia (pseudolymphoma) – clinical presentations. A Oval erythematous infiltrated plaque involving the lateral areola and nipple (inset) which was *Borrelia burgdorferi*-associated. **B**. Several pink and pink–violet papules on the buttocks at the sites of arthropod bites. *Courtesy Lorenzo Cerroni, MD.*

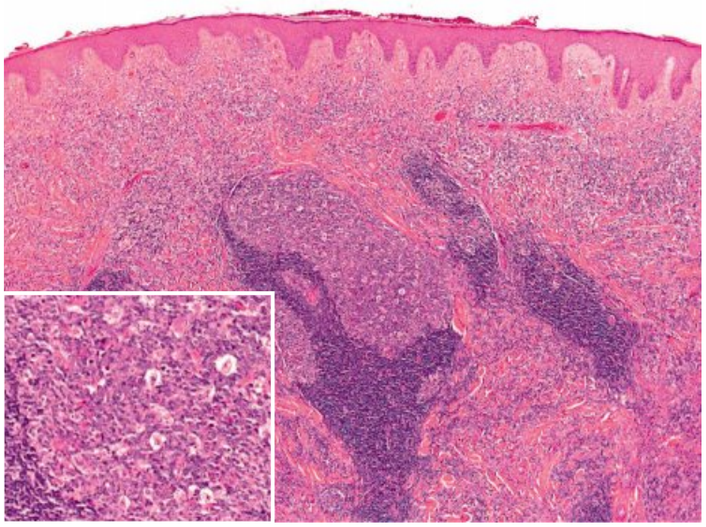

Fig. 121.5 Cutaneous lymphoid hyperplasia (pseudolymphoma) – histopathologic features. Lymphoid cells are seen throughout the dermis in a nodular and diffuse pattern. There is germinal center formation and tingible-body macrophages are present within the germinal centers (inset). The patient had *Borrelia burgdorferi*-associated lymphocytoma cutis. *Courtesy Lorenzo Cerroni, MD.*

MICROSCOPIC DIFFERENCES BETWEEN CUTANEOUS LYMPHOID HYPERPLASIA (PSEUDOLYMPHOMA) AND PRIMARY CUTANEOUS FOLLICLE CENTER LYMPHOMA	
Cutaneous lymphoid hyperplasia (pseudolymphoma)	**Primary cutaneous follicle center lymphoma**
Histologic features	
Mixed cellular infiltrate, including eosinophils and plasma cells	Predominantly lymphocytic infiltrate (eosinophils and plasma cells present in some cases)
Reactive germinal centers	Neoplastic germinal centers
Mantle zone present	No or reduced mantle zone
Tingible-body macrophages present	No tingible-body macrophages
Polarization of follicles with light and dark areas	Monomorphous appearance of follicles without polarization
Immunophenotypic features	
T and B lymphocytes	Predominance of B lymphocytes ($CD20^+$)
Bcl-6^+ cells restricted to lymph follicles	Clusters of Bcl-6^+ cells outside of lymph follicles
Bcl-2 positivity only on T lymphocytes	Bcl-2 positivity on neoplastic B cells (small minority of cases)
High proliferation of germinal centers	Reduced proliferation of germinal centers
Ig genes: polyclonal pattern	Ig genes: monoclonal rearrangement, restricted light chain expression

Table 121.2 Microscopic differences between cutaneous lymphoid hyperplasia (pseudolymphoma) and primary cutaneous follicle center lymphoma. Ig, immunoglobulin.

in pseudolymphomas (see Fig. 119.10)[9,14]. PCR analysis for *Borrelia burgdorferi* DNA is positive in *Borrelia*-associated lymphocytoma cutis and pseudolymphomatous acrodermatitis chronica atrophicans[9,14].

In *T cell-predominant* infiltrates, $CD4^+$ T helper lymphocytes are commonly observed within the dermis, admixed with a minority of $CD8^+$ cytotoxic/suppressor T cells. An accompanying population of B lymphocytes is usually present. A mycosis fungoides-like pattern is most often encountered in drug-induced pseudolymphomas (see Table 121.1). Histologically, epidermotropism, spongiosis, vacuolar degeneration of the basal layer, papillary dermal edema, and red cell extravasation may be seen. Prominent papillary dermal fibrosis, which can be seen in mycosis fungoides, is absent, but T cell clonality may be present.

$CD30^+$ pseudolymphomas include persistent arthropod bite reactions, drug reactions, and the atypical lymphoid infiltrates associated with cutaneous poxvirus infections (e.g. molluscum contagiosum, orf). Additional findings related to the underlying disorder can aid in diagnosis, and there is polyclonal rearrangement of the TCR genes[9,13].

Differential diagnosis

Pseudolymphomas may be difficult to differentiate from *cutaneous lymphomas* (see Pathology section). Although the presence of clonality may aid in distinguishing reactive from neoplastic processes, it should not be used alone to establish malignancy. In addition to clinicopathologic correlation, longitudinal evaluation plays a key role in making this distinction.

Acral pseudolymphomatous angiokeratoma of children (APACHE), originally thought to represent a vascular nevus, is now categorized as a pseudolymphoma. In contrast to other pseudolymphomas, it favors the extremities of children between the ages of 2 and 16 years, usually presenting as a unilateral grouping of small, red to violet, "angiomatous" papules. Histologically, there is a dermal infiltrate of lymphocytes, histiocytes, and plasma cells accompanied by prominently thickened capillaries[9].

Kikuchi–Fujimoto disease, also known as histiocytic necrotizing lymphadenitis, is an idiopathic systemic inflammatory disease most commonly seen in young adult women. It is associated with a variety of viral and bacterial infections (e.g. Epstein–Barr virus, cytomegalovirus) as well as autoimmune diseases (e.g. systemic LE). In addition to fever, malaise, weight loss, and gastrointestinal symptoms, patients develop cervical lymphadenopathy. Histologically, involved lymph nodes show infiltration of plasmacytoid dendritic cells in the paracortical area and later histiocytes and necrosis in the absence of an identifiable pathogen. Cutaneous findings, present in 40% of patients, include acneiform eruptions, urticaria, ulcers, and indurated erythematous plaques. Histologically, dense superficial and deep perivascular lymphohistiocytic infiltrates with nuclear debris (in the absence of neutrophils) are seen; interface changes are commonly present[15,16].

In *"pseudolymphomatous folliculitis"*, there is typically a solitary facial nodule that is due to a predominantly perifollicular and periadnexal dermal infiltrate. It is unclear whether these cases really represent an entity or, as the authors of this chapter believe, a mixture of different reactive conditions. The infiltrate is typically mixed with a predominance of T or B cells that may have cellular atypia; granulomas are variably present[17,18]. There is irregular hyperplasia and distortion of the follicular epithelium, with blurring of the dermal–epidermal junction, and infiltrates of $CD1a^+$/$S100^+$ mononuclear cells surround and infiltrate these distorted follicles. This entity should be distinguished from primary cutaneous $CD4^+$ small/medium-sized pleomorphic T cell lymphoproliferative disorder, which is characterized by more pronounced pleomorphism of the cells[17–19]. Distinction from pilotropic mycosis fungoides is based on the presence of a mixed infiltrate of T and B lymphocytes as well as absent or minimal folliculotropism in pseudolymphomatous folliculitis.

Cutaneous and systemic plasmacytosis is a benign condition of unknown etiology observed primarily in Asians, especially those of Japanese ancestry. It is characterized by multiple, reddish-brown, infiltrated maculopapules and plaques, most often on the trunk. Histopathologically, variably dense superficial and deep perivascular infiltrates composed predominantly of mature polyclonal plasma cells are seen[9,20,21]. The plasmacytosis may be accompanied by anemia, B symptoms, and hypergammaglobulinemia, as well as lymphadenopathy, hepatosplenomegaly, interstitial pneumonia, and mesangial proliferative glomerulonephritis. A reactive dysfunction of plasma cells triggered by various stimuli has been postulated[22]. As in Castleman disease, there is an elevation in circulating/tissue IL-6, but in the absence of HHV-8 infection[9,20,21].

Intralymphatic histiocytosis (formerly intravascular histiocytosis) has been observed most often in patients with rheumatoid arthritis or metallic orthopedic implants[23]. It has also been reported in association with severe osteoarthritis, solid organ malignancies (e.g. breast cancer), lymphedema, and various skin disorders (e.g. Morbihan disease, granulomatous cheilitis, healing cellulitis). Clinically, intralymphatic histiocytosis usually presents with poorly defined erythematous plaques that may have a reticular pattern (Fig. 121.6A). The lesions can co-localize anatomically with underlying disorders or implants. Histologically, collections of epithelioid histiocytes are seen within dilated lymphatic

vessels – findings that resemble intravascular large cell lymphoma (Fig. 121.6B)[9,23]. The histiocytes are CD68$^+$, S100$^-$, and CD1a$^-$; the endothelial cells express D2-40. Intralymphatic histiocytosis can be differentiated from reactive angioendotheliomatosis and other intravascular proliferations via immunohistology[9,23].

Additional examples of pseudolymphoma are outlined in Table 121.3.

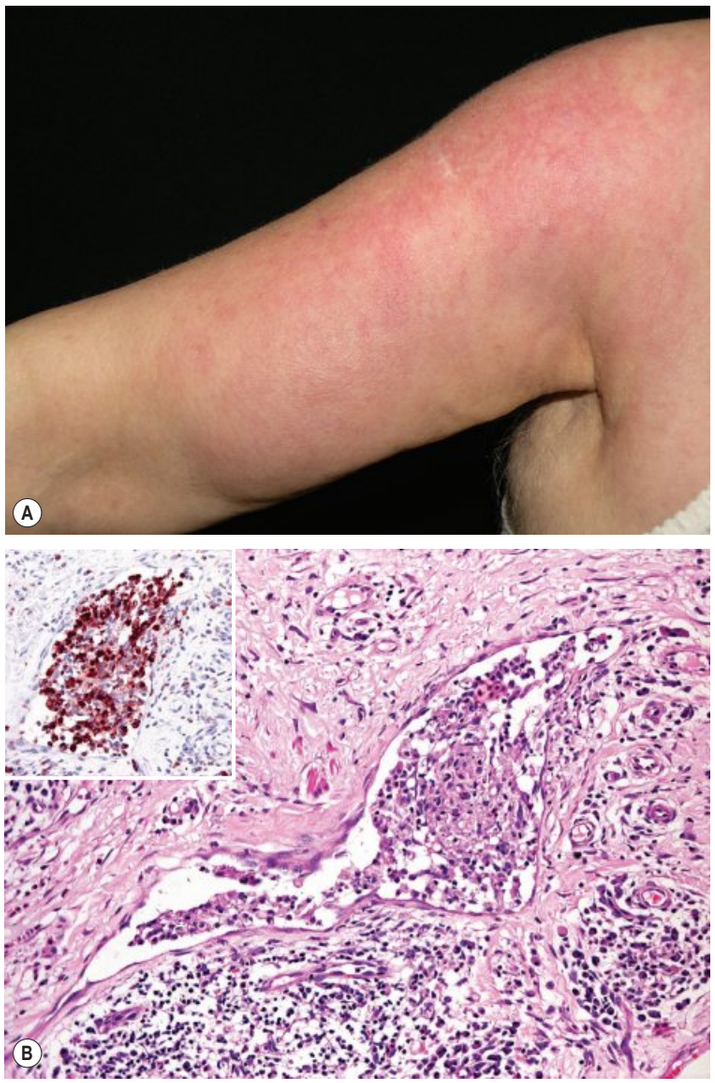

Fig. 121.6 Intralymphatic histiocytosis. A Reticulated erythematous plaque of the upper arm and shoulder in a patient with rheumatoid arthritis. **B** Dilated dermal lymphatic vessel filled with histiocytes, admixed with some leukocytes, and surrounded by a lymphoplasmacytic perivascular infiltrate; note CD68 positivity of the histiocytes (inset). *A, Courtesy Luis Requena, MD; B, Courtesy Lorenzo Cerroni, MD.*

Treatment

CLH is a benign, reactive condition and it should be treated conservatively. Spontaneous resolution may occur without scarring, and performance of a biopsy, even if partial, can be followed by spontaneous regression. Medication-associated CLH usually resolves after drug discontinuation[12]. Topical and intralesional corticosteroids or topical tacrolimus may lead to improvement. For persistent lesions, simple excision, cryosurgery, laser ablation, photodynamic therapy, phototherapy, and radiation therapy are other options. Hydroxychloroquine, thalidomide, and intralesional or intravenous rituximab have also been reported as successful therapies[17,24]. For *Borrelia*-associated pseudolymphoma, appropriate antibiotics are administered (see Ch. 19).

CUTANEOUS EXTRAMEDULLARY HEMATOPOIESIS

Key features

- Evidence of bone marrow dysfunction
- Most common associations are TORCH (*t*oxoplasmosis, *o*ther agents, *r*ubella, *c*ytomegalovirus and *h*erpes simplex virus) infections in neonates and myelofibrosis in adults
- Widely disseminated erythematous to violaceous papules and nodules, with neonatal form referred to as "blueberry muffin baby"
- Diffuse dermal infiltrate of immature erythrocytes, leukocytes, and megakaryocytes

Epidemiology

Cutaneous extramedullary hematopoiesis (CEMH) is a reflection of bone marrow dysfunction and is most commonly seen in neonates following congenital infections. It may also occur in adults with myelodysplasia or myeloproliferative neoplasms (myelofibrosis, polycythemia vera, essential thrombocythemia)[9], as well as following splenectomy for myeloproliferative neoplasms. A very rare association is primary hypertrophic osteoarthropathy[25].

Pathogenesis

CEMH occurs normally during early embryogenesis and abates prior to birth. Thereafter, it occurs only as a secondary phenomenon in response to altered bone marrow function. Dermal hematopoiesis reflects an expansion of follicular, dermal, or circulating hematopoietic stem cells and is probably induced by cytokines (e.g. IL-3, G-CSF, TGF-β)[25]. Rarely, in otherwise healthy individuals, primary cutaneous neoplasms such as pilomatricomas, nevus sebaceus, hemangiomas, and pyogenic granulomas may be associated with localized CEMH[9,25,26].

Clinical Features

The clinical presentation consists of erythematous to violaceous papules and nodules which may ulcerate. When widely disseminated in

ENTITIES THAT CAN MIMIC CUTANEOUS T AND B CELL LYMPHOMAS		
More common	**Uncommon**	**Rare**
• Persistent arthropod bites, scabies • *Borrelia* infections, in particular lymphocytoma cutis and acrodermatitis chronica atrophicans (Europe) • CD30$^+$ reactive lymphoid infiltrates in the context of cutaneous infections (e.g. herpes simplex, herpes zoster, molluscum contagiosum) • Drug eruptions (lichenoid, lymphomatoid) (see Table 121.1) • Lichenoid (lymphomatoid) keratosis • Pseudolymphomatous infiltrates in cutaneous lupus erythematosus • Lichen sclerosus of genital skin	• Lymphomatoid contact dermatitis • Pigmented purpura, lichenoid variant • Pityriasis lichenoides (acute or chronic forms) • Pseudolymphomatous atopic dermatitis • Pseudolymphomatous folliculitis • Pseudolymphomatous reactions to tattoo pigments • Syphilis, primary and secondary	• Actinic reticuloid • APACHE (acral pseudolymphomatous angiokeratoma of children) • Cutaneous IgG4-related disease* • Cutaneous plasmacytosis • Hydroa vacciniforme • Intralymphatic histiocytosis • Kikuchi–Fujimoto disease • Lobular panniculitis in children with congenital immunodeficiencies • Pseudolymphomatous reactions to vaccinations • Vitiligo (inflammatory stage)
*Increased IgG4-positive plasma calls and sclerotic stroma; can also be seen in granuloma faciale-like lesions.		

Table 121.3 Entities that can mimic cutaneous T and B cell lymphomas. These entities are sometimes referred to as pseudolymphomas. For details see reference 9.

neonates, it leads to the classic "blueberry muffin baby" (Fig. 121.7)[25]. This can be seen in association with congenital viral infections and prenatal anemias (Table 121.4). Dermal hematopoiesis is most often seen with rubella and cytomegalovirus, and serologic titers for TORCH infections can aid in diagnosis.

Pathology

CEMH is characterized by a dermal infiltrate of immature white and red blood cell precursors (erythroblasts) and megakaryocytes, centered around vessels of the superficial vascular plexus. It may also extend into the deeper reticular dermis and exhibit a diffuse pattern. All three hematopoietic cell lines are present in varying ratios, depending upon the underlying disease process.

Differential Diagnosis

The clinical differential diagnosis in neonates is outlined in Table 121.4 and in adults the possibility of leukemia cutis needs to be considered. Histologically, the differential diagnosis is limited. Distinguishing CEMH from disseminated congenital leukemia cutis and neonatal neuroblastoma is important. Whereas all three hematopoietic cell lines (erythrocytes, leukocytes, and megakaryocytes) are represented in CEMH, there is an atypical, monomorphous infiltrate of immature leukocytes in leukemia cutis.

Fig. 121.7 Extramedullary hematopoiesis. "Blueberry muffin baby" secondary to congenital rubella. *Courtesy Eugene Mirrer, MD.*

DIFFERENTIAL DIAGNOSIS OF "BLUEBERRY MUFFIN BABY"
Disseminated extramedullary hematopoiesis

• Congenital TORCH infections
  • Toxoplasmosis
  • Other – coxsackievirus, parvovirus
  • Rubella
  • Cytomegalovirus
• Severe hemolytic anemias
  • Congenital spherocytosis
  • Rhesus hemolytic disease
  • ABO incompatibility
• Other causes of severe anemia
  • Twin–twin transfusion
  • Chronic fetomaternal hemorrhage
  • Severe internal bleeding (e.g. intracranial)
  • Congenital leukemia or myelodysplasia
• Aicardi–Goutières syndrome

Neoplastic infiltration
• Congenital leukemia cutis, transient myeloproliferative disorder • Neonatal neuroblastoma, peripheral primitive neuroectodermal tumor • Congenital Langerhans cell histiocytosis, disseminated xanthogranulomas (early lesions), hemophagocytic lymphohistiocytosis • Congenital alveolar rhabdomyosarcoma • Infantile myofibromatosis • Multifocal infantile hemangiomas, other vascular lesions (e.g. multifocal lymphangioendotheliomatosis, glomuvenous malformations)

Table 121.4 Differential diagnosis of "blueberry muffin baby". TORCH, toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex virus.

Treatment

Treatment of the underlying bone marrow dysfunction results in reversal of the cutaneous process. Spontaneous resolution can occur with some viral infections.

MALIGNANT HEMATOPOIETIC INFILTRATES

Leukemia Cutis

Key features

- Pink to red–brown or purple papules and nodules; hemorrhagic ulcers
- Diffuse dermal infiltrate of neoplastic leukocytes
- Monomorphic immature precursor cells in some types

Epidemiology

Multiple types of leukemia exist, each with its own epidemiologic characteristics. Acute lymphoblastic leukemia (ALL) tends to be a neoplasm of childhood. Acute myelogenous leukemia (AML) and chronic myelogenous leukemia (CML) occur primarily in adults, and chronic lymphocytic leukemia (CLL) and hairy cell leukemia are most common in elderly patients[28,29]. Development of CML-associated leukemia cutis can be a harbinger of blast transformation[9], while the development of leukemia cutis in a patient with myelodysplastic syndrome (MDS) points to progression to AML[27]. In some patients with MDS, cutaneous lesions with an accumulation of benign-appearing dendritic and myeloid cells and a chronic course have been described. Leukemia cutis is most commonly seen in patients with *NPM1*-mutated AML and less often in CLL[9,28,29a,29b].

Pathogenesis

Specific chromosomal abnormalities are associated with particular subtypes of leukemia. The Philadelphia chromosome, the primary diagnostic feature of CML, represents a translocation between chromosomes 9 and 22 [t(9;22)]. This translocation results in fusion of the two genes *BCR* and *ABL*, with constitutive activation of the tyrosine kinase activity of the fusion oncoprotein. It is this kinase activity that is selectively inhibited by imatinib mesylate (Gleevec®). Additionally, 95% of patients with promyelocytic leukemia have a t(15;17) translocation, which leads to abnormal expression of a fusion retinoic acid receptor that is the target of all-*trans* retinoic acid therapy.

A variety of non-random chromosomal abnormalities exists in ALL and AML that can influence prognosis, and in AML mutations in particular genes can be favorable (e.g. *CEBPA*) or unfavorable (e.g. *FLT3*-ITD)[29a,29b]. *NPM1* is the most frequently mutated gene in patients with AML and normal cytogenetics; as noted previously, *NPM1*-mutated AML is the subtype most commonly associated with leukemia cutis[29a,29b]. Table 121.5 outlines the relationship between specific abnormalities and prognosis in CLL[28,29].

RELATIONSHIP BETWEEN SPECIFIC MOLECULAR ABNORMALITIES AND PROGNOSIS IN CHRONIC LYMPHOCYTIC LEUKEMIA	
Molecular abnormalities	**Prognosis**
Chromosomal	
13q deletion	Favorable
Trisomy 12	Intermediate
11q deletion	Poor
17p deletion	Poor
Genetic mutations	
TP53	Poorest
Other	
Unmutated *IGHV* genes	Poor

Table 121.5 Relationship between specific molecular abnormalities and prognosis in chronic lymphocytic leukemia. *TP53* is located on chromosome 17p and 17p deletions often involve *TP53*. *IGHV*, immunoglobulin heavy chain variable region gene.

Clinical features

Leukemia can lead to nonspecific reactive skin lesions (Table 121.6) or specific infiltrates. The latter most commonly present as multiple, generalized or localized, firm papules and nodules that vary in color from pink to red–brown to purple. The papulonodules often become hemorrhagic and thrombocytopenia usually plays a role in this associated hemorrhage. Ulcerative and rarely bullous lesions occur. Leukemia cutis can develop in any location, but the head, neck, and trunk are most commonly involved (Fig. 121.8A). Leukemic infiltrates may arise at sites of trauma or scars.

Rarely, myelogenous leukemias may present with dermal or subcutaneous nodules known as myeloid sarcomas or chloromas. These skin lesions may precede the development of systemic leukemia by months.

"INFLAMMATORY" DISORDERS ASSOCIATED WITH LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Cutaneous disorder	Associated leukemias and MDS
Neutrophilic dermatoses	
Sweet syndrome, including histiocytoid variant*	AML > MDS, CML, hairy cell leukemia, CNL > ALL, CLL
Pyoderma gangrenosum†	AML, MDS, CML, hairy cell leukemia > ALL, CLL
Neutrophilic eccrine hidradenitis	AML ≫ ALL, CML, CLL
Reactive erythemas	
Eosinophilic dermatosis of hematologic malignancy (including exaggerated reactions to arthropod bites)	CLL >>> AML, CML
Erythroderma	CLL‡
Facial erythema and edema	T cell prolymphocytic leukemia
Vasculitis	
Polyarteritis nodosa	Hairy cell leukemia ≫ CMML, MDS
Vasculitis (small vessel/ leukocytoclastic)	Hairy cell leukemia, CLL > AMML, ALL, MDS
Erythema elevatum diutinum	Hairy cell leukemia, CLL
Panniculitis	
Erythema nodosum¶	AML, CML, CMML
Other panniculitides§	Hairy cell leukemia, AML, CMML
Other	
Urticaria	CLL, hairy cell leukemia
Erythema multiforme‖	CLL
Paraneoplastic pemphigus	CLL
Recalcitrant adult-onset eczema	CLL (T cell)
Acral ischemia with lividity	CML#
Reactive granulomatous dermatitis including interstitial granulomatosis dermatitis, sarcoidal, GA-like	MDS
Pernio	CMML

*Histiocytoid variant linked to hematologic malignancies and MDS.
†Especially bullous.
‡Many probably represented Sézary syndrome.
¶Isolated case reports; may occur concomitantly with Sweet syndrome and some cases better classified as subcutaneous Sweet syndrome.
§Sweet syndrome may have a subcutaneous component.
‖May have represented paraneoplastic pemphigus.
#Leukostasis/hyperleukocytosis syndrome.

Table 121.6 "Inflammatory" disorders associated with leukemias and myelodysplastic syndromes[18–21]. Most patients with CML who develop vitiligo-like changes are receiving imatinib. Infiltrates of leukemic cells (CLL > AML) may be seen in post-herpes zoster scars (see Table 80.7). ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; AMML, acute myelomonocytic leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; CNL, chronic neutrophilic leukemia; GA, granuloma annulare; MDS, myelodysplastic syndrome.

Gingival hyperplasia, secondary to leukemic infiltrates, favors acute monocytic or acute myelomonocytic leukemia, especially those with *NPM1* mutations.

In one series, cutaneous eruptions of leukemia accounted for 30% of all skin biopsy specimens in patients with leukemia[30]. Other diagnoses included GVHD, drug eruptions, infectious processes, purpura, and small vessel vasculitis. In most patients with acute leukemia, cutaneous lesions are present at the time of diagnosis or recurrence, but occasionally, skin involvement precedes the appearance of leukemia in the peripheral smear ("aleukemic" leukemia cutis). Rarely, leukemia cutis predates apparent bone marrow involvement by months or even years.

Of note, asymptomatic dermal leukemic infiltrates of CLL may be evident in biopsy specimens of primary cutaneous neoplasms (e.g. squamous cell carcinoma) and inflammatory or infectious disorders such as herpes simplex and herpes zoster viral infections. This phenomenon indicates that these neoplastic cells retain the capability to respond to chemotactic stimuli and migrate into tissues (inflammatory oncotaxis)[31,32].

The characteristics of the different forms of leukemia cutis are summarized in Table 121.7.

Pathology

Histologic features of leukemia cutis vary with the type of leukemia. The neoplastic infiltrates may be perivascular, interstitial, nodular, and/or diffuse; occasionally, they densely surround the eccrine glands[30–32]. Diagnosis is more difficult when the perivascular and periadnexal infiltrates are sparse and mimic inflammatory disorders[32].

AML represents a neoplastic proliferation of immature myeloid cells and encompasses multiple subtypes[29a,29b]. In general, the neoplastic cells recapitulate myeloid precursor cells in their immature stages of development (Fig. 121.8B). In many cases, cytoplasmic granules can be found. The most common forms of AML that involve the skin and present *de novo* (without previous evidence of systemic disease) are the more differentiated subtypes – acute myelomonocytic and acute monocytic leukemia. Immunohistochemically, the infiltrates of AML are positive for myeloid markers such as myeloperoxidase, CD33, CD34, and CD68 and are usually negative for CD123[9,29a,29b].

In CML, there is a range of myeloid precursors, including promyelocytes, metamyelocytes, bands, and mature neutrophils. Although cutaneous lesions of CML are rare, they are typically seen in patients with chronic myelomonocytic leukemia and are associated with blast transformation and a poor prognosis[9,29a,29b].

ALL represents a clonal expansion of immature lymphocytes, most commonly of B cell lineage and less commonly T cell lineage. Rarely, cytoplasmic granularity may be present, and this corresponds with a precursor B cell immunophenotype. Cells of ALL may be difficult to identify in skin biopsy specimens and immunostaining for terminal deoxytransferase may prove helpful[9,28,29].

Cutaneous CLL is characterized by a dense infiltrate of uniform-appearing, small, round lymphocytes of B cell lineage (Fig. 121.9). The cells appear mature, but the monomorphous nature and paucity of other cell types within the infiltrate suggest a leukemic infiltrate. The lymphocytes often surround adnexal and vascular structures. Immunohistochemically, CLL shows positivity for LEF1, CD5 (variable), CD20, and CD23[9,28,31,33].

Differential diagnosis

The clinical differential diagnosis includes cutaneous lymphoma, cutaneous lymphoid hyperplasia, infectious emboli, vasculitis, panniculitis, and drug eruptions. The histologic differential diagnosis of leukemia cutis depends upon the type of leukemia present. Distinguishing some cases of leukemia cutis from lymphomas involving the skin can be difficult. For myeloid leukemias, the differential diagnosis includes mainly extramedullary hematopoiesis (see above), diffuse large cell lymphomas, and histiocytoid Sweet syndrome. Of note, in some cases of histiocytoid Sweet syndrome[34] neoplastic cells of AML may be present within the infiltrate[35].

Treatment

No specific treatment for leukemia cutis currently exists. The cutaneous eruptions typically resolve following successful treatment of the leukemia.

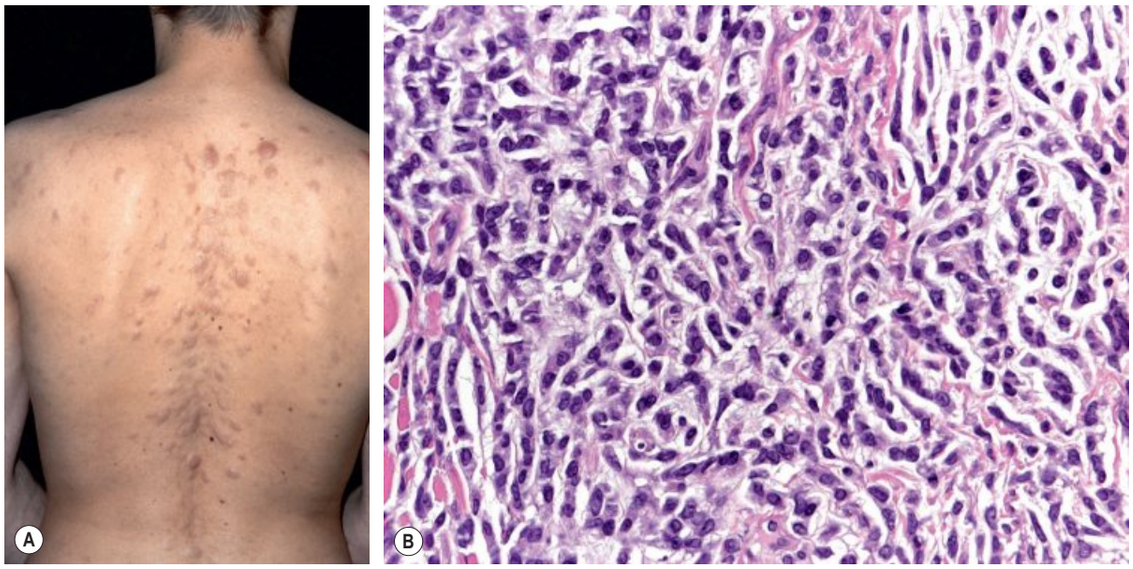

Fig. 121.8 Leukemia cutis. A Numerous violet–brown papules and plaques on the back of a patient with acute myelogenous leukemia. **B** Histologically, an infiltrate of atypical monocytoid cells characterized by nuclear pleomorphism and relatively abundant cytoplasm is seen.

CHARACTERISTICS OF DIFFERENT TYPES OF LEUKEMIA CUTIS				
Type of leukemia	**ALL**	**CLL**	**AML**	**CML**
Characteristic age	Between 2 and 5 years of age	Late 7th decade or older	Variable, most commonly 7th decade	Variable, most commonly after 50 years of age
Presenting anatomic site	Predominantly head and neck	Generalized; may appear at sites of infection (e.g. herpes zoster) or neoplasms (e.g. SCC)	Generalized	Variable
Clinical course	Aggressive	Indolent	Aggressive	Intermediate*
Subtype of leukemia/ immunophenotype	• 85%: B cell ALL ($CD19^+$, TdT^+, $CD20^+$, $CD5^+$, $CD10^+$, $CD22^+$, $CD79a^+$, $PAX\text{-}5^+$) • 15%: T cell ALL (TdT^+, $CD1a^+$, $CD2^+$, $CD3c^+$, $CD4^+$, $CD5^+$, $CD7^+$, $CD8^+$)	• B cell type ($CD5^+$, $CD23^+$, $LEF1^+$, $CD20^+$)	• $CD33^+$, $CD34^+$, myeloperoxidase$^+$ > $CD13^+$, $CD68^+$ • Markers may not be present if undifferentiated	• Most commonly, CMML • Cutaneous involvement associated with blast transformation
Incidence of cutaneous involvement	• Rare	• Not infrequent • Usually an incidental finding in biopsy specimens†	• More common with *NPM1*-mutated AML • May be presenting sign	• Rare
Time of presentation	• Late	• Late	• Early or late • May be the first sign of recurrence after treatment	• Late
Clinical appearance‡	• Large, non-ulcerated tumors • Nonspecific papulonodules	• Nonspecific papulonodules	• Nonspecific papulonodules	• Nonspecific papulonodules

*When acceleration or blast transformation occurs, becomes aggressive.
†Including primary cutaneous neoplasms (e.g. SCC), inflammatory disorders, and infectious diseases (see text).
‡Less common presentations reviewed in the text.

Table 121.7 Characteristics of different types of leukemia cutis. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; SCC, squamous cell carcinoma; TdT, terminal deoxytransferase.

Cutaneous Hodgkin Lymphoma

Synonyms: ■ Cutaneous Hodgkin disease ■ Cutaneous Hodgkin's disease

Key features

- Advanced stage in most patients with skin involvement
- Dermal nodules and plaques, sometimes ulcerated
- Dense dermal infiltrate with lymphocytes and eosinophils
- Atypical cells (lacunar cells, Reed–Sternberg cells)

History

In 1832, Thomas Hodgkin described a series of patients with lymphadenopathy, splenomegaly, and weight loss, all of whom died of their disease. Wilks reported a subsequent series of patients in 1885, and designated the illness Hodgkin's disease.

Epidemiology

Cutaneous involvement by Hodgkin lymphoma (HL) is rare[9,36–38]. In one large study, only 0.5% of patients with HL had cutaneous involvement[38], primarily in the setting of advanced disease and serving as a marker of poor prognosis. The existence of true primary cutaneous HL is debatable[9].

The incidence of HL peaks during early adulthood, with a second, smaller peak in the sixth decade. Of note, compared to the general population, mycosis fungoides and LyP occur at higher rates in patients with HL[37,39]. This reflects the increased incidence of non-Hodgkin lymphomas in general in HL patients. The underlying reason for this phenomenon is not known.

Pathogenesis

Approximately 30% of patients with classic HL (see below) have Epstein–Barr virus (EBV) DNA within the pathognomonic Reed–Sternberg tumor cells. The precise role of EBV in HL pathogenesis is not known[40]. In classic HL, the Reed–Sternberg cells represent the malignant population and are usually derived from B cell lymphocytes.

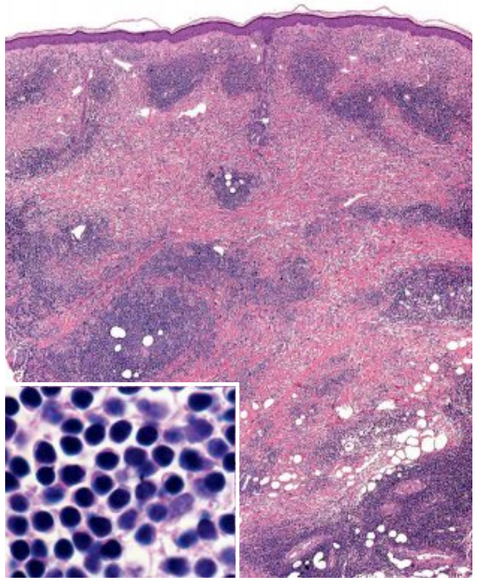

Fig. 121.9 Chronic lymphocytic leukemia (CLL). Nodular-diffuse infiltrates of lymphocytes are present within the entire dermis and superficial subcutis. The cells in CLL are small, monomorphous, hyperchromatic lymphocytes that lack significant cytologic atypia (inset). *Courtesy Lorenzo Cerroni, MD.*

Fig. 121.10 Blastic plasmacytoid dendritic cell neoplasm. Multiple firm violaceous nodules and plaques on the back. The scale-crust is at the site of a previous biopsy. *Courtesy Lorenzo Cerroni, MD.*

Clinical features

Classic HL includes the nodular sclerosing (most common), mixed cellularity, and lymphocyte-depleted forms of the disease, and it is characterized histologically by the presence of Reed–Sternberg cells. A small minority of patients have a non-classic, more indolent form of the disease, referred to as nodular lymphocyte-predominant HL.

Cutaneous involvement usually consists of multiple papulonodules or plaques in a patient with known, advanced disease. The trunk is the most common site of involvement[38], and lesions often appear in sites distal to affected lymph nodes. Lymphadenopathy, splenomegaly, and constitutional symptoms (e.g. fevers, chills, night sweats) are additional signs and symptoms.

In 20%–50% of patients with HL, paraneoplastic cutaneous disorders can develop. These include primary pruritus, acquired ichthyosis, persistent dermatitis, widespread eczema craquelé, hyperpigmentation, and occasionally, erythema nodosum[37].

Pathology

The histologic features of cutaneous HL are similar to those of affected lymph nodes. A nodular or diffuse dermal infiltrate consisting of lymphocytes admixed with eosinophils and plasma cells is present; epidermotropism is not seen. Depending upon the histologic subtype, Reed–Sternberg cells (or mononuclear variants) and lacunar cells may be present. The latter, most common in the nodular sclerosing subtype of HL, are large cells with abundant eosinophilic cytoplasm. The retraction of this cytoplasm from adjacent cells during fixation gives rise to a giant cell residing within a clear space. Areas of dermal sclerosis may be seen and extension into the subcutaneous fat is common.

Reed–Sternberg cells express CD30, fascin, and CD15, but not CD45RB (leukocyte common antigen) or CD20. They are positive for PAX-5, MUM-1, and in ~30% of cases, EBV (EBER-1). The background infiltrate of lymphocytes is composed predominantly of T cells[32]. In non-classic lymphocyte-predominant HL, the malignant cells stain positively for CD20[9,29].

Differential diagnosis

The histologic differential diagnosis of HL includes cALCL and LyP, both of which have cells that stain positively for CD30 (see Ch. 120). Clinicopathologic correlation is important in differentiating between these entities. Both LyP and cALCL can present with variably ulcerated papules and nodules, but patients with LyP do not have evidence of systemic involvement and crops of their lesions appear and then spontaneously resolve. Sheets of atypical $CD30^+$ cells are usually seen in cALCL, and the cells in LyP and most cases of cALCL do not stain positively for CD15 or PAX-5[9].

Treatment

Patients with stage IV HL, who may have secondary cutaneous disease, have a cure rate of ~70%–80% following combination chemotherapy. Treatments for recurrent disease include salvage chemotherapy, autologous HSCT, and anti-CD30 (brentuximab) and anti-PD-1 antibodies[41].

Blastic Plasmacytoid Dendritic Cell Neoplasm

Synonyms: ■ $CD4^+/CD56^+$ hematodermic neoplasm ■ Blastic NK cell lymphoma

Key features

- Single to multiple, non-tender papules, nodules, and plaques that can resemble bruises
- At initial presentation, skin is the most common site of involvement
- Dense perivascular infiltrate of uniformly atypical, medium-sized mononuclear cells
- Immunohistochemical profile: $CD123^+$, $CD4^+$, $CD56^+$, $TCF4^+$
- T cell receptor (TCR) and IgH gene rearrangements are not present
- Predictable good initial response to chemotherapy, but relapses common and poor survival

History and epidemiology

In 1994, blastic plasmacytoid dendritic cell neoplasm (BPDCN) was described by Adachi et al.[42] as a $CD4^+/CD56^+$ lymphoma presenting predominantly in the skin. Initially classified as blastic NK cell lymphoma due to its CD56 expression, this rare tumor was subsequently reclassified, first as a hematodermic neoplasm and then as a neoplasm of plasmacytoid dendritic cells[43]. Currently, BPCDN is listed as a myeloid-related specific entity in both the 2022 International Consensus Classification of Myeloid Neoplasms and in the recent WHO classification of Myeloid and Histiocytic/Dendritic Neoplasms[29a,29b,44].

BPDCN is a disease of adults, usually those >50 years of age, but pediatric cases have been reported. The male-to-female ratio is 3:1.

Pathogenesis

BPDCN represents a malignant proliferation of plasmacytoid dendritic cells. These cells produce large amounts of type I interferons (IFN), specifically IFN-α, and they express several Toll-like receptors (e.g. TLR7, TLR9), making them critical in the defense against viruses and other pathogens[29a,29b,45].

Clinical features

Clinically, BPDCN presents as solitary or multiple, non-tender, variably pruritic, erythematous to violaceous papules, plaques, or nodules that can resemble bruises (Fig. 121.10). Ulceration is uncommon. In most patients, the skin is the presenting site of involvement. However, further evaluation usually reveals subclinical regional lymph node, peripheral

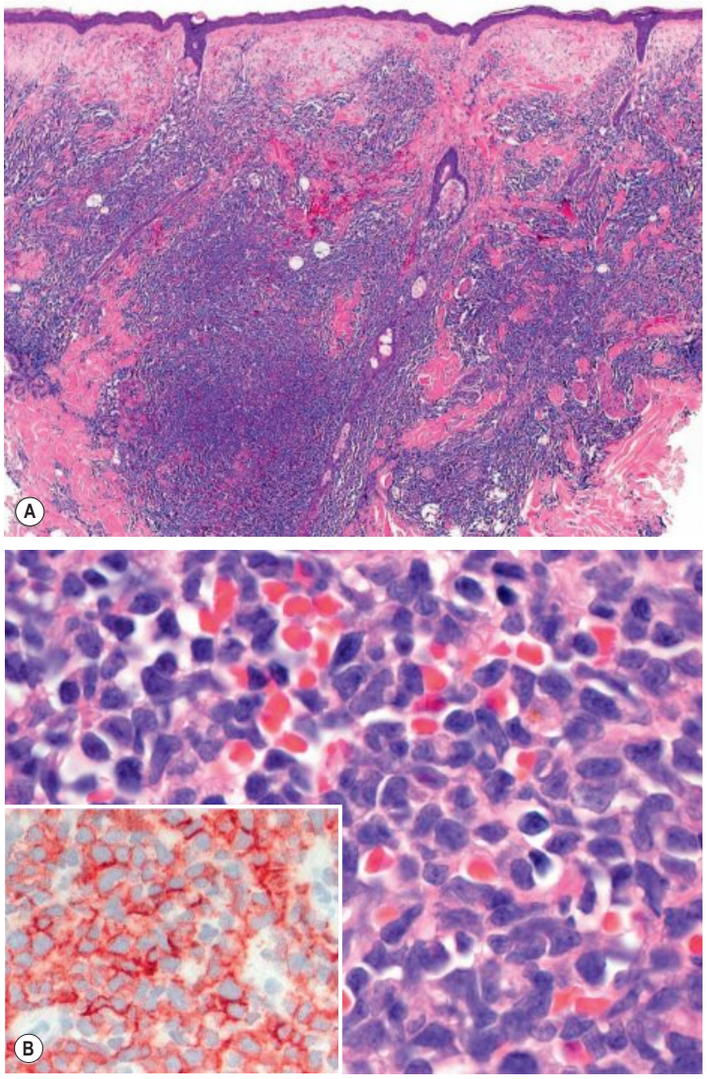

Fig. 121.11 Blastic plasmacytoid dendritic cell neoplasm. A Dense diffuse infiltrates of monomorphous blastoid cells within the entire dermis, with a grenz zone below the epidermis. **B** Diffuse infiltrate of medium-sized blastoid mononuclear cells admixed with extravasated erythrocytes; positive immunohistochemical staining for CD56 (inset). *Courtesy Lorenzo Cerroni, MD.*

blood, and bone marrow involvement in the majority of patients. Those individuals with initial negative staging eventually develop hematologic involvement. Symptoms of fevers, chills, night sweats, or weight loss are uncommon at presentation but may develop with disease progression.

Pathology

A diffuse dermal infiltrate of monotonous, atypical, medium-sized mononuclear cells is seen (Fig. 121.11A). These cells have fine blastic chromatin, indistinct nucleoli, and scant agranular eosinophilic cytoplasm. Intratumoral hemorrhage is common. In early lesions, the infiltrate may be perivascular and periadnexal. A grenz zone is almost always present and the infiltrate commonly extends into the subcutis[9,46,47].

Immunohistochemical studies are necessary to establish the diagnosis. The cells are $CD4^+$, $CD56^+$, $CD123^+$, $TCL1^+$, $CD2AP^+$, $BDCA2^+$/$CD303^+$, $TCF4^+$, myeloperoxidase$^-$, and EBV^- (Fig. 121.11B). TdT is variably positive. Although there are descriptions of aberrant $CD4^-$, $CD56^-$, or $CD123^-$ cases, diagnostic immunophenotypic criteria have been established[9,28,29a,29b,46,48].

The tumor cells have germline configurations of Ig (H and L) and TCR genes, i.e. lack rearrangement. Abnormalities of several chromosomes, including regions that contain genes involved in cell cycle regulation, have been reported[43,49–51].

Differential diagnosis

The differential diagnosis includes AML and other cutaneous lymphomas. BPDCN, however, lacks IgH and TCR gene rearrangements and has a characteristic immunohistochemical profile (see above). There are subtypes of AML that may express CD4, CD56, and CD123, but expression of TCL1, BDCA2/CD303, TCF4, and CD2-associated protein (CD2AP) points to the diagnosis of BPDCN[9,52]. Of note, there are reports of patients with BPDCN developing AML[29a,29b,44].

Treatment

Initial treatment of BPDCN originally consisted of multidrug chemotherapeutic regimens. Although response rates were high (up to 80%), invariably patients relapsed followed by progression, with one year being the median overall survival. Currently, tagraxofusp (an anti-CD123 fusion protein composed of recombinant IL-3 fused to truncated diphtheria toxin) is the recommended first-line therapy for BPDCN. Depending upon duration of response, which is yet to be determined, it may serve as a bridge to allogeneic HSCT[53,54].

Angioimmunoblastic T Cell Lymphoma

Synonyms:
- Angioimmunoblastic lymphadenopathy
- Angioimmunoblastic lymphadenopathy with dysproteinemia

Key features

- Constitutional symptoms (fever, sweats, weight loss)
- Variable cutaneous manifestations, including morbilliform eruption, urticaria, and rarely, erythroderma
- Polyclonal gammopathy, autoantibodies, autoimmune hemolytic anemia, immune thrombocytopenia, and peripheral eosinophilia
- Generalized lymphadenopathy, hepatosplenomegaly, and pleural effusions
- Most commonly, a superficial perivascular infiltrate within the dermis with eosinophils, but not atypia of the lymphocytes

History

This disease was initially described in 1974 as angioimmunoblastic lymphadenopathy with dysproteinemia, and its features included generalized lymphadenopathy, hepatosplenomegaly, polyclonal hypergammaglobulinemia, and a hemolytic anemia[55,56].

Epidemiology

Angioimmunoblastic T cell lymphoma (AITL) is a relatively rare disease of the middle-aged and elderly, with a nearly equal incidence in men and women[56]. It represents the second most common subtype of peripheral T cell lymphoma (PTCL; see Ch. 120)[28,56].

Pathogenesis

AITL was originally considered to be an atypical reactive process or an abnormal immunologic reaction, until next-generation sequencing identified recurrent mutations in several genes (e.g. *DNMT3A*, *TET2*, *IDH2*, *RHOA*) within neoplastic T cells[57]. In addition, EBV is often present in non-neoplastic B cells[28,29], thus explaining the occasional development of B cell lymphomas in these patients. Currently, in the 5th edition of the WHO classification of hematolymphoid neoplasms and in the 2022 International Consensus Classification of mature lymphoid neoplasms, it is considered to be a subtype of follicular helper T-cell lymphoma[28,29].

Clinical features

Patients with AITL usually present at an advanced stage with fever, weight loss, night sweats, generalized lymphadenopathy, and hepatosplenomegaly[28,29,56,57]. Approximately one-half of the patients have cutaneous manifestations. The most common presentation is a widespread morbilliform eruption that resembles a viral exanthem. Other cutaneous findings include petechiae (often associated with thrombocytopenia), urticaria, purpura, papulonodules, and rarely, erythroderma[57–59]. EBV positivity has been reported to be more common in those with papulonodules as opposed to other cutaneous manifestations[59]. As with HD, generalized pruritus may be a presenting symptom[57].

Patients can develop a host of autoimmune diseases including rheumatoid arthritis, vasculitis, and the entities listed in key features. In addition hypergammaglobulinemia, multiple autoantibodies, and

peripheral eosinophilia, laboratory abnormalities include lymphopenia, elevated LDH, and cold agglutinins[28,29,55–57]. AITL has an aggressive behavior, with a median survival of <3 years[28,29,56,57]. Both circulating EBV DNA copy number and EBV positivity within skin lesions are considered negative prognostic markers[59].

Pathology

In the skin, the histopathologic features vary, with five patterns described to date. These include: (1) a superficial perivascular infiltrate composed of plasma cells, eosinophils, and lymphocytes that lack atypia (most common pattern); (2) a sparse perivascular infiltrate with atypical lymphocytes; (3) a dense superficial and deep infiltrate of pleomorphic lymphocytes; (4) a vasculitis, with or without atypical lymphocytes; and (5) necrotizing granulomas[28,29,56,57]. A presentation with necrotizing granulomas resembling an infectious process has been reported[58]. Similar to involved lymph nodes, the skin may have increased numbers of venules with a prominent endothelial lining ("high endothelial venules").

By immunohistochemistry, the neoplastic cellular phenotype corresponds to T follicular helper cells ($CD3^+$, $CD4^+$, $CD8^-$, $CD10^+$, PD-1^+, $ICOS^+$, Bcl-6^+, chemokine ligand $CXCL13^+$) plus clusters of $CD21^+$ follicular dendritic cells[60]. As noted previously, EBV-encoded RNA (EBER) is often detected within non-neoplastic B cells but not in the neoplastic T cells[29,59], and EBER-1^+ B cells more commonly accompany dense, superficial and deep infiltrates of pleomorphic, large-sized atypical lymphocytes[59].

Molecular analysis demonstrates a monoclonal TCR rearrangement and usually a polyclonal immunoglobulin pattern[29]. The most common chromosomal abnormalities are trisomy 3 and tristomy 5[61].

Differential diagnosis

The morbilliform nature of the eruption belies its malignant nature. Consequently, confusion with a drug eruption or viral exanthem is common. As cutaneous histologic changes are subtle, a specific diagnosis often cannot be rendered. Differentiation from other cutaneous lymphomas with a T follicular helper cell phenotype may be very difficult, and the diagnosis of cutaneous AITL can only be established in patients with proven extracutaneous AITL.

Treatment

The majority of patients present with stage III–IV disease[56,57] and treatment options include multidrug chemotherapeutic regimens (e.g. cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]) versus CHOP plus brentuximab vedotin in those who have any evidence of CD30 expression in tumor cells. This may be followed by autologous HSCT. In patients with relapsed or refractory disease and a good performance status, allogeneic HSCT can be performed. Gentler palliative options include epigenetic modifiers such as histone deacetylase (HDAC) inhibitors (e.g. romidepsin) and possibly phosphoinositide-3-kinase inhibitors[56].

Lymphomatoid Granulomatosis

Key features

- EBV-driven angiocentric/destructive lymphoproliferative disorder
- Presents with cough, dyspnea, chest pain, and constitutional symptoms
- Cavitary pulmonary nodules on chest radiograph
- Nodular or ulcerative cutaneous lesions in 25%–50% of patients

History

Lymphomatoid granulomatosis (LG) was first described in 1972 as a pulmonary angiitis/granulomatosis that mimicked granulomatosis with polyangiitis. Initially thought to represent a reactive process, subsequent studies demonstrated a malignant clonal B cell population admixed with an abundant, polyclonal, reactive T cell population[28,29].

Epidemiology

LG is a rare disease of adults, usually presenting in the fifth to sixth decade of life. The male-to-female ratio is approximately 2:1. The disease can affect children, most commonly in the setting of immunodeficiency syndromes[28,29,62].

Pathogenesis

The pathogenesis of LG is often related to EBV infection, occasionally in combination with immunosuppression. Factors associated with LG include use of immunosuppressive medications (e.g. azathioprine, methotrexate, imatinib), HIV infection, Wiskott–Aldrich syndrome, X-linked lymphoproliferative syndrome, and additional lymphoproliferative disorders[28,29]. In the WHO classification of hematopoietic tumors, LG is categorized as an angiocentric/angiodestructive lymphoproliferative disease with variable histological grades[28,29].

Clinical features

Patients with LG present with symptoms related to pulmonary involvement, such as cough, dyspnea, and chest pain. Constitutional symptoms include fever, weight loss, malaise, arthralgias, and myalgias. Cutaneous lesions develop in 25%–50% of patients and usually present as nodules or ulcerated plaques (Fig. 121.12). Rarely, LG may present as a maculopapular exanthem. The kidney, brain, and gastrointestinal tract may be affected. In contrast to angioimmunoblastic T cell lymphoma, the lymph nodes and spleen are rarely involved.

Pathology

In LG, there are three histopathologic grades: (1) *grade 1* – polymorphous lymphoid infiltrate without cytologic atypia, along with a few large cells, and few cells are positive for EBV-encoded RNA 1 (EBER-1) and latent membrane protein via *in situ* hybridization and immunohistochemistry, respectively; (2) *grade 2* – polymorphous inflammatory background with scattered large cells and more abundant EBER-1^+ cells; and (3) *grade 3* – sheets of large B cells and numerous EBER-1^+ cells predominate over the inflammatory background. The amount of necrosis increases with the grade and angiocentricity/angiodestruction is consistently present. Granulomatous changes are often present. The neoplastic cells stain positively for CD20 and CD79a, and in most high-grade lesions there is a monoclonal rearrangement of the J_H genes[9,28,29].

Differential diagnosis

The clinical differential diagnosis includes various forms of cutaneous lymphoma, as well as infectious and inflammatory disorders (e.g. medium-sized vessel vasculitis, pyoderma gangrenosum). The histopathologic differential diagnosis is broad and encompasses most of the lymphoproliferative disorders mentioned above, including B cell and T cell lymphomas. Other disorders with histologic evidence of granulomatosis include granulomatosis with polyangiitis, sarcoidosis, and infectious processes. Diagnosis is based upon histopathologic findings plus immunohistochemical and molecular analyses. Because the existence

Fig. 121.12 Lymphomatoid granulomatosis. Ulcerated violaceous plaque in the popliteal fossa. *Courtesy Jean L. Bolognia, MD.*

of skin-limited disease without pulmonary involvement is debatable, such a diagnosis requires compelling evidence.

Treatment

LG follows an aggressive course, with the 5-year mortality ranging from 60% to 90%. For higher-grade disease, treatment commonly involves multidrug chemotherapy and/or rituximab (anti-CD20 monoclonal antibody), and, for grade 1 disease, IFN-α. Reversal of exogenous immunosuppression may also lead to clinical improvement[28,29].

Cutaneous Metastases 122

Christine J. Ko and Jennifer M. McNiff

Key features

- Cutaneous metastases are uncommon and rarely may be the presenting sign of an internal malignancy
- In general, cutaneous metastases are associated with a poor prognosis
- In women, breast carcinoma and melanoma are the malignancies that most frequently metastasize to the skin
- In men, melanoma and carcinomas of the head and neck, lung, and colon are the malignancies that most frequently metastasize to the skin
- Among common malignancies, breast carcinoma is the most likely to metastasize to the skin
- The most common clinical presentation for a cutaneous metastasis is a firm, painless, erythematous nodule
- Cutaneous metastases may arise in the anatomic vicinity of the primary cancer
- Cutaneous metastases typically have histologic features similar to, but not necessarily identical to, those of the primary malignancy
- Treatments include excision, chemotherapy, immunotherapy, and radiotherapy; the latter is often administered for palliation

INTRODUCTION

Given their prognostic implications, cutaneous metastases represent an important dermatologic entity. The skin is not a particularly common site for metastatic spread, and because the clinical appearance of cutaneous metastases can mimic more common disorders, e.g. epidermoid cysts (inflamed and non-inflamed; Fig. 122.1), lipomas, cellulitis, there may be a delay in diagnosis. This is especially true when the primary malignancy is occult. An understanding of the clinical spectrum as well as advances in histological assessment of skin metastases is vital to establishing the correct diagnosis.

Fig. 122.1 Cutaneous metastasis of small cell lung carcinoma. A skin-colored nodule on the neck that resembles an epidermoid cyst or lipoma. *Courtesy Ian Odell, MD, PhD.*

EPIDEMIOLOGY

Depending upon the series, cutaneous metastases occur in 1% to 10% of patients with metastatic disease (to any organ)[1]. Although uncommon, their recognition is important because they can be the first sign of metastatic disease and, as a result, have profound prognostic implications. The proportion of patients with metastatic disease who have cutaneous metastases depends upon the particular malignancy, e.g. the highest incidence is in individuals with metastatic melanoma, where up to 45% of patients can develop skin metastases (Table 122.1)[1]. Sex-specific cancer rates also influence the frequency of the various types of cutaneous metastases. In women, skin metastases are most often due to breast carcinoma (70%) and melanoma (12%), followed by carcinomas originating from the ovary, head and neck, and lung[1]. In men with skin metastases, the most common underlying malignancies are melanoma (32%), followed by carcinomas of the head and neck (16%), lung (12%), and colon (11%).

The overall prevalence of a cancer is also an important determinant. For instance, although skin metastases develop in only 2.5% of patients with metastatic lung cancer, they account for 12% of all cutaneous metastases in men due to the high prevalence of lung cancer[1] (Fig. 122.2).

CUTANEOUS METASTASES IN PATIENTS WITH METASTATIC CANCER

Primary malignancy	Percentage of all patients with cutaneous metastases*	Percentage of all patients *with metastatic disease* who developed cutaneous metastases*
Breast	50	30
Melanoma	18	45
SCC (head and neck)†	7	13
Lung	5	2.5
Unknown	4.5	7.5
Colon/rectum	4	4.5
Ovary	2.5	4
Urinary bladder	1.5	8
Endocrine glands	1	12.5
Esophagus	1	8.5
Gallbladder/bile ducts	<1	5.5
Liver	<1	5
Kidney	<1	4.5
Stomach	<1	2
Pancreas	<1	2
Uterine cervix	<1	1
Prostate	<1	<1
Testes	<1	<1

*The percentages are for men and women combined.
†Larynx, oropharynx, nasal sinuses.

Table 122.1 Cutaneous metastases in patients with metastatic cancer. Rates of metastatic spread do vary depending upon the series. *Adapted from Lookingbill DP, Spangler N, Helm KF. Cutaneous metastases in patients with metastatic carcinoma: a retrospective study of 4020 patients. J Am Acad Dermatol 1993;29:228–36.*

Similarly, the age of the patient plays a role, with rhabdomyosarcoma and neuroblastoma responsible for the majority of cutaneous metastases seen in children[2,3].

Cutaneous metastases develop an average of 36 months (range, 1 to 177 months) after the initial diagnosis of the primary malignancy[2,4]. Unfortunately, the vast majority (~95%) of patients with cutaneous metastases have advanced, stage III or IV disease. Rarely, cutaneous metastases can be the presenting sign of an internal malignancy (<1% of all new cancer diagnoses).

PATHOGENESIS

In 1889, Dr Stephen Paget espoused the "seed and soil" hypothesis as the paradigm of metastatic disease – a malignancy must develop the capability to dissociate from its native environment, survive during transit, and then propagate in a new milieu. This process includes detachment, intravasation, circulation, stasis, extravasation, and finally proliferation[5,6]. It is estimated that ≤0.01% of tumor cells shed into the vasculature form metastatic foci at distant sites[7].

The ability of a malignancy to acquire metastatic potential is thought to occur via one of two mechanisms[8]. In the clonal expansion or linear progression model, selective growth advantages are acquired during the course of tumor development. Over time, subpopulations of cells acquire genetic characteristics that enable them to dissociate and then propagate in distant tissues. In this model, metastatic foci have similar phenotypes and genotypes to the original tumor. Alternatively, in the variant or parallel progression model, rare, highly aggressive stem cell-like clones with high metastatic potential exist within the tumor and can cause dissemination at any point during tumorigenesis.

It is generally accepted that certain cancers tend to metastasize to distinct tissues. The mechanism by which they choose their final destination is related to hemostatic forces and surface protein expression patterns. When tumor emboli lodge in the first vascular bed they encounter, adhesion molecule interactions (e.g. integrins) facilitate extravasation and account for the commonly noted involvement of regional nodal basins. Yet, certain cancers have an affinity for specific tissues that are not anatomically convenient, such as prostate cancer spreading to bone and ocular melanoma metastasizing to the liver[3]. Adhesion molecule expression seems likely to influence this tissue-specific homing of metastases. However, these mechanisms may be attenuated in highly aggressive, undifferentiated tumors that display a more random distribution of metastases.

CLINICAL FEATURES

The clinical characteristics of cutaneous metastasis can provide important clues. When a patient with a known history of cancer presents with an extremely firm and rapidly growing erythematous nodule or an eruption of multiple skin nodules in close proximity to the primary tumor (Table 122.2), the diagnosis of cutaneous metastasis is relatively straightforward. However, the skin lesions may grow more slowly, and while metastases typically appear within several years of the diagnosis of the primary malignancy, they can present decades later.

The color of cutaneous metastases varies, from skin-colored to pink–red to blue–black, with the latter most commonly observed in metastatic melanoma (Fig. 122.3). In general, dermal and subcutaneous metastases are firmer on palpation than lipomas or epidermoid and tricholemmal (pilar) cysts. Cutaneous metastases can arise from hematogenous or lymphatic spread as well as direct extension. In the case of the latter two scenarios, as stated previously, proximity of the

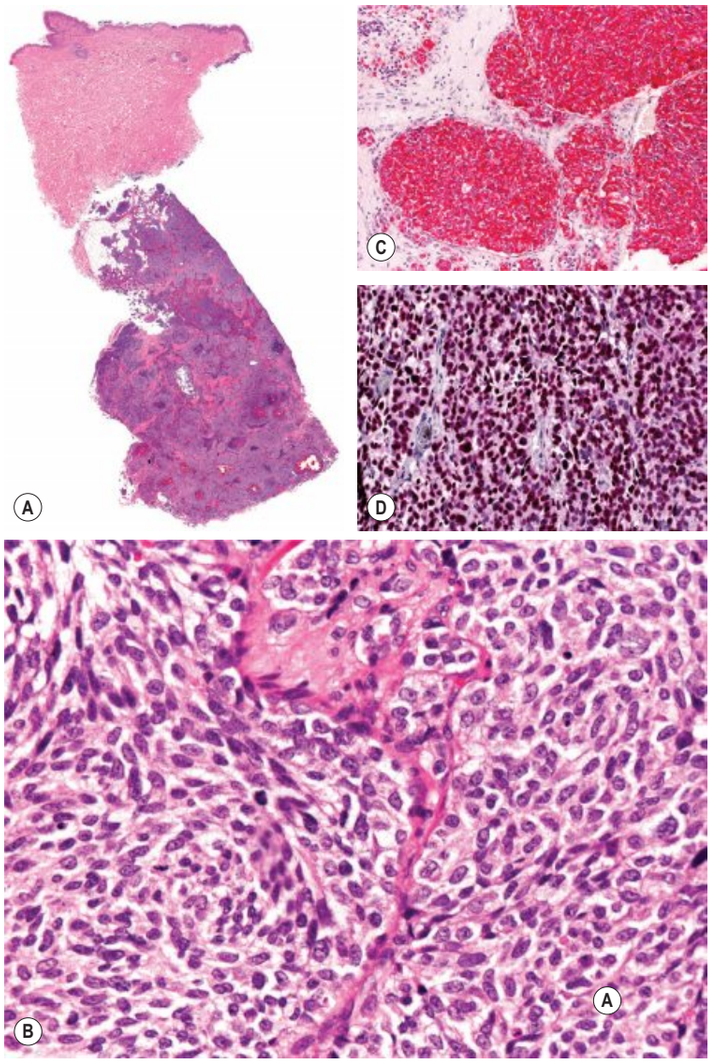

Fig. 122.2 Subcutaneous metastasis of small cell lung carcinoma. ANATOMIC LOCATIONS OF CUTANEOUS METASTASES			
Anatomic site	**Primary malignancy (men)**	**Primary malignancy (women)**	**Comments**
Scalp	Lung, renal	Breast	Can lead to alopecia ("alopecia neoplastica"; Fig. 122.3A)
Head & neck	SCC of the head & neck*, lung	Breast	Eyelid metastases from breast carcinoma have been reported; breast & lung metastases can lead to a "clown nose"
Upper extremities	Lung, renal, colon	Breast	Uncommon site in men and usually occurs late during disease
Back	Lung	Breast	20% of BSA, but site of 8% of metastases
Chest	Lung	Breast	
Abdomen	Colon, lung, stomach	Colon, ovary, breast	Sister Mary Joseph nodule (Fig. 122.4): most commonly gastric, colon, ovarian, or pancreatic cancers
Pelvis	Colon	Colon, ovary	Site of 8% of cutaneous metastases
Lower extremities	Melanoma > lung, renal	Melanoma > lung, renal	Uncommon site: 36% of BSA but site of only 4% of metastases

*e.g. larynx, oropharynx, nasal sinuses.

Table 122.2 Anatomic locations of cutaneous metastases. The trunk is the most common site (~55% of metastases) and the scalp is the site of ~15% of metastases[1]. BSA, body surface area; SCC, squamous cell carcinoma.
Adapted from Klein CA. Parallel progression of primary tumours and metastases. Nat Rev Cancer 2009;9:302–12.

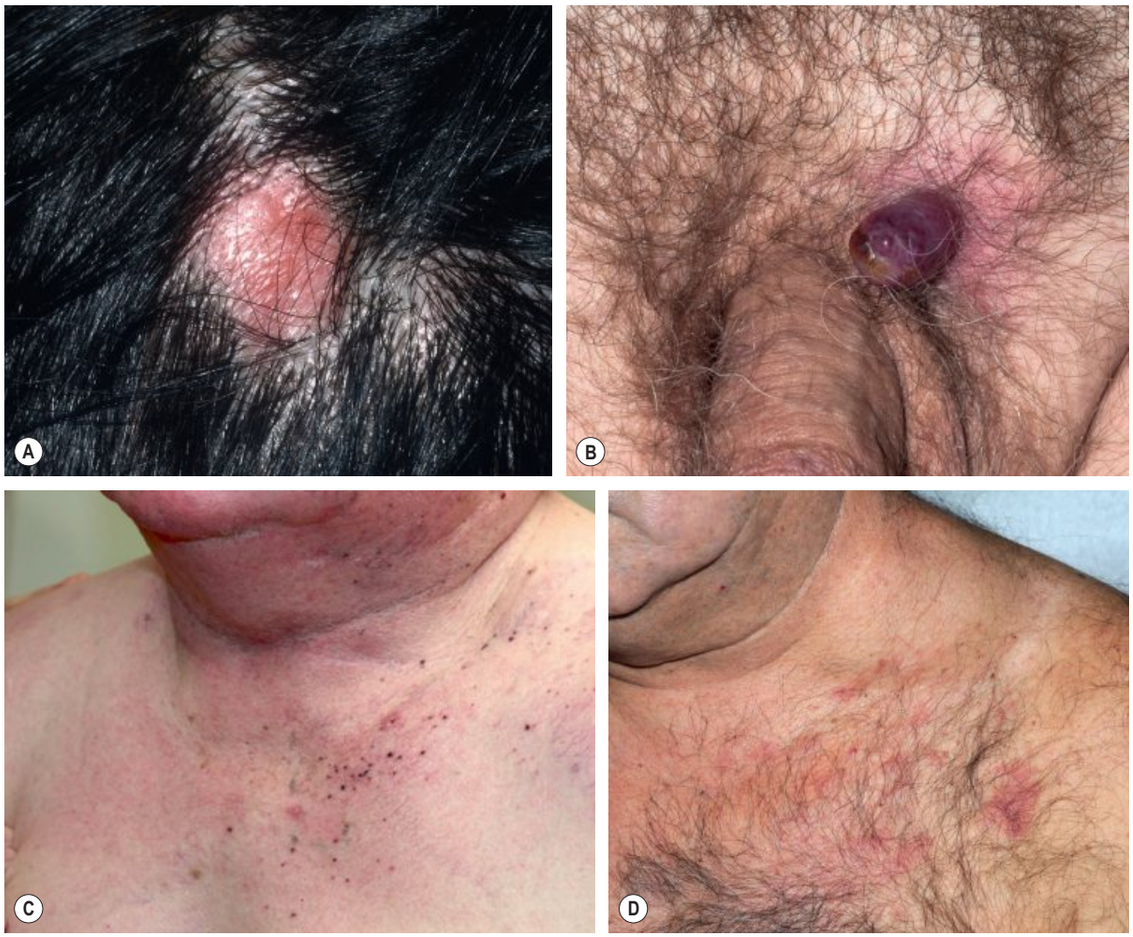

Fig. 122.3 Cutaneous metastases. **A** Pink nodule on the scalp with associated alopecia due to a metastasis from lung carcinoma (alopecia neoplastica). **B** Red–purple eroded nodule due to a metastasis from renal cell carcinoma; such lesions may be confused with vascular tumors. **C** Multiple small dark purple to black papules on the left neck and chest due to metastatic melanoma. **D** Pink papules and plaques on the chest due to metastases from adenocarcinoma of the colon. The patient was referred for treatment of dermatitis. *A, Courtesy Lorenzo Cerroni, MD; B, Courtesy Edward Cowen, MD; C, Courtesy Chris Bunick, MD; D, Courtesy Kalman Watsky, MD.*

metastasis to the primary malignancy serves as a diagnostic clue. An example of lymphatic spread is in-transit metastases of melanoma while direct extension is most commonly observed with breast carcinoma and squamous cell carcinoma of the head and neck.

There are additional examples of anatomic localization, including the predilection of gastrointestinal malignancies to metastasize to the periumbilical region, referred to as a Sister Mary Joseph nodule (Fig. 122.4). Occasionally, implantation of tumor occurs at the time of a surgical procedure, e.g. chest tube placement for a malignant pleural effusion due to lung cancer. Although the distribution of cutaneous metastases is usually more random in the case of hematogenous spread, the scalp can be a preferred site for some malignancies, e.g. renal cell carcinoma.

Of all the carcinomas that metastasize to the skin, breast cancer may be the one with the widest range of clinical presentations (Table 122.3), varying from papulonodules to patches of erythema mimicking erysipelas (inflammatory carcinoma) to woody induration with a *peau d'orange* appearance (Fig. 122.5). The latter is often referred to as "*en cuirasse*" due to its clinical resemblance to the leather armor of a soldier (*cuirassier*)[1]. In addition, intravascular metastases can lead to erythematous papules that may resemble vascular proliferations, including the angiosarcomas that can follow breast irradiation (see Ch. 114).

Less common presentations include the dermatitis-like appearance of Paget disease, both mammary and extramammary (see Table 122.3). Metastases of renal cell carcinoma can resemble pyogenic granulomas, including a tendency to bleed (see Fig. 122.3B). Rarely, intravascular metastases lead to a reticulated vascular pattern that is reflective of a vaso-occlusive process or the cutaneous metastases assume an unusual distribution pattern, e.g. zosteriform.

In addition to metastases from solid organs, leukemias and systemic lymphomas can also involve the skin (see Chs. 119–121). The lesions are often pink–violet to red–brown papulonodules and therefore may be clinically indistinguishable from cutaneous metastases due to solid organ malignancies. Skin involvement by leukemia or lymphoma is classically not referred to as "metastases".

PATHOLOGY

Adenocarcinoma, squamous cell carcinoma (SCC), and melanoma represent the three major categories of cutaneous metastases (Table 122.4). In broad terms, these metastatic tumors generally lack an epidermal connection or involvement, are situated in the dermis or subcutis, and are composed of nodules, nests, or cords of atypical cells with mitoses (Table 122.5). However, it is important to note that occasionally there are primary "dermal" nodular melanomas[9], and primary cutaneous spindle cell SCCs often lack a prominent epidermal component. In addition, cutaneous metastases of both melanoma and

Fig. 122.5 Various presentations of cutaneous metastases of breast carcinoma. A Eroded erythematous nodules in the axilla. **B** Inflammatory form (carcinoma erysipeloides) with patches of erythema that may initially be misdiagnosed as infectious cellulitis. **C** Primarily *en cuirasse* form with obvious induration and *peau d'orange* appearance in addition to papulonodules. **D** Mixed pattern – reticulated erythema of carcinoma erysipeloides as well as *peau d'orange* appearance near the areola. *A, D, Courtesy Stuart Lessin, MD.*

CLINICAL PRESENTATIONS OF CUTANEOUS METASTASES AND HISTOLOGIC CORRELATES			
Type	**Clinical description**	**Histology**	**Associated primary malignancy**
Dermal or subcutaneous nodules	Small miliary lesions to large tumors; single or multiple	Tumor cells infiltrating among collagen bundles or replacing dermis; grenz zone often present	Most common presentation; any type
Inflammatory carcinoma (carcinoma erysipeloides)	Erythematous patch with spreading border; resembles erysipelas	Tumor cells within dilated lymphatic vessels	Breast ≫ lung, ovary, prostate, GI, others
En cuirasse	Morpheaform or sclerodermoid, depending upon extent; indurated with *peau d'orange* appearance	Fibrosis with infiltrating tumor cells	Breast ≫ lung, GI, kidney, others
Carcinoma telangiectodes	Red–violet papules; purpuric patches with telangiectasias	Tumor cells within superficial blood vessels and RBC sludging	Breast
Paget disease*	Patches extending from the nipple and areola that resemble dermatitis	Large, atypical epithelial cells with abundant pale cytoplasm arranged in solitary units and small nests within all layers of the epidermis	Breast
Alopecia neoplastica	Nodules or plaques on the scalp in association with alopecia	Cords of tumor cells between collagen bundles	Breast > lung (Fig. 122.3A), renal, others
Pyogenic granuloma-like	Rapidly growing nodule resembling a vascular tumor (particularly a pyogenic granuloma)	Neoplastic cells in cords and lobules admixed with prominent hemorrhage and "pseudovascular" spaces	Renal clear cell carcinoma (Fig. 122.3B), hepatocellular carcinoma > others

*Lesions of extramammary Paget disease share similar histopathologic features with those of Paget disease of the breast, but usually represent (>75% of patients) primary cutaneous adenocarcinomas (see Ch. 73); an underlying visceral malignancy is most likely when there is perianal involvement.

Table 122.3 Clinical presentations of cutaneous metastases and histologic correlates. An individual patient can have an admixture of the various types. Occasionally, cutaneous metastases have a zosteriform distribution pattern and clinically they can resemble dermatoses, including eczema, vasculitis, and erythema annulare centrifugum. Obviously, they can also mimic cutaneous tumors, including non-melanoma skin cancers, epidermoid or pilar cysts, lipomas, granular cell tumors, or angiosarcoma[4]. GI, gastrointestinal; RBC, red blood cell.

PATHOLOGIC FINDINGS IN CUTANEOUS METASTASES			
Malignancy	**Possible histological clues**	**Immunohistochemical markers**	**Comments**
Adenocarcinomas – CEA positive and typically negative for p40/p63, CK5/6, D2–40 (podoplanin)			
Breast	Single filing or cords of cells (lobular CA); tumor cells form glandular structures (ductal CA); signet ring cells	CK7, ER/PR, mammoglobulin, gross cystic disease fluid protein-15 (GCDFP-15), GATA3	Breast CA can be ER/PR-negative; GCDFP-15 positivity also seen in cutaneous adnexal and salivary gland tumors; occasionally, ER/PR positivity in some primary cutaneous adnexal carcinomas
Colon	Columnar cells with basally oriented nuclei and intracytoplasmic mucin production; gland formation; "dirty" necrosis	CK20, CDX2, villin, SATB2	Mucinous CA can develop from other tissues (lung, ovary, uterine cervix) and rarely can be primary cutaneous
Non-small cell lung, adenocarcinoma		CK7, TTF-1, napsin A	Non-small cell lung CA can be TTF-1-negative; TTF-1 positivity not limited to lung or thyroid CA
Ovarian	Psammoma bodies can be seen in papillary serous CA	CA125, CK7, ER/PR, mesothelin, WT-1 (serous CA), PAX8	Mucinous ovarian CA may closely resemble other types of mucinous CA
Prostate		PSA, PSAP, NKX3.1	High-grade CA may lose glandular differentiation as well as PSA & PSAP expression
Pancreatobiliary		CK7, CK20, CA19.9, CA125	CA19.9 is not specific for pancreatobiliary tumors
Gastric	Signet ring cells (signet ring type)	CK7, CK20, lysozyme, CDX2, CDH17	Non-signet ring cell type gastric CA may not have distinct morphology; signet ring cell CA is not limited to the stomach (e.g. can be seen in breast CA)
Thyroid	Thyroid follicle formation (follicular CA); papillary structure, psammoma bodies (papillary CA)	TTF-1, thyroglobulin, napsin A	High-grade tumors (insular CA, anaplastic CA) may lose characteristic thyroid gland morphology
Squamous cell carcinoma – islands of keratin-producing epithelial cells that stain positively for cytokeratins (e.g. CK5/6, CK903, MNF116) and p40/p63			
Melanoma – stains positively for S100, SOX10, HMB45, MITF, MelanA (MART-1); see Ch. 113			
Merkel cell carcinoma – stains positively for CK20, SATB, and in a majority of cases, Merkel cell polyomavirus; see Ch. 115			
Neuroendocrine (non-Merkel cell carcinoma)			
Small cell carcinoma (including lung)	Nuclear molding, scant cytoplasm, indistinct nucleoli	Keratins, INSM1, TTF-1, CD56, neuron-specific enolase, chromogranin, synaptophysin; negative for CK20	Some small cell CAs, including lung, may not express neuroendocrine markers
Neuroendocrine tumor, including carcinoid tumor and atypical carcinoid tumor	Nests of cells with neuroendocrine morphology	Neuroendocrine markers (INSM1, CD56, chromogranin); medullary thyroid CA: calcitonin and TTF-1	Poorly preserved tissue may resemble lymphoma, carcinoma or small cell CA
Other			
Renal (clear cell)	Clear cytoplasm, highly vascular	Co-expression of EMA and vimentin, PAX8, CD10, RCC-Ma, napsin A	Renal cell CA can be composed of other cell types (e.g. granular or spindle)
Bladder and urothelial	Medium-sized tumor cells arranged in nests or sheets	p40/p63, CK5/6, CK7, CK20, GATA3; uroplakin II	May resemble high-grade cutaneous adnexal CA

Table 122.4 Pathologic findings in cutaneous metastases. p40/p63 negativity favors metastases, but it may be negative in some cutaneous adnexal carcinomas, particularly mucinous eccrine carcinoma. CA, carcinoma; CDH17, cadherin 17; CDX2, homeobox protein CDX2; CEA, carcinoembryonic antigen; CK, cytokeratin; EMA, epithelial membrane antigen; ER, estrogen receptor; GATA3, a transcription factor that regulates mammary epithelial differentiation; INSM1, insulinoma-associated protein 1; MITF, microphthalmia transcription factor; MNF116, pankeratin marker; NKX3.1, NK3 homeobox 1; PAX8, paired box 8; PR, progesterone receptor; PSA, prostate-specific antigen; PSAP, prostatic-specific acid phosphatase; RCC-Ma, renal cell carcinoma marker – detects a renal tubule antigen (highly specific); SATB2, special AT-rich sequence-binding protein 2/SATB homeobox 2; SCC, squamous cell carcinoma; SOX-10, SRY-box transcription factor 10; TTF-1, thyroid transcription factor 1; WT-1, product of Wilms tumor gene.

HISTOLOGIC CLUES TO THE DIAGNOSIS OF CUTANEOUS METASTASES
Well-circumscribed, usually symmetric, dermal or subcutaneous nodules of atypical cells with numerous mitoses and without connection to the epidermis (rarely cutaneous metastases are epidermotropic)
Presence of atypical cells within lymphatic vessels (differential diagnosis: intravascular lymphoma [neoplastic cells found in blood, not lymphatic, vessels], intravascular angiosarcoma [neoplastic cells in blood or lymphatic vessels], intralymphatic histiocytosis, intralymphatic cutaneous anaplastic large cell lymphoma, benign intralymphatic proliferation of T cell lymphoid blasts, Merkel cell carcinoma [neoplastic cells usually in lymphatic vessels, rarely in blood vessels])
Atypical cells arranged in lines within the dermis (differential diagnosis: myelogenous leukemia)
Presence of necrosis *en masse* at the center of a nodule of atypical cells (differential diagnosis: some lymphomas, some primary cutaneous adnexal carcinomas)

Table 122.5 Histologic clues to the diagnosis of cutaneous metastases.

SCC (cutaneous, oropharyngeal, or solid organ) may show significant epidermal involvement so that distinction from a synchronous or metachronous primary skin tumor can be difficult. Four primary histopathologic patterns of cutaneous metastases are: (1) nodular; (2) diffuse, including infiltrative; (3) intravascular, including intralymphatic; and (4) epidermotropic (Fig. 122.6).

The following can serve as histologic clues to the diagnosis of cutaneous metastases, in addition to those outlined in Table 122.5: (1) atypical single cells infiltrating through collagen bundles (breast carcinoma[10]; see Fig. 122.6B); (2) clear cells plus abundant hemorrhage (renal cell carcinoma; Fig. 122.7); (3) "dirty" necrosis within glandular structures (colon carcinoma); (4) formation of colloid within

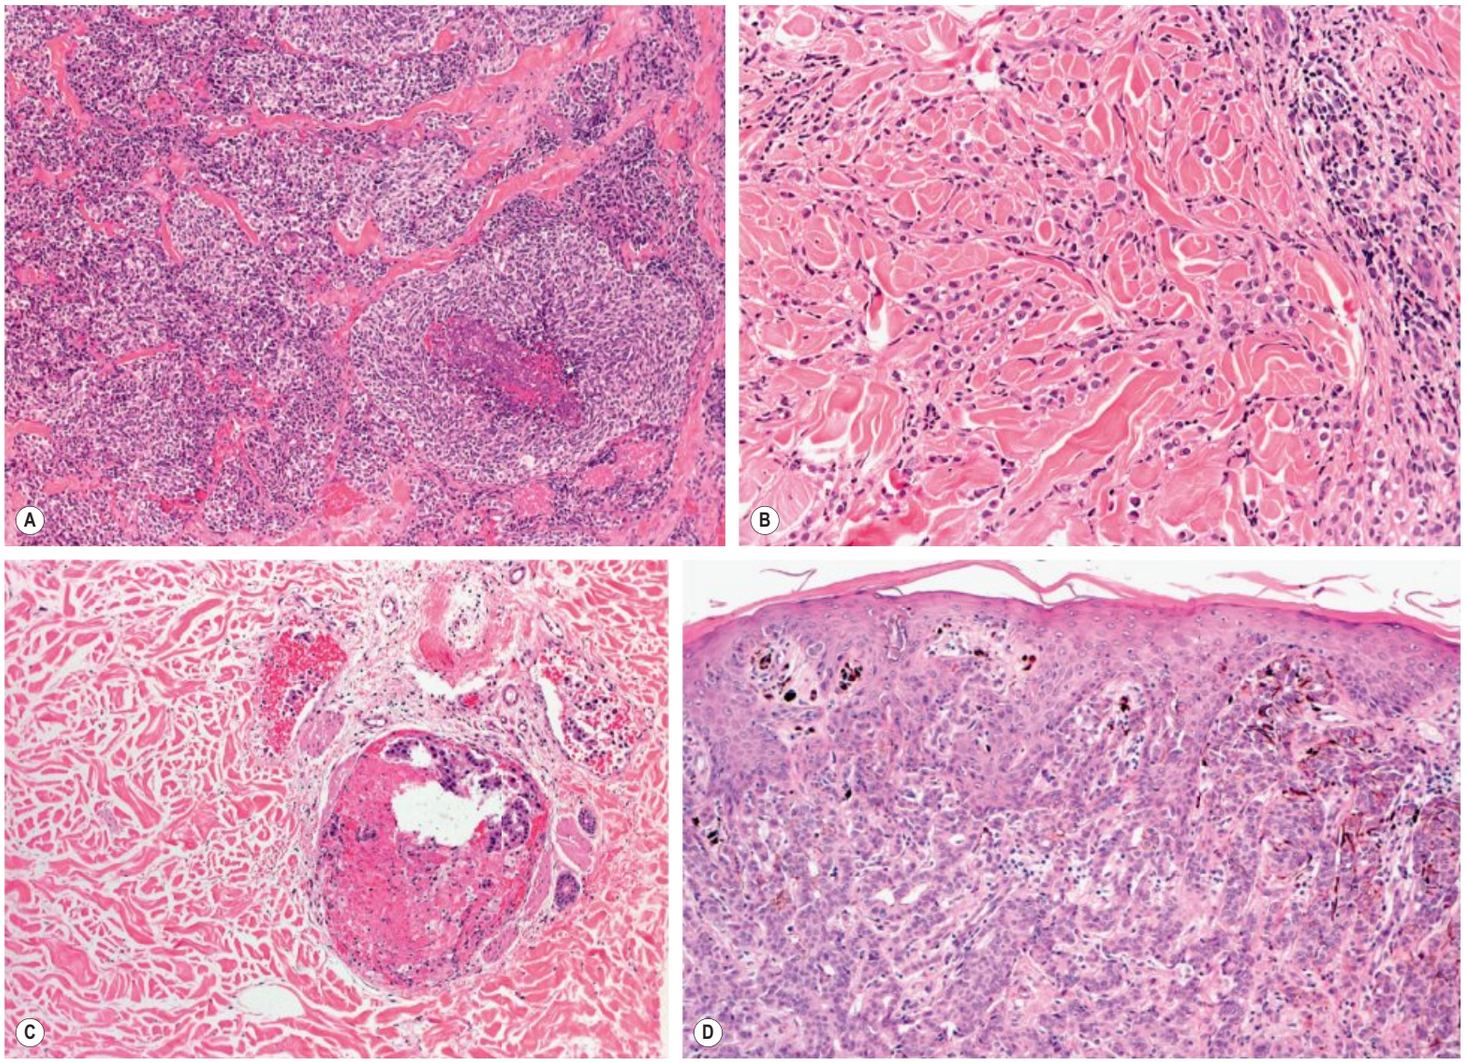

Fig. 122.6 Major patterns of cutaneous metastases. A Nodular pattern with focal, prominent necrosis in a cutaneous metastasis of small cell lung carcinoma. **B** Diffuse pattern with linear arrays of single cells in a metastasis of breast carcinoma. **C** Intralymphatic pattern in a metastatic breast carcinoma; tumor cells are confined to dilated lymphatic vessels. **D** Epidermotropic pattern in a metastasis of breast carcinoma; tumor cells are in both the dermis and the epidermis. The presence of focal pigmentation and melanocyte hyperplasia could lead to the misdiagnosis of a melanocytic tumor. *Courtesy Lorenzo Cerroni, MD.*

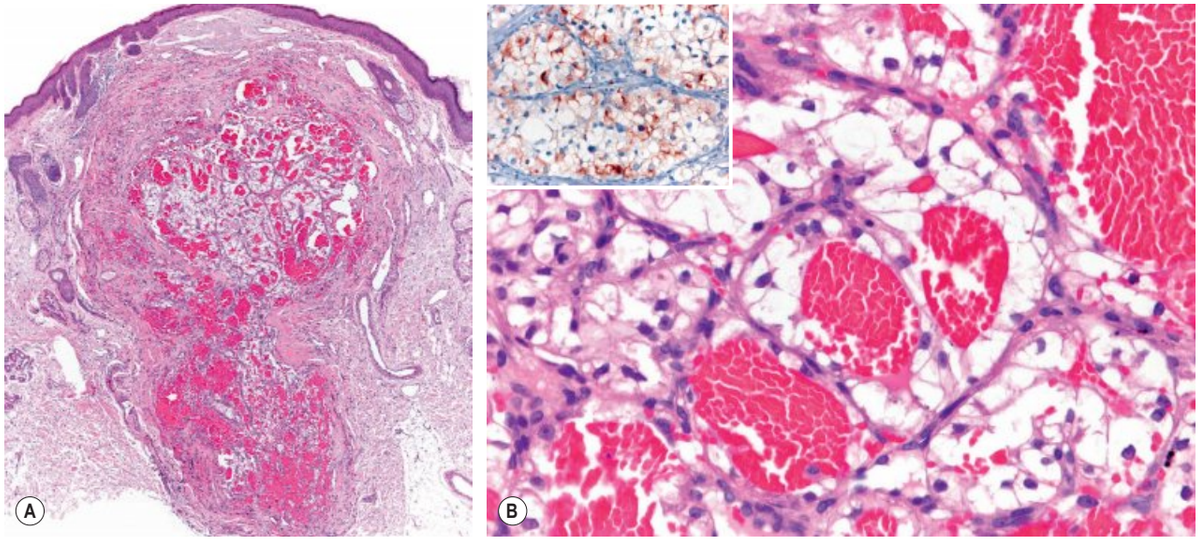

Fig. 122.7 Histopathologic features of cutaneous metastasis from clear cell renal cell carcinoma. A Vertically oriented hemorrhagic tumor within the dermis resembling an angiomatous tumor. **B** Tumor cells with clear cytoplasm arranged as fine trabecular structures and lobules surrounding hemorrhagic areas. The lack of prominent atypia can be misleading and lead to the erroneous diagnosis of hemangioma. Positive immunohistochemical staining with RCC-Ma (renal cell carcinoma marker), a monoclonal antibody directed against a proximal tubule antigen, labels clear cell renal cell carcinoma (inset). *Courtesy Lorenzo Cerroni, MD.*

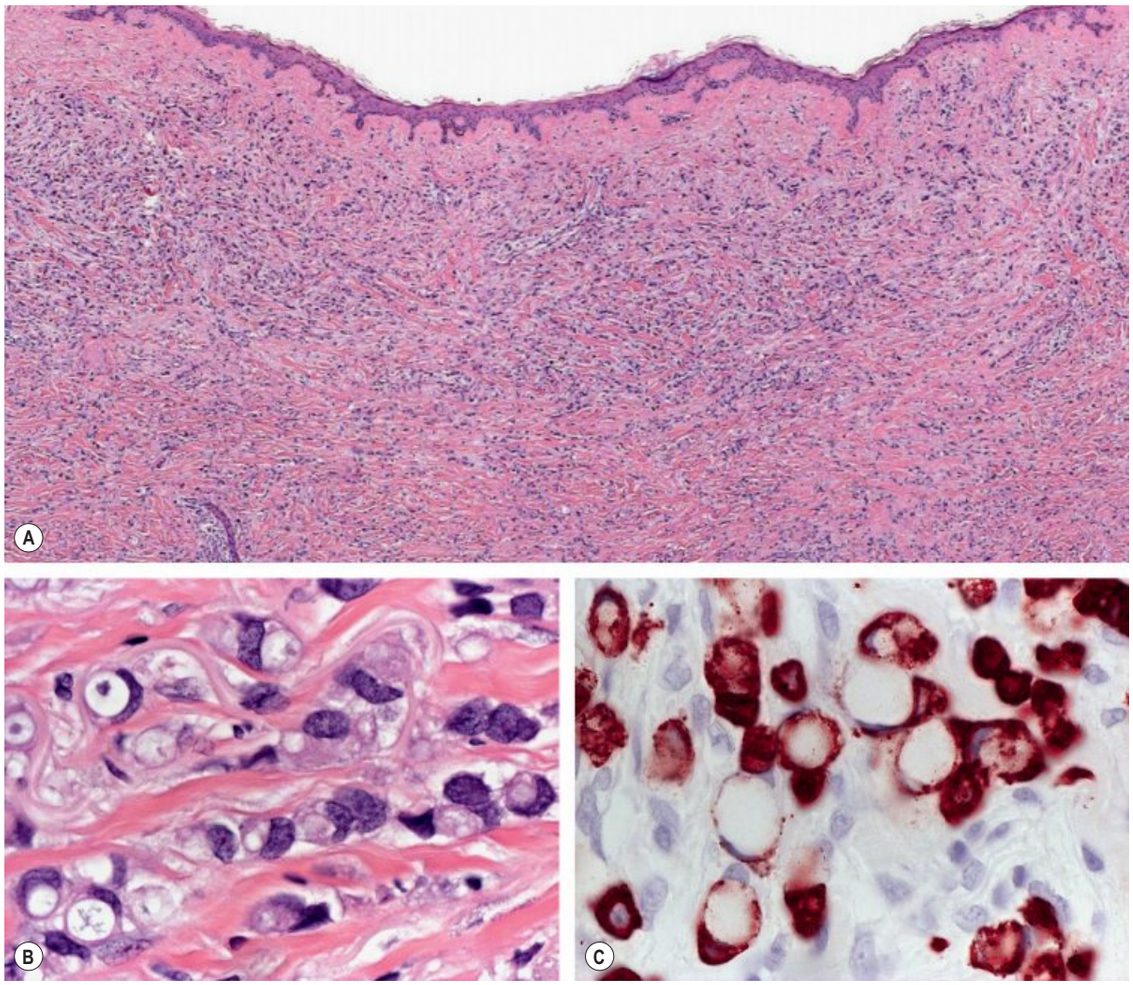

Fig. 122.8 Histopathologic features of cutaneous metastases of signet ring adenocarcinoma of the breast (A, B) and stomach (C). A Diffuse infiltration of neoplastic cells throughout the entire dermis. **B** Detail of neoplastic cells with signet ring cell morphology due to intracellular mucin accumulation. **C** Signet ring cells are not unique to breast carcinoma and may be observed in primary cutaneous carcinomas (e.g. histiocytoid carcinoma of the eyelid), non-epithelial neoplasms (e.g. melanoma), and a variety of adenocarcinomas, particularly those from the gastrointestinal tract. A cytokeratin (pan-CK) stain in this metastatic signet ring cell carcinoma of the stomach highlights the peculiar morphology of the cells, with intracellular mucin pressing the nuclei and distorting them, thus conferring the characteristic shape similar to that of a signet ring. *Courtesy Lorenzo Cerroni, MD.*

lumina (thyroid carcinoma); (5) psammoma bodies (thyroid or ovarian carcinoma); and (6) signet ring cells (gastric or breast carcinoma; Fig. 122.8)[11]. In addition to melanoma and SCC (see above), epidermotropism can occasionally be seen in cutaneous metastases from other malignancies, in particular breast carcinoma, and less often carcinomas of the prostate, colon, larynx, penis, or vagina[11]. Rarely, epidermotropic metastases, especially from breast carcinoma, may contain pigment and even an intratumoral increase in melanocytes, leading to the misdiagnosis of a melanocytic tumor (see Fig. 122.6D). When there is intravascular involvement, this may be confused with benign entities such as intralymphatic histiocytosis (Fig. 122.9).

Complete evaluation of a cutaneous metastasis often requires the use of a panel of histochemical stains (Fig. 122.10; see Table 122.4)[12]. While such stains are not a substitute for a detailed history and physical examination plus diagnostic imaging and biopsy of the primary tumor[12], the resulting information does provide direction and may circumvent the need for a more invasive biopsy of another tissue. In order to distinguish between a primary cutaneous tumor (usually an adnexal carcinoma) and a cutaneous metastasis (especially of adenocarcinoma), immunostains, in particular p40/p63, CK5/6 and D2–40 (podoplanin), can prove helpful[13–15]. Primary cutaneous tumors are typically positive for some or all these markers and metastases lack staining. Important exceptions are p63-positivity in some metastatic adenocarcinomas (breast, urothelial, and lung) and an absence of p63 staining in some primary cutaneous adnexal carcinomas.

In the case of cutaneous metastases from adenocarcinomas, various combinations of CK7 and CK20 expression can provide useful information (see Fig. 122.10)[15]. This panel is also employed to evaluate extramammary Paget disease, in which CK20 positivity points to a secondary form of the disease that is originating from a visceral malignancy (see Fig. 73.16).

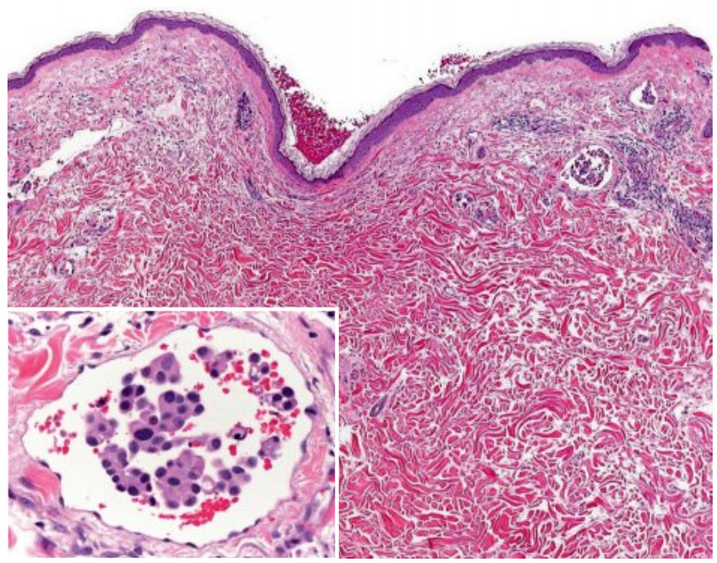

Fig. 122.9 Histopathologic features of cutaneous metastasis of urothelial micropapillary bladder carcinoma. Complexes of neoplastic cells within dilated lymphatic spaces in the dermis. Detail of a lymphatic space with intravascular tumor complexes admixed with erythrocytes (inset). Neoplastic urothelial (transitional) cells exhibit round–ovoid nuclei and abundant eosinophilic cytoplasm, and they form small rosette-like aggregates. These histopathologic features may simulate a benign condition, namely, intralymphatic histiocytosis. *Courtesy Lorenzo Cerroni, MD.*

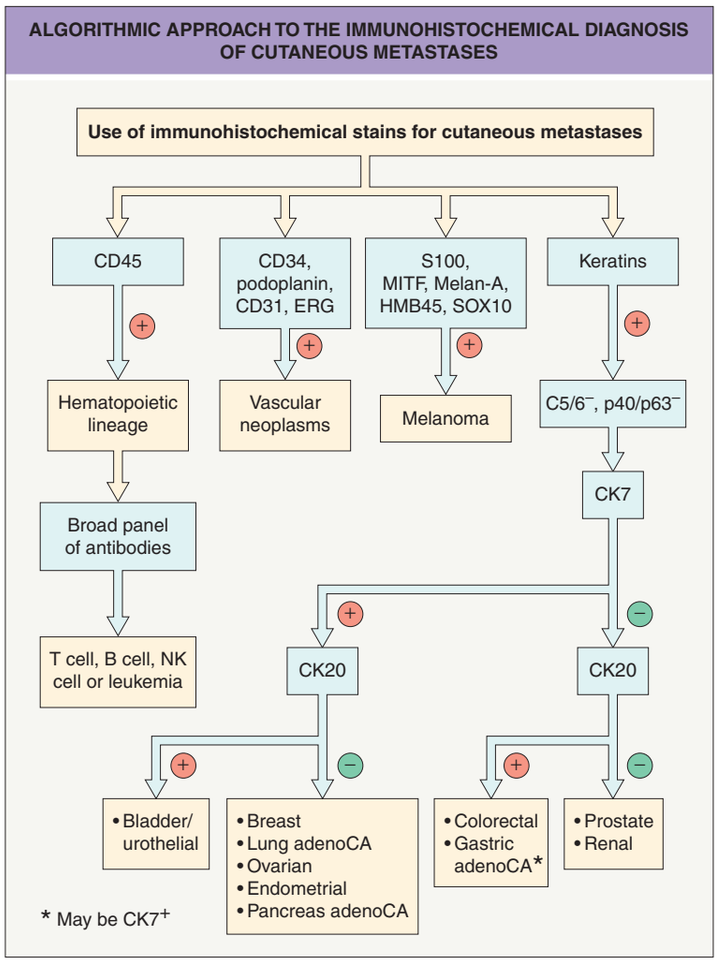

Fig. 122.10 Algorithmic approach to the immunohistochemical diagnosis of cutaneous metastases. The main differential diagnosis of metastatic adenocarcinoma is a primary cutaneous adnexal tumor (generally CK5/6$^+$, p40$^+$/p63$^+$). For tumors not clearly classifiable as a primary skin tumor, clinical history and directed immunohistochemical stains can be key to confirming the diagnosis. adenoCA, adenocarcinoma. *Adapted from Handa U, Kundu R, Dimri K. Cutaneous metastasis: a study of 138 cases diagnosed by fine-needle aspiration cytology. Acta Cytol 2017;61:47–54; Saeed S, Keehn CA, Morgan MB. Cutaneous metastasis: a clinical, pathological, and immunohistochemical appraisal. J Cutan Pathol 2004;31:419–30.*

Certain organ-restricted markers may also be useful including: CD10, RCC, and PAX8 (positive in renal and ovarian tumors); thyroid-specific transcription factor-1 (TTF-1) (thyroid, lung; see Fig. 122.2); thyroglobulin (thyroid); prostate specific antigen (PSA) and NKX3.1 (prostate); CDX2, CDH17, and SATB2 (gastrointestinal); Hep Par1 and arginase-1 (hepatocellular carcinoma); and CD56 and insulinoma-associated protein 1 (INSM1) (neuroendocrine) (see Table 122.4). In cutaneous metastases of SCC, staining for pankeratins and EMA may be positive, but this information is not helpful in determining the site of the primary SCC.

In addition to the histologic examination of conventional skin biopsies, cutaneous metastases can be sampled via fine-needle aspiration cytology[16].

TREATMENT AND PROGNOSIS

Typically, cutaneous metastases are a harbinger of late-stage or progressive disease and as such portend a poor prognosis. The average survival time following the initial diagnosis of cutaneous metastasis is 7.5 months[17] and half of patients expire within the first 6 months[18]. Whether the patient has a known or unknown primary malignancy, the development of cutaneous metastases calls for a multidisciplinary approach, including medical and surgical oncologists, radiation oncologists, and mental health care providers when appropriate. Localized treatment of cutaneous metastases can be undertaken for functional, palliative, or cosmetic indications. When feasible, surgical excision is performed; however, radiation and focal chemotherapeutics or immunotherapies can be considered on a case-by-case basis. Systemic therapies are indicated for immuno- or chemotherapy-responsive tumors. When malodorous, topical metronidazole solution (supplied for intravenous use) can be applied via cotton gauze or pump spray once to twice daily or crushed metronidazole tablets can be sprinkled onto the tumor twice daily.

Public Health and Dermatology 123

Eric J. Yang, Eleni Linos and Abrar A. Qureshi

INTRODUCTION

As a dermatologist walks into the examination room of the patient in Fig. 123.1, several diagnostic possibilities likely come to mind. The patient's history, additional physical findings, and other clues help narrow the differential diagnosis. In this case, knowing the patient's history of atopic dermatitis lends context to the appearance of monomorphous punched-out erosions and allows one to arrive at the diagnosis of eczema herpeticum. Therefore, awareness of the epidemiology of a disease, how it is distributed within populations, and the factors that influence its distribution can assist in establishing a diagnosis[1–3].

Considering the high or increasing prevalence of many skin conditions, dermatologists have the potential to play an important role in public health research and policy. This chapter highlights the relevance of dermatologic conditions to public health, the impact epidemiology can have on a dermatology practice, and major types of public health studies, as well as research design concepts and terminology used in epidemiology.

THE PUBLIC HEALTH IMPORTANCE OF DERMATOLOGY

Skin conditions are a major cause of morbidity worldwide. Based on analysis of global burden of disease data[4], skin diseases accounted for over 41 million disability-adjusted life years (DALYs) lost in 2013 and ranked as the fourth most common cause of non-fatal disease burden (Table 123.1). In the US, dermatology accounts for 4% of *all* outpatient visits, representing the third most common subspecialty ambulatory visit (after ophthalmology and orthopedics). In addition, ~5%–8% of primary care and 4% of emergency department visits are primarily for dermatologic conditions, with the most common outpatient diagnoses including eczema, skin infections, benign neoplasms, acne, psoriasis, and skin cancer[5–7]. Notably, in 2010, the symptom of itch accounted for 1% of all outpatient visits in the US[8].

Not only are dermatologic conditions common, but some are rising in incidence. For example, the incidence of melanoma increased by ~3% per year in the US from 1981 to 2005, and then at a lower rate of ~1% per year from 2005 to 2019[9]; these increases have included all tumor thickness groups, although mortality has overall been stable, with improvement more recently, especially in women and younger individuals[10]. In addition, many countries have experienced an increase in the frequency of keratinocyte carcinomas, i.e. basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs)[11–15]. Indoor tanning is associated with an increased risk of skin cancer and has reached alarming rates among youth, with indoor tanning exposure in nearly 20% of adolescents in the US, Canada, and Northern and Western Europe[16].

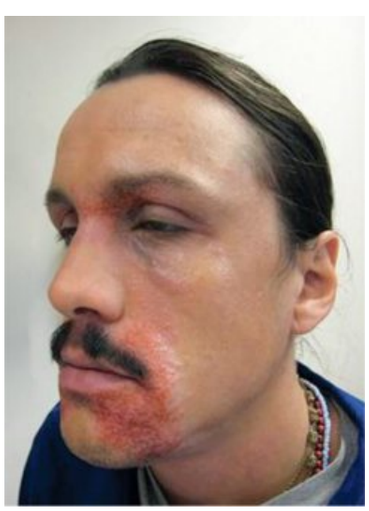

Fig. 123.1 Eczema herpeticum: diagnosis facilitated by knowledge of epidemiology. Grouped vesicles and punched-out erosions are evident. Based on this information alone, eczema herpeticum is in the differential diagnosis. However, awareness of the patient's history of atopic dermatitis, in combination with knowledge regarding the epidemiology of eczema herpeticum, allows for greater certainty in establishing the diagnosis.

Ensuring the health of Lesbian, Gay, Bisexual and Transgender (LGBT) persons is important for all physicians, including dermatologists. Recognition and treatment of sexually transmitted infections such as HIV and syphilis is essential, with the associated cutaneous manifestations often alerting one to the diagnosis[17] (see Chs. 78 and 82). In addition, high rates of skin cancer are a concern for gay men, based upon reports of six-fold higher rates of tanning bed use and over double the rates of skin cancer as compared to heterosexual men[18]. Cutaneous carcinomas are also more common and more aggressive in HIV-infected individuals.

Dermatologic care for transgender patients receiving gender-affirming hormonal and surgical treatments may include therapy for acne vulgaris and androgenetic alopecia exacerbated by testosterone treatment, terminal hair removal, and use of neurotoxin and dermal fillers to feminize or masculinize the face. Dermatologists must continue to address deficits in cultural competence related to transgender patients; an example would be recent modifications to make the FDA-mandated iPledge risk mitigation program more inclusive of transgender patients[19]. As emerging data suggest continued health disparities amongst the LGBT community, there is a greater need for healthcare providers who are culturally competent in LGBT health as well as more research on how to evaluate and address the existing disparities. Important considerations on the approach to caring for LGBT patients are outlined in Table 123.2.

ROLE OF EPIDEMIOLOGY IN DERMATOLOGY

Epidemiologic studies have yielded information on the etiology, risk factors, natural history, prognosis, incidence, prevalence, and effective treatments of dermatologic diseases. The impact that epidemiologic data can have on patient care and systems-based practice in dermatology is outlined in Table 123.3.

OBSERVATIONAL STUDIES

Participants in observational studies are observed and certain outcomes are measured, without external manipulation or an attempt to affect the outcome.

Descriptive Studies

Many of the studies currently being done in dermatology are descriptive. These include case reports and case series. A *case report* is a detailed description of an individual patient's demographics, clinical presentation, diagnosis, treatment, and disease course. A *case series* reports on some aspect(s) of a disease, diagnostic procedure, or treatment in a group of patients with common characteristics[20]. Case reports and series are useful for determining the manifestations of rare conditions, reporting the preliminary outcomes of experimental therapies, and generating hypotheses for larger studies. A major limitation of case series is the lack of a control group (Table 123.4)[20,21], although previous data (e.g. on the prevalence of risk factors in the general population) can sometimes be utilized for comparison.

An example of a valuable case series is the description of scalp involvement in patients with dermatomyositis by Kasteler and Callen[22]. Fourteen of the 17 patients with dermatomyositis who were

DISABILITY-ADJUSTED LIFE YEAR (DALY) RATES FOR ALL SKIN CONDITIONS COMBINED (2013)	
DALY rate/ 100 000 individuals	**Region**
<500	Central Asia
500–600	Central Europe, Eastern Europe, Central Latin America, East Asia, North Africa, Middle East
600–700	South Asia, Sub-Saharan Africa
700–800	High-income North America, Western Europe, Southern Latin America
>800	Australasia, Oceania

Table 123.1 Disability-adjusted life year (DALY) rates for all skin conditions combined (2013). Data from reference 4.

APPROACHES TO CARE FOR LESBIAN, GAY, BISEXUAL AND TRANSGENDER (LGBT) PATIENTS	
Goal	**Actions**
Create a safe and welcoming environment	• Display inclusive images in the office and waiting areas • Train staff on LGBT cultural competence and establish a zero-tolerance policy for discrimination • Include LGBT-specific demographic options on medical intake forms • Provide gender-neutral restrooms; allow patients to use the restroom of their choice • Recognize health disparities including health risk factors, barriers to care, discrimination, and minority stress
Use inclusive and patient-centered language	• Ask patients how they would like to be addressed • Ask which pronouns the patient prefers and use the patient's preferred terminology • Ask for clarification from the patient when needed • Apologize for errors when appropriate • Respect the patient's support system
Elicit sexual history when clinically appropriate	• Normalize sexual history taking in the context of medical care • Ask if the patient is sexually active; if they have sex with men, women, or both • Ask about which body parts the patient uses to have sexual intercourse • Ask about plans to become pregnant and/or contraceptive measures • Ask about methods of protection from HIV and other STDs • Ask transgender patients about completed/planned gender-affirming medical or surgical treatments

Table 123.2 Approaches to care for Lesbian, Gay, Bisexual and Transgender (LGBT) patients[19]. HIV, human immunodeficiency virus; STDs, sexually transmitted diseases.

seen in the authors' practice over a 5-year period had scalp involvement, manifesting as atrophic, erythematous, scaly plaques. Five of the 14 affected individuals had previously been diagnosed with scalp psoriasis or seborrheic dermatitis. This study helped raise awareness of scalp involvement as a manifestation of dermatomyositis.

Using Epidemiology to Identify the Cause of Disease

Case–control, cohort, and cross-sectional studies are often performed to help elucidate the etiology and risk factors of a disease (see Table 123.4). These methods involve studying a disease of interest (e.g. cutaneous SCC) and an exposure that is suspected of being a risk factor for the disease (e.g. ultraviolet [UV] radiation), so that the study participants can be categorized as having the disease or not and as being exposed to the potential risk factor or not (Table 123.5).

USES FOR EPIDEMIOLOGY IN DERMATOLOGY
Epidemiology applied at the patient care level
• Provide context to assist with diagnosis • Give guidance to patients on avoiding triggers and modifiable risk factors for their disease • Provide evidence for management strategies • Prevent associated comorbidities for patients and their families through early screening
Epidemiology applied at the systems level
• Raise awareness of the burden and distribution of skin disease in the community • Allow for appropriate allocation of resources for common and emerging conditions • Determine changing and future healthcare needs • Affect public policy

Table 123.3 Uses for epidemiology in dermatology.

Case–control study

A case–control study identifies a group of individuals with a disease, as well as a comparison group without the disease from the same population. The study design retrospectively evaluates the level of exposure in the disease group (cases), as compared to that in the group without disease (controls). To ensure that those with disease and without are comparable, both types of participants should be sampled from a single population and data collected in the same way for each group[23]. In addition, cases and controls should be matched on possible confounding factors; for example, if there is a 60-year-old female case, then a 60-year-old female control from the same general population would be selected.

A *confounder* is an extraneous variable that is associated with both the exposure and the disease being studied; it could therefore account for a part or all of the relationship between the exposure and disease. Although the confounder may be a contributing factor to the disease, it is not caused by the exposure and thus is not along the "causal pathway" between the exposure and disease[1,2] (Fig. 123.2). Age and sex are examples of possible confounders. These and other characteristics that may be associated with both the exposure and the disease should also be recorded and placed in the statistical model. If an association remains after accounting for confounders, it is more likely to be a true one.

In a case–control study, one can calculate the odds of having had the exposure among those with disease (a/c), as compared to the odds of having had the exposure among those without disease (b/d) (see Table 123.5). The association measure used for case–control studies is an *odds ratio* (OR), which equals (a/c)/(b/d) or ad/bc. An OR = 1 denotes a null association, whereas an OR statistically significantly greater or less than 1 indicates a positive or negative association, respectively. An OR is different from a *relative risk* (RR), the rate of disease among those exposed divided by that among those unexposed, (a/a+b)/(c/c+d) (see Cohort study section below). While the RR cannot be directly calculated from a case–control study, the OR approximates the RR when the disease is rare.

One of the major advantages of a case–control study is that it can yield information on a disease with many possible predictors, yet use only a limited number of participants. Therefore, it is well-suited for the investigation of rare conditions. Also, these studies are relatively inexpensive and time-efficient. One of the disadvantages of a case–control study is that it is not clear if the exposure preceded the disease, so causality cannot be established. In addition, this type of study has several potential biases. *Sampling bias* can occur when cases and controls are collected separately and may not be comparable. Because of the retrospective ascertainment of exposure, *recall bias* can occur; for example, those with disease may recall the exposure with greater detail because they have been contemplating the potential causes of their condition. Of note, a case–control study does not yield information on the incidence or prevalence of a disease.

An example of a case–control study is that by Picard et al.[24], which examined the association between psoriasis (here the "exposure") and coronary artery disease. They compared the prevalence of psoriasis in

STUDY TYPES AND THEIR CHARACTERISTICS						
Type of study	**Study group**	**Control group**	**Association measure frequently used**	**Advantages**	**Limitations**	**Level of evidence for whether a therapy is efficacious***
Case series	Persons with disease	None	Varies (e.g. percentile)	• Describes rare conditions and therapies	• No control group, no information on background level of exposure for comparison	4
Case–control	Persons with disease	Persons without disease	OR (approximates the RR in rare diseases)	• Can study rare diseases • Short duration, inexpensive, small size	• Potential for bias and confounding because sampling two different populations • Does not establish causal relationship • Limited to one disease	3
Cohort	Persons exposed	Persons not exposed	RR or absolute risk†	• Causal inference • Can evaluate a number of diseases • Yields incidence of disease • Can study rare exposures	• Often requires a large sample size • Less feasible for rare diseases	2‡
Cross-sectional	Persons with disease or exposed	Either of the above	OR or relative prevalence	• Can study several exposures and diseases • Relatively short duration • Yields *disease and exposure prevalence*	• Does not establish causality • Less feasible for rare diseases	2‡
Randomized controlled trials (RCTs)	Persons randomized to treatment	Persons randomized to control	Varies (e.g. RR or percentiles)	• Ability to demonstrate causality • Randomization and blinding help to decrease bias or confounding	• Expensive • Can expose participants to potential harm • Answers a narrow clinical question	1

*The level of evidence for a therapeutic efficacy has a scale of 1–5, 1 being the best. Expert opinions represent level 5. The level of evidence for therapeutic efficacy for a systematic review depends on the types of studies it reviews. A systematic review of RCTs with good homogeneity ranks above an individual RCT.
†***Absolute risk reduction*** is the incidence rate of disease in the exposed group subtracted by that of the unexposed group. This is affected by the rate of disease in the population; the greater the prevalence of disease, the higher the absolute risk reduction. The reciprocal of absolute risk reduction is the ***number needed to treat*** to avoid one person getting the disease.
‡In general, a cohort study (2b) is ranked as better than a cross-sectional study (2c).

Table 123.4 Study types and their characteristics[2,21,23]**.** OR odds ratio; RR, relative risk.

CATEGORIZATION OF STUDY PARTICIPANTS, BASED ON THEIR DISEASE AND EXPOSURE		
	Disease (e.g. cutaneous SCC)	**No disease (e.g. no cutaneous SCC)**
Exposed (e.g. high-dose UV)	a	b
Non-exposed (e.g. no high-dose UV)	c	d

Table 123.5 Categorization of study participants, based on their disease and exposure. An odds ratio (OR) = (a/c)/(b/d) whereas relative risk (RR) = (a/a+b)/(c/c+d). SCC, squamous cell carcinoma; UV, ultraviolet radiation.

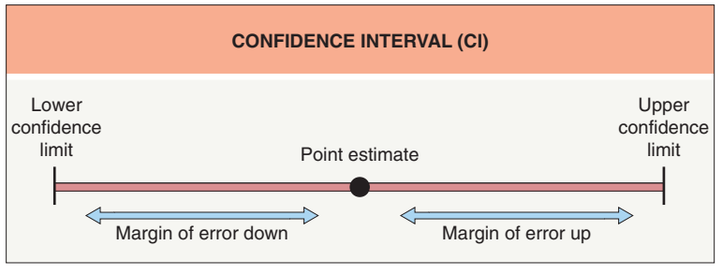

Fig. 123.3 Confidence interval (CI). A confidence interval derived from a valid analysis will, over unlimited repetitions of the study, contain the true parameter 95% of the time.

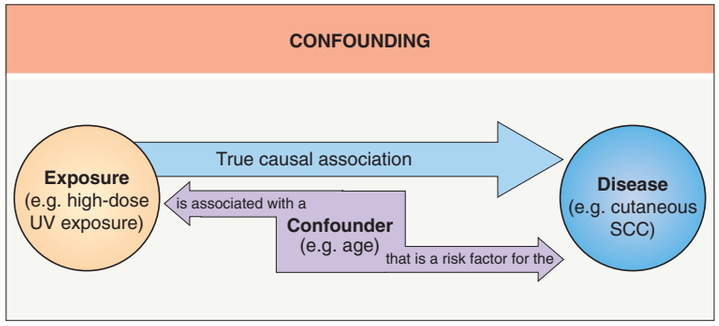

Fig. 123.2 Confounding. The blue arrow represents a true association, in this case a causal one. The purple arrow does not represent a true association, but one found because of confounding. SCC, squamous cell carcinoma; UV, ultraviolet radiation.

case patients referred to a cardiologist for coronary artery disease (CAD; confirmed by angiography) to that in age- and sex-matched control patients without CAD (lack of history or symptoms; no Q wave on electrocardiogram) who were referred to a surgeon for a non-cardiovascular condition. The investigators found that psoriasis was present in 8.0% of cases and 3.4% of controls, with an OR of 2.64 (95% confidence interval [CI], 1.42–4.88). In other words, those with CAD had 2.64 times greater odds of having psoriasis, when compared to those without CAD. The 95% CI does not include 1, signifying that the OR is statistically significant (Fig. 123.3). However, upon adjusting for potentially confounding cardiovascular risk factors in multivariate analysis, the OR decreased to 1.84 (95% CI, 0.99–3.40), which includes 1 and is therefore only of borderline significance.

Cohort study

A cohort study recruits its participants from the general population, and those recruited must be without the disease of interest. Using the example given in Table 123.5, all participants would need to be

SCC-free at the onset of the study. They are then categorized as having or not having high-dose UV exposure and are followed over time. At the end of the study, one can calculate the rate of cutaneous SCC among those with high-dose UV exposure (a/a+b) and compare it to the rate of SCC among those without high-dose UV exposure (c/c+d). Therefore, a cohort study compares the incidence of disease between those exposed and not exposed to particular risk factor(s). This is usually expressed in terms of a RR (see definition above). Similar to an OR, a RR of 1 represents a null association, whereas a RR statistically significantly greater or less than 1 indicates a positive or negative association, respectively. A cohort study can be done prospectively, allowing for more control over measuring outcomes (preferred particularly for fatal diseases), or retrospectively, which is less expensive and requires less time.

One of the advantages of a cohort study is that it can determine the *incidence* of a disease, which is the number of new cases divided by the total number of people at risk in a particular population (e.g. participants in the study) over a specified time period (e.g. length of study)[1]. It also gives information on the natural history of a disease, since it captures data from the time of disease onset. Another advantage is that a cohort study establishes temporality, as the exposure precedes the outcome, and therefore allows for causal inference between the exposure and disease. The disadvantages are that a cohort study often requires a large sample size and is less feasible for rare outcomes.

A cohort study by Zhang et al.[25] looked at the association between tanning bed use and development of skin cancers. Their study population included >70 000 female nurses who were followed between 1989 and 2009. After adjusting for possible confounders (e.g. age, skin type, sun exposure, UV index at place of residence), they found that for an incremental increase of 4 sessions/year in mean use of tanning beds prior to age 35 years, the RR of developing BCC was 1.15 (95% CI, 1.11 to 1.19). Thus, the use of tanning beds a mean of 4 or 8 times per year resulted in a ~15% or ~30% higher risk of BCC, respectively, compared to not using tanning beds. This demonstrates a "dose response" effect, i.e. women who used tanning beds more often had a higher skin cancer risk. Furthermore, the authors noted that women exposed to tanning beds in their teenage or college years were at higher risk than those exposed later in life.

Effect modification or *interaction* occurs when the association between the exposure and disease varies across levels of a variable (e.g. age; Fig. 123.4). Therefore, the exposure and effect modifier have an interdependent role in their effect on the disease. When this happens, the association between exposure and disease should be displayed at various levels or strata of the effect modifier[1,2].

Cross-sectional study

A cross-sectional study is similar to a cohort study, except that the initial population does not need to be free of the disease of interest and both the exposure and disease are measured at a single time point, without a follow-up period. It yields information on the *prevalence* of disease, which is the number of affected individuals divided by the number of people in the population at risk (e.g. total number of study participants), at a given time. It allows one to study the association between exposure and disease, but it does not provide information about which preceded the other. Cross-sectional study results are often expressed in terms of ORs or *relative prevalence*, which compares the prevalence rate of a disease among those exposed to that among the unexposed. While mathematically it is represented by (a/a+b)/(c/c+d) (see Table 123.5), here a/a+b and c/c+d are prevalence rates, rather than incidence rates, as in a cohort study.

The advantages of a cross-sectional study are that it is relatively fast, inexpensive, and does not require follow-up. It is the only epidemiologic study that gives the prevalence of a disease, exposure, or other risk factor. One of its weaknesses is that it does not demonstrate temporality, and so it cannot establish a causal relationship between the exposure and disease. Also, it is not practical for rare diseases or rare exposures, which would require a very large study population.

An example of a cross-sectional study is one by Love et al.[26], which used a national database representative of the non-institutionalized civilian US population, the National Health and Nutrition Examination Survey. It found that the prevalence of metabolic syndrome was 40% among psoriasis cases, compared to 23% among controls. After adjusting for age, sex, race/ethnicity, smoking status, and C-reactive protein levels, the OR for the association between psoriasis and metabolic syndrome was 1.96 (95% CI 1.01–3.77). Therefore, patients with psoriasis had a 1.96 times or 96% greater odds of having metabolic syndrome, as compared to those without psoriasis.

ASSESSING THE EFFICACY OF A PREVENTIVE OR THERAPEUTIC INTERVENTION

Clinical Trials

Unlike observational studies, clinical trials involve an intervention. In a randomized controlled trial (RCT), participants are randomized to receive the intervention versus a placebo or an alternative therapy. Participants can be blinded to their group, as can the observers (double-blinded). The participants are followed for a given period of time, during which disease outcomes and safety are measured. Table 123.6 presents the four phases for testing of new drug therapies. *Intention-to-treat analysis* is then performed, which classifies participants into the intervention group that they were assigned through randomization, rather than the actual intervention that they received; variation can arise if participants crossed over into the other intervention group because of non-compliance, side effects, or other reasons. This preserves the randomization of the study design. However, an analysis taking into account the actual intervention received is done as well, for comparison. The outcome measures for a RCT vary according to the outcome of interest (e.g. relative risk, percentile improvement comparison across groups, prognosis measures; Table 123.7). The concept of statistical significance is applied to assess whether the differences in outcome occurred by chance or likely represent a true effect of the intervention.

The major advantage of a controlled trial is its ability to demonstrate causality (Table 123.8). Randomization can eliminate confounding effects and blinding can eliminate bias. The disadvantages are that controlled trials are relatively expensive, can expose participants to potential harm, and answer a narrow clinical question. Therefore, RCTs are often reserved for well-developed research questions that

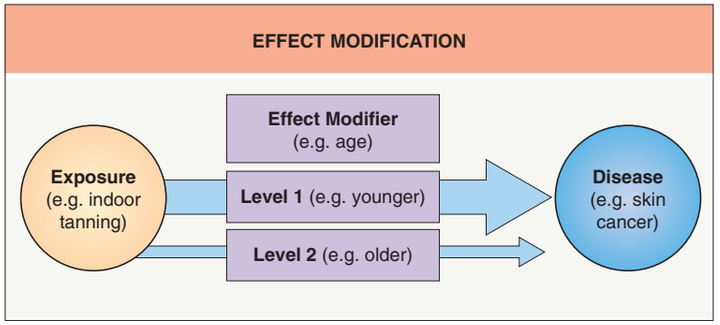

Fig. 123.4 Effect modification. The blue arrow represents a true association, in this case a causal one; the thicker it is, the stronger the association. If a variable causes effect modification, the strength of the association between exposure and disease varies across levels of the effect modifier. In some cases, there may not be an association for a given level of the effect modifier. Age is an effect modifier for many conditions. Interaction represents a similar concept that occurs when the exposure and another variable are interdependent in their effect on disease. MI, myocardial infarction.

THE FOUR PHASES OF TESTING A NEW DRUG	
Phase I	An unblinded, uncontrolled study that involves a few volunteers and focuses on a drug's safety and pharmacologic profile
Phase II	A small, randomized trial that tests for efficacy as well as relative safety
Phase III	A larger, randomized trial that tests for effectiveness and safety
If the drug passes phase III, it can be approved by the FDA	
Phase IV	A trial or observational study used for post-marketing surveillance to assess the rate of serious side effects and evaluate for additional therapeutic uses

Table 123.6 The four phases of testing a new drug[2,23]. FDA, Food and Drug Administration.

FIVE WAYS OF EXPRESSING PROGNOSIS AND SURVIVAL DATA	
Case-fatality rate	The number who died from the disease of interest divided by the number of those with the disease; used more for short-term acute conditions
Five-year survival	The percentage of patients who are alive 5 years after diagnosis or after treatment begins; often used in evaluating cancer research
Observed survival rate	Expressed in probability of survival each year of the study (e.g. a life table) or based on the time interval from baseline to when a study participant dies (e.g. a Kaplan–Meier plot)
Median survival rate	The length of time at which half of the study population survives; can be useful for diseases with extremes in survival
Relative survival rate	The observed survival in those with the disease divided by expected survival if the disease were absent

Table 123.7 Five ways of expressing prognosis and survival data. Considering that there are some dermatologic conditions that are fatal, being aware of survival measures is useful.

FACTORS THAT STRENGTHEN CAUSAL INFERENCE
Evidence of temporality – the exposure preceded the disease or outcome
Consistent across other studies and reproducible
A strong association (e.g. the further the RR or OR is from 1), given that it is statistically significant in a well-powered study
A dose–response relationship – the greater the exposure, the greater the risk of disease
Cessation of the exposure is associated with *decreased risk of disease*
Biological plausibility and *consistency with other scientific knowledge* – there is a mechanism linking the exposure to the disease that makes sense

Table 123.8 Factors that strengthen causal inference. A well-designed randomized controlled trial provides the best evidence for establishing causality. Cohort studies can infer causality, as the exposure precedes the disease in these studies[2,23]. OR, odds ratio; RR, relative risk.

are based on previous evidence from smaller or observational studies. Generally, participants in clinical trials should be easy to recruit as well as reasonably likely to benefit and unlikely to be harmed from the intervention; participants with a high level of adherence to the treatment and follow-up plan are also desirable. The design of the intervention should balance efficacy and safety, with interim monitoring during the trial to ensure that participants are not exposed to a harmful intervention, denied a beneficial intervention, or continued in a trial that cannot answer the question it was intended to answer. Whenever possible, trials should include comparison with placebo. When comparing active treatments in an equivalence or superiority trial, comparison with the gold-standard treatment for the patient population being studied can maximize the relevance to clinical practice. A well-designed blinded RCT is thought of as the gold standard for study design[21] (see Table 123.4).

An example of an RCT is assessment of the efficacy and safety of etanercept in children and adolescents with moderate to severe plaque psoriasis by Paller et al.[27]. It involved randomizing 211 pediatric patients (4 to 17 years of age) with psoriasis to a double-blinded trial of once-weekly subcutaneous injections of etanercept or placebo, for 12 weeks. The primary endpoint was ≥75% improvement from baseline in the psoriasis area and severity index (PASI 75). The patients randomized to receive etanercept were significantly more likely to achieve a PASI 75 (57%) than those receiving placebo (11%) ($P < 0.001$). The authors were able to conclude that etanercept significantly reduced disease severity in children and adolescents with moderate to severe plaque psoriasis.

Systematic Reviews

A systematic review identifies completed studies that address a specific research question and then aggregates and statistically analyzes the results across studies, to arrive at a conclusion about a body of research[1]. Although traditionally applied to RCTs, systematic reviews can also draw data from observational studies. A systematic review should have a written protocol addressing the research question it seeks to answer, utilize comprehensive and unbiased methods for identifying studies, and clearly describe the statistical aspects of the review, i.e. meta-analysis. It should also include a summary estimate of effect plus CI based on the findings of all eligible studies (see Fig. 123.3). In addition, it should have an assessment of heterogeneity across the studies used, to indicate the degree of variability in the findings in different studies. It should address publication bias by taking into account unpublished studies, as positive studies are more likely to get published. It also usually includes subgroup analyses based on additional measures done by some or all of the studies that are supplemental to the main research question. If any of the design decisions were questionable or arbitrary, analyses should be done to assess how sensitive the findings of the meta-analysis are to decisions taken in designing particular studies or inclusion of certain studies. Here, the less sensitive the study the better. The characteristics and the findings of individual studies should be displayed clearly in tables and figures to allow the reader to visualize the data and not rely solely on the conclusions of the meta-analysis[2,23].

The advantage of a systematic review is that it enables the integration of the results of multiple studies, allowing for greater power. While it is often time-consuming, it does not require significant financial resources. In addition, the results are sometimes used to develop practice guidelines. However, a systematic review is only as valuable as the quality of the studies upon which it is based. Caution must be exercised in interpreting systematic reviews, with recognition that they may not take into account unpublished studies, the quality of all of the studies may not be equal, studies may not be comparable (e.g. different outcome measures), and adjusting for biases can be a formidable task. In addition, having a single estimate of risk based on those from several studies may give a false sense of certainty regarding the magnitude of the risk[2,23]. A systematic review of RCTs that have homogeneous results gets the highest ranking of all study types[21] (see Table 123.4), but the level of evidence is considerably lower for systematic reviews limited by the factors discussed above.

The Cochrane Skin Group, which stems from the larger Cochrane Collaboration Group that reviews a variety of healthcare studies, is dedicated to the production of systematic reviews on dermatologic topics[28]. An example of a systematic review is that by Wehner et al.[16], which utilized available studies to summarize the effects of indoor tanning on risk of BCC and cutaneous SCC. The authors searched large databases (e.g. PubMed, Embase, Web of Science) and extracted data from the 12 studies (all observational) that met their inclusion criteria, with assessment of methodologic quality, heterogeneity, and publication bias through established methods. They found summary RRs of 1.29 (95% CI, 1.08–1.53) for BCC and 1.67 (95% CI, 1.29–2.17) for SCC in individuals who reported ever using a tanning bed compared to those who never used tanning beds[16]. By applying these summary RRs to the prevalence of indoor tanning in the US, they calculated the population attributable risk fraction of indoor tanning to be 8.2% for SCC and 3.7% for BCC.

GENETIC EPIDEMIOLOGY

When considering the etiology of a disease, it is important to account for genetic susceptibility as well as environmental factors. Because of advances in molecular and genetic techniques, epidemiologic studies have expanded to include use of biologic samples. Upon completion of the Human Genome Project in 2003 and the International HapMap Project in 2005, researchers were able to use a technique known as the genome-wide association study (GWAS). This method examines the association between disease and single nucleotide polymorphisms (SNPs), markers for groups of DNA variation inherited together in blocks (haplotypes). Findings from these studies can be used to investigate the molecular pathways of disease. One can look for associations in a hypothesis-driven or non-hypothesis-driven manner.

A study by Petukhova et al.[29] illustrates the use of GWAS techniques to explore the pathogenesis of alopecia areata (AA). Using genetic samples from 1054 cases and 3278 controls, they identified 139 SNPs significantly associated with AA ($P \leq 5 \times 10^{-7}$). They found an association between these SNPs and the genomic regions containing several genes that control the activation of T cells and cytokine production.

The results of the study implicated both innate and acquired immunity in the pathogenesis of AA and suggested potential autoimmune mechanisms for this condition.

HEALTH SERVICES RESEARCH

The field of health services research applies techniques of epidemiologic investigation to assess the association between health services provided in the community and disease outcomes. Outcomes for this kind of research include traditional endpoints such as mortality and morbidity, as well as others such as usage and access, patient satisfaction, quality of life, and disability measures. In addition to the *efficacy* of an intervention in an ideal, controlled environment, it is important to assess *effectiveness* in real life situations (e.g. with factors that decrease adherence; Table 123.9) and *efficiency* (e.g. cost : benefit ratio).

ADHERENCE IN DERMATOLOGIC CARE: OBSTACLES AND POTENTIAL SOLUTIONS

Obstacles	Potential solutions
Lack of understanding of the disease process or frustration with previous treatment failures	• Increased education for patients/families, including in-office discussion, written materials, online resources, and disease support groups • Express empathy and recognition of the disease's impact on the patient's life
Lack of understanding of the treatment regimen	• Provide a written treatment plan tailored to individual patient needs • Give specifics, e.g. where to apply topical medications and how much to use • Avoid complex regimens in patients who are less motivated or less medically sophisticated
Treatment too time-consuming	• Simplified regimens, e.g. once daily administration when possible, combination products
Products are difficult, bothersome, or unpleasant to use	• For topical medications, choose a vehicle that is easy to apply and readily absorbed • Tailor the vehicle or method of administration to the patient's preferences, e.g. less greasy for teens, less burning for young children
Concern about or occurrence of side effects	• Ask about and address specific concerns, e.g. steroid phobia, desire for "natural" products • Provide anticipatory guidance on potential side effects and how to prevent or improve them, e.g. taking an oral medication with food/water, moisturizer use, and dose adjustments
Giving up because expect immediate/rapid results	• Inform patients/families of the expected time course of improvement
Don't receive or forget to use the medication	• Anticipate potential issues with receiving the medication, e.g. need for prior authorization, problems with insurance coverage, or lack of immediate availability at the pharmacy • Prescribe an adequate amount of the medication • Plan a follow-up call or text, especially within the week after starting treatment • Discuss making the medicine part of a daily routine (e.g. brushing teeth) and putting it in a visible/accessible location • Reminder systems utilizing charts/calendars, electronic devices, or help from family members • Schedule follow-up appointments sooner/more frequently • Have patients/families bring their bottles/tubes to the visit or check electronic medical record to see if refills obtained • Ask specifically about how often medications are used

Table 123.9 Adherence in dermatologic care: obstacles and potential solutions.

HEALTH POLICY IMPLICATIONS OF RESEARCH

The ultimate goal of medical research is to benefit patients. The appropriate application of research findings to healthcare policy and practice is a critical component of medical advances. The international "choosing wisely" campaign is a physician-led, patient-focused initiative with the goal of utilizing evidence-based medicine to improve quality of care and reduce the unnecessary and potentially harmful use of tests, procedures, and treatments. Patient-centered communication and shared decision-making have also been highlighted as top priorities in cancer care. For example, overdiagnosis of asymptomatic BCCs in patients near the end of life may lead to anxiety and intensive treatments with harms that outweigh the benefits, whereas an individualized approach that incorporates the patient's input and overall prognosis can optimize their overall well-being[30].

Quality-of-Life Measures

Quality of life (QOL) has been defined by the World Health Organization (WHO) as "the individuals' perception of their position in life, in the context of the cultural and value systems in which they live and in relation to their goals, expectations, standards, and concerns". QOL is an important outcome measure for dermatologic conditions because, while many conditions are not fatal, they can cause significant morbidity leading to decreased QOL. Patients may place different weights on various QOL measures depending on their personal values, background, and education. Therefore, development of a QOL measure that is valid can be challenging. The most commonly used QOL instrument in dermatology is the Dermatology Life Quality Index (DLQI), which has been employed for numerous conditions. It is a self-administered, 10-item questionnaire about patients' perceptions of the impact of their skin disease over the last week[31]. The DLQI has been validated for dermatology patients aged ≥16 years, with good-to-excellent internal consistency, high test–retest reliability, and results that correlate with those of other QOL instruments (although less so for mental and emotional aspects)[32]. Another commonly used, validated dermatologic QOL instrument is Skindex, which is available in 29- and 16-item versions with separate scores for symptoms, emotions, and functioning[33,34].

IMPORTANT CONCEPTS WHEN DESIGNING AND REVIEWING A STUDY

Research Question and Design

There are important concepts to consider when planning research or interpreting published literature. These concepts apply to both observational studies and clinical trials (Table 123.10). First, it is important to be aware of the study design needed to best answer the research question of interest. Furthermore, one must recognize the questions that a particular study design can and cannot answer; for example, a case–control study cannot determine causality.

Methods

When considering study methodology, it is important to recognize the importance of a control group and to understand random (due to chance) and systematic errors that may affect the study. *Systematic errors* are due to bias, "sources of variation that distort the study findings in one direction"[23]. The opposite of systematic errors is validity. Several types of bias that can occur in epidemiologic studies are described in Table 123.11. Some studies are particularly prone to certain types of bias. For example, retrospective studies are especially susceptible to recall bias, a type of information bias (see section on Case–control study). An effort should be made in the study design to decrease systematic errors.

The baseline patient characteristics, exposures, other risk factors, and disease characteristics should be measured reliably and accurately (Fig. 123.5). Information on validity (accuracy) is often expressed using sensitivity and specificity or predictive values. *Sensitivity* represents the likelihood of testing positive for someone who has the disease (a/a+c) (Table 123.12). *Specificity* is the likelihood of testing negative for someone who does not have the disease (d/b+d). These measures yield

IMPORTANT CONSIDERATIONS WHEN REVIEWING A STUDY	
Research question and study design	• Given the study design, what are the questions it can and cannot answer? (See Table 123.4)
Methods	• ***Is there a control group?*** • Was an effort made to decrease systematic errors? • Were exposure and disease measured reliably and accurately? • ***Were potential confounders included in the statistical model examining the association between exposure and disease?*** • Were tests done looking for effect modification or interaction between the exposure and other study variables? (See Fig. 123.4)
Results	• Are baseline characteristics significantly different across exposure groups? If so, were these variables adjusted for in the statistical model? • ***Was the correct outcome measure for a given study design used?*** • Is the association statistically significant? (e.g. P value <0.05 or a 95% CI that does not include 1, in the case of a ratio) • Did the study have enough power, usually referring to number of participants, to detect statistical significance?
Conclusions	• ***How strong is the evidence for a causal association?*** (See Table 123.8) • Could a type I error have occurred (false-positive)? • Could a type II error have occurred (false-negative)? • ***What conclusions can be drawn given the type of the study design, its strengths and limitations, including biases?*** (See Table 123.4) • How generalizable are the findings? • Was the study industry-sponsored? • Do the authors have significant conflicts of interest? • Are the findings compelling enough to affect current clinical practice and the direction of future research?

Table 123.10 Important considerations when reviewing a study. Common pitfalls are in ***bold italics***. CI, confidence interval; OR, odds ratio[2,23].

TYPES OF ERRORS AND BIAS	
Type of error	**Example**
Random errors	
Systematic errors	
• *Ascertainment bias:* all of those who are supposed to be represented in a population are not represented	Study enrolling patients from a dermatology clinic only includes those who have access to care
• *Selection bias:* participants are selected differently across exposure or disease categories	Study enrolling patients with bullous pemphigoid from inpatient settings may select for higher disease severity
• *Misclassification bias:* participants are wrongfully thought to belong to one category of exposure or disease, when they actually belong to another	Patients with self-reported eczema may not actually have atopic dermatitis
• *Information bias:* inaccuracies in collection of data regarding the exposure or disease (e.g. *recall bias*)	Patients diagnosed with melanoma may be more likely to recall sunburns and UV exposure in childhood than patients without skin cancer history

Table 123.11 Types of errors and bias. There are two types of errors: random (due to chance) and systematic. UV, ultraviolet.

information on how well we are able to identify those who have or do not have the disease, when we test the general population. A different perspective on the validity of a test is gained through measuring predictive value. This allows us to inform individual patients about what their test results mean. The *positive predictive value* is the likelihood of having the disease when testing positive (a/a+b). The *negative predictive value* is the likelihood of not having the disease when testing negative (d/c+d).

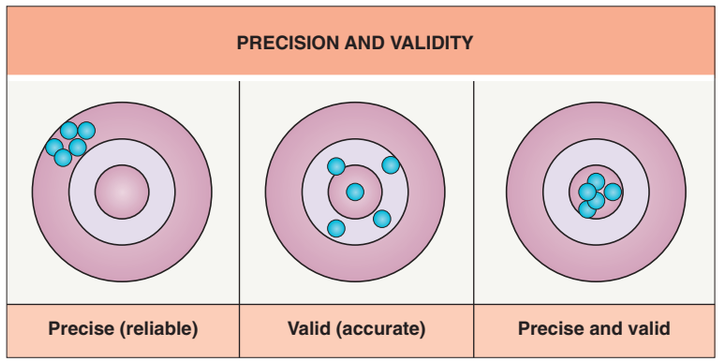

Fig. 123.5 Precision and validity. Precision (reliability) is the relative lack of random error, and validity (accuracy) is the relative lack of systematic error. *From Porta M. Dictionary of Epidemiology, 5th edn. Cary, NC: Oxford University Press, 2008:2. © 2008. Oxford University Press. All rights reserved.*

CONCEPTS OF SENSITIVITY, SPECIFICITY, POSITIVE PREDICTIVE VALUE, AND NEGATIVE PREDICTIVE VALUE			
Result of screening test	**True condition (as determined by gold standard)**		
	Disease	**No disease**	
Positive	a (true positives)	b (false positives)	Positive predictive value = a/a+b (increases with increased disease prevalence)
Negative	c (false negatives)	d (true negatives)	Negative predictive value = d/c+d (decreases with increased disease prevalence)
	Sensitivity = a/a+c	Specificity = d/b+d	

Table 123.12 Concepts of sensitivity, specificity, positive predictive value, and negative predictive value.

Predictive values depend on the prevalence of a disease – the higher the prevalence, the higher the positive predictive value and the lower the negative predictive value.

Statistical methods should include adjustments for potential confounders including when examining the association between exposure and disease (see Fig. 123.2). If not adjusted for, confounders may lead to a false association between an exposure and a disease. When analyzing disease outcome, it is also important to test for effect modification of the exposure by other study variables suspected of playing an interdependent role with the exposure (see Fig. 123.4). If there is a significant effect modification variable for an association, then the association measure should be presented for different levels of the effect modification variable.

Results

In analyzing results, it is important to assess whether baseline characteristics significantly differ across both exposure and outcome groups. If this occurs, such potential confounders need to be placed in the statistical model addressing the association between the exposure and disease so that they may be adjusted for. Next, the correct outcome measure must be reported for a given study design, e.g. OR for a case–control study. *Statistical significance* is typically demonstrated by a P value ≤0.05 and/or by a 95% CI that does not include 1 within the interval for measures that represent a ratio (zero for measures that represent a difference). A *95% CI* that shows significance indicates that there is 95% confidence that the association is not due to chance alone (see Fig. 123.3). Whether the study was sufficiently powered to detect a statistically significant difference should also be determined. *Power* is affected by the number of participants. When planning a study, performance of a power calculation assists the investigator in including enough participants to detect a statistically significant difference between study groups if it exists. The

variables included in the calculation vary according to study design, but they always include the expected magnitude of the association being measured, desired level of significance, and sample size.

Conclusions

In drawing conclusions about the results, the factors that support causality for the association in question should be determined (see Table 123.8). If statistical significance is found, one needs to determine whether the association makes biological and clinical sense. If it does not make sense, a *type I error* may have occurred, where a statistically significant association is found when one does not truly exist (false positive). The more statistical tests that are performed for a study, the more likely a statistically significant association will be found based on chance alone. In studies utilizing large databases where many comparisons are made, the false discovery rate increases and statistical methods (e.g. the Benjamini–Hochberg procedure) should be used to adjust P values in order to mitigate the risk of type I errors[35]. Alternatively, if an association is not found when one would be expected, a *type II error* may have occurred, where no statistical significance is found when one truly exists (false negative). This can be caused by a study not having enough power.

The conclusions that can be drawn given the type of study design must be recognized, taking into account the strengths and limitations, including potential biases. In extrapolating the results, the *generalizability* of the study must also be considered. This pertains to how applicable the results are to the greater population and groups that did not participate in the study. It should also be noted if a trial was industry-sponsored. Lastly, it is important to consider the implications of the study on current clinical practices and the direction of future research.

Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) and the Consolidated Standards for Reporting Trials (CONSORT)

There is a need to ensure appropriate reporting of findings from dermatologic studies. Langan et al.[36] found that dermatologic papers infrequently reported sample size calculations, missing data, losses to follow-up, and statistical methods. Ubriani et al.[37] noted that in 2004–2005 only 20%–49% of articles published in three prominent dermatology journals reported the design of their study in the title or abstract of the paper.

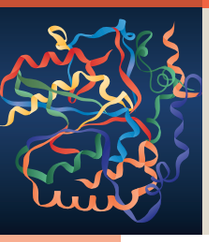
In order to improve the quality of reporting of observational studies in medical research, criteria for reporting have been suggested in the form of the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) checklist. Items critical for inclusion include the design of the study in the title or abstract and an informative summary of what was done in the abstract. The methods section should describe: (1) eligibility criteria, sources, and selection methods for participants; (2) methods of follow-up, matching criteria (if applicable), and numbers of exposed/unexposed individuals; (3) all outcomes, exposures, predictors, potential confounders, and effect modifiers, as well as diagnostic criteria; (4) all statistical methods (including those dealing with confounding), examination of subgroups and interactions, how missing data and losses to follow-up were addressed, and any sensitivity analysis[38]. The Consolidated Standards for Reporting Trials (CONSORT) statement is a similar initiative for improving the quality of reporting for RCTs. This 25-item checklist emphasizes reporting how the trial was designed, analyzed, and interpreted. It also includes a flow diagram that displays the progress of all participants through the trial[39].

OPPORTUNITIES FOR RESEARCH IN DERMATO-EPIDEMIOLOGY

While each of the study types discussed above provides valuable information, there is a relative paucity of studies that include a control group or a large study population in dermatologic research. Considering the high prevalence of many skin conditions and the rising incidence of diseases such as melanoma, the field of dermatology is likely to play a bigger role in public health research in the future. Therefore, it is important for dermatologists to understand epidemiologic and clinical research techniques, and to advocate for the inclusion of dermatology-related questions in local, state, and national surveys, allowing for larger epidemiologic studies to be conducted.

Associations of dermatologic conditions with comorbid diseases have become increasingly well characterized, and the implications of skin disease treatment on population health are now being explored. For example, patients with psoriasis have an increased risk of metabolic syndrome, myocardial infarction, and stroke; studies are now evaluating the effect of psoriasis treatment on coronary artery disease and other cardiovascular risk markers[40]. Further research may help clarify the role of dermatologic care in improving the overall health of the population.

Multiple sources of data can be analyzed for information on skin conditions, including national databases and disease registries. Other opportunities for epidemiologic research include conducting systematic reviews, participating in multicenter clinical trials, and utilization of molecular technologies (e.g. genomics, proteomics). Dermatologists interested in gaining greater experience in epidemiologic research may consider enrolling in public health classes, connecting with mentors in the field, or getting involved with communities of researchers in this area. Multiple funding sources are currently available for dermato-epidemiology research, including those from dermatologic societies or foundations and national grants. As dermatologists become more active in these arenas, patients will be more likely to reap the benefits of research in dermato-epidemiology.



Acknowledgment

The authors wish to thank Ken Katz, MD, MSc, MSCE for his valuable contribution to this chapter.

STRUCTURAL BASIS FOR THE PERMEABILITY BARRIER

The skin provides the largest interface between the human body and the external environment[1,2]. Therefore, one of its most important functions is to prevent ingress of potentially harmful exogenous substances (outside-in barrier). However, because desiccation is incompatible with life (inside-out barrier requirement), the skin must also prevent excessive loss of water and other bodily constituents[3]. Tight junctions not only play an important role in directly blocking passage of some molecules – they also direct epidermal differentiation and formation of the lipid barrier[4,5]. Of note, the tight junction barrier develops before the lipid barrier, both in a fetal rat model and in human epidermal equivalents (HEE), with tight junction expression receding as the lipid barrier develops[6].

The skin's remarkable barrier properties are sustained in large part by epidermal homeostasis[1,2], which insures that the generation of corneocytes and lipids is optimized in order to support this function[7]. The corneocytes within the stratum corneum are composed primarily of keratin filaments encased in a cornified envelope (CE), and they have been likened to "bricks". Corneocytes are further surrounded by a cornified lipid envelope (CLE) and an extracellular milieu of lipids organized as multiple lamellar bilayers, analogous to "mortar" (Fig. 124.1)[8].

At the stratum granulosum–stratum corneum interface, keratinocytes contain abundant filament aggregating protein (filaggrin), which also plays a role in barrier function. Filaggrin has a predominance of arginine over lysine residues and is found within liquid-like keratohyalin condensates. As a result of their phase separation- and pH-driven assembly and disassembly during keratinocyte terminal differentiation, these membrane-less structures become osmotically active amino acids. The latter undergo deamination regulated by changes in environmental humidity[9].

As they differentiate, keratinocytes accumulate lipid-containing lamellar bodies, i.e. tubuloreticular structures, whose secreted contents play a key role in the formation of the stratum corneum (see Fig. 124.1). These extracellular structured lipids will comprise ~10% of the volume of the stratum corneum[10]. They prevent excessive loss of body water and likewise block entry of exogenous compounds, including most topically applied drugs (except for those that are lipid-soluble and of low molecular weight).

STRATUM CORNEUM FORMATION AND ORGANIZATION

The formation of the stratum corneum barrier involves various cellular organelles within differentiating keratinocytes as well as degradation of the nucleus. The resulting flattened corneocytes along with an extracellular milieu of lipids are structurally organized as "bricks and mortar" (see Fig. 124.1; Table 124.1)[3]. For most of the skin surface in humans, the stratum corneum is typically comprised of about 20 corneocyte cell layers, which differ in their thickness, packing of keratin filaments, filaggrin content and number of corneodesmosomes, depending on body site[8]. Corneocytes are reinforced by a highly resilient sheath of multiple proteins, cross-linked into the CE, while the cell interior is packed with keratin filaments embedded in a matrix composed primarily of filaggrin and its breakdown products. Some of these breakdown products serve as "natural moisturizing factor" while others have antimicrobial properties[11].

At the stratum granulosum–stratum corneum interface, lamellar body contents are secreted, fused end-to-end, and progressively elongated into lamellar membrane sheets[12,13], a sequence requiring the action of a battery of lipolytic "processing" enzymes (see below) (Fig. 124.2). Glucosylceramide-based bilayers with cubic-like symmetry are organized within the extracellular spaces into ceramide-based lamellar membranes that surround the corneocytes[14] (lipid processing). Variations in the number of lamellar membranes (which determines lipid weight %), membrane substructure, and/or lipid composition provide the structural and biochemical basis for site-related variations in permeability[15].

The volume of the extracellular lipid-enriched matrix of the stratum corneum includes the structures that limit transdermal delivery of hydrophilic drugs as well as the so-called stratum corneum "reservoir"[16]. Within this reservoir, lipid-soluble drugs (e.g. topical corticosteroids) can accumulate and be slowly released. Of note, its volume can vary dramatically. For example, at baseline, these domains account for ~10% of stratum corneum volume, but with hydration or the inspissation of topical agents, they can account for up to 50% of stratum corneum volume.

The exceptionally low permeability of normal stratum corneum to water-soluble drugs is the consequence of several characteristics of the lipid-enriched extracellular matrix (Table 124.2)[14]. Moreover, not only the paired-bilayer arrangement of extracellular lipids, but also their hydrophobicity and the composition and distribution of the three key species (ceramides, cholesterol and free fatty acids) in a critical (1 : 1 : 1) molar ratio, are further characteristics that provide for optimal barrier function.

Ceramides account for ~50% of the total stratum corneum lipid mass and are crucial for the lamellar organization of the stratum corneum barrier[17]. Of the nine ceramide species, acylceramides or ceramides 1, 4, and 7 (which contain ω-hydroxy-linked essential fatty acids in an ester linkage) are epidermis-unique compounds, known to be important for barrier function[12]. Keratinocytes also synthesize triglycerides, with the final step in the pathway catalyzed by diacylglycerol transferase (DGAT). Lipases and acyltransferases then break down the triglycerides, thereby releasing fatty acids that serve as building blocks for ceramides and acylceramides. The latter are both essential for lamellar bilayer and CLE formation.

Free fatty acids, which consist predominantly of very-long-chain, saturated species with ≥18 carbon atoms, and *cholesterol* each account for 10%–15% of stratum corneum lipids. A subset of fatty acids contains linoleic acid thus providing an explanation for the abnormal extracellular matrix observed in essential fatty acid deficiency. Cholesterol promotes the intermixing of different lipid species and regulates its "phase" behavior[18]. A decrease in the concentration of any of these critical lipid species alters their molar ratio within lamellar membranes which then compromises barrier integrity and function.

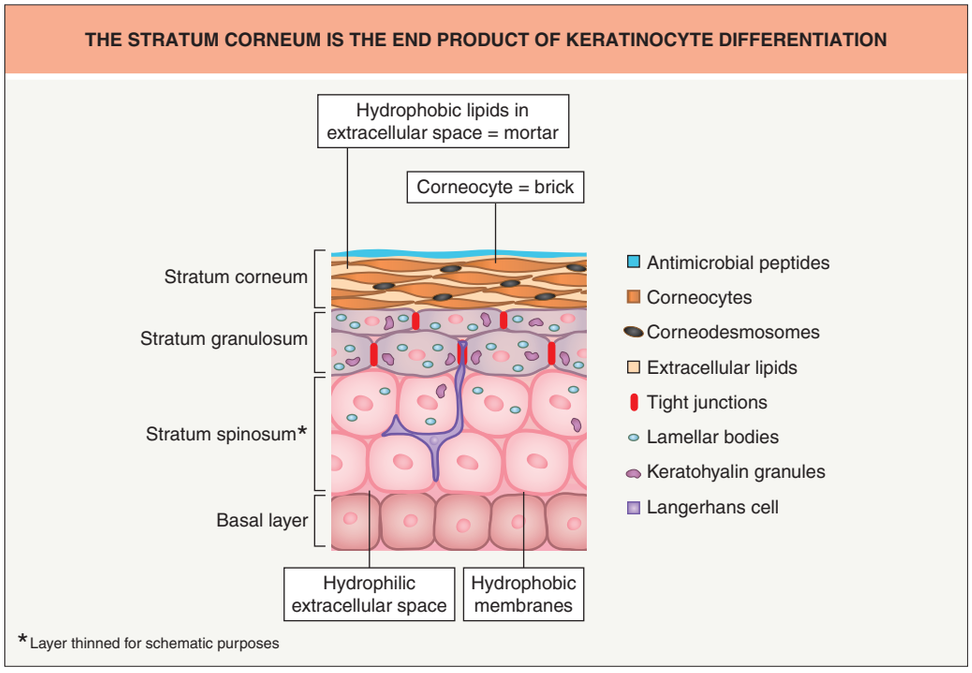

Fig. 124.1 The stratum corneum is the end product of keratinocyte differentiation. In a vectorial process, keratinocytes differentiate while moving outward from the basal to the outer epidermal layer, forming lipid-enriched lamellar bodies and tight junctions within the granular layer. The skin barrier is intimately linked with the innate immune system, e.g. antimicrobial peptide production, Langerhans cell activation. The stratum corneum barrier is a unique two-compartment system, analogous to a brick wall. Whereas lipids are sequestered extracellularly within the stratum corneum, the corneocytes are lipid-depleted but protein-enriched.

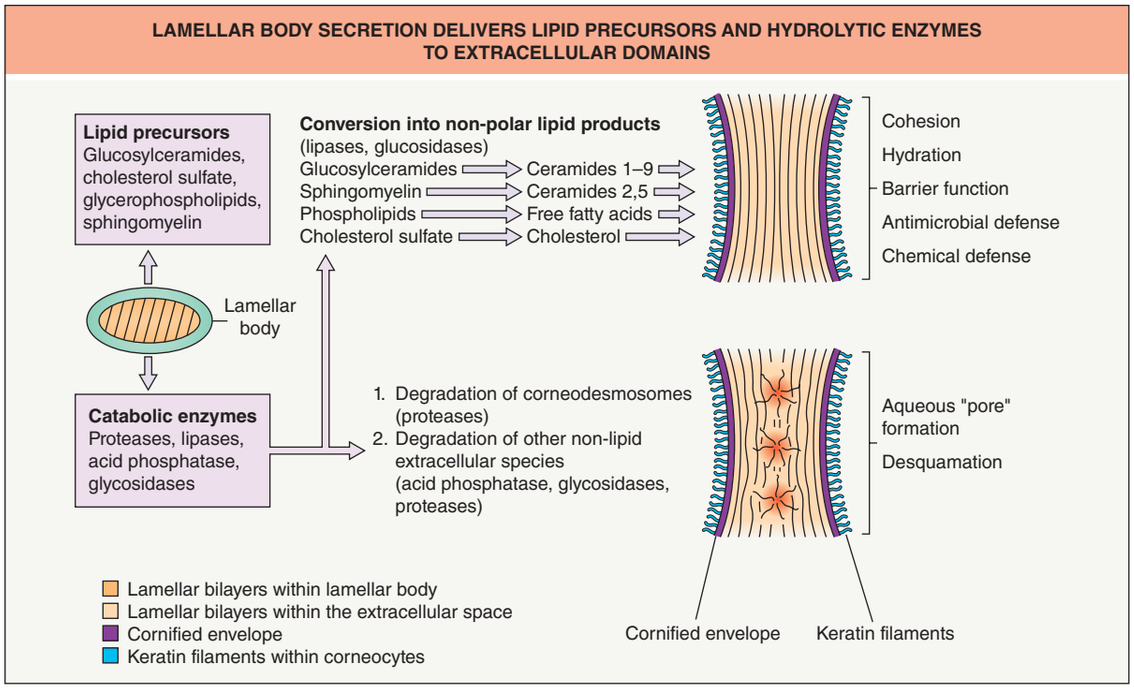

Fig. 124.2 Lamellar body secretion delivers lipid precursors and hydrolytic enzymes to extracellular domains. These organelles also release antimicrobial peptides, including human β-defensin 2 and LL-37 (the carboxy-terminal fragment of human cathelicidin). As a result, the antimicrobial barrier is intimately linked to the permeability barrier. In atopic dermatitis, for example, there is both an impaired permeability barrier and reduced expression of antimicrobial peptides, explaining in part the predisposition to colonization with *Staphylococcus aureus*. Reduced conversion of cholesterol sulfate to cholesterol via steroid sulfatase and sphingomyelin to ceramide via sphingomyelinase leads to X-linked ichthyosis and Niemann–Pick disease, respectively.

FEATURES OF THE STRATUM CORNEUM

- Primary barrier to water-soluble drug absorption into skin and maintaining skin hydration
- Two-compartment organization: “bricks and mortar”
- Microheterogeneity within extracellular spaces: “There’s more to the mortar than lipid”
- Persistent metabolic activity: dynamic changes in cytosol, cornified envelope, and interstices from inner to outer stratum corneum
- Homeostatic links to the nucleated cell layers: barrier function regulates epidermal DNA and lipid synthesis
- Pathophysiologic links to deeper skin layers: barrier abrogation and/or epidermal injury initiates epidermal hyperplasia and inflammation
- Stratum corneum as a biosensor: changes in external humidity alone regulate proteolysis of filaggrin, epidermal DNA and lipid synthesis, and initiation of inflammation

Table 124.1 Features of the stratum corneum.

FACTORS AFFECTING HOW STRATUM CORNEUM LIPIDS MEDIATE BARRIER FUNCTION

- Predominantly extracellular localization
- Amount of lipid (lipid weight %)
- Elongated, tortuous pathway: increases diffusion length
- Organization into lamellar membrane structures
- Hydrophobic composition: absence of polar lipids and presence of very long-chain saturated fatty acids
- Correct molar ratio: approximately 1 : 1 : 1 of three key lipids: ceramides, cholesterol, and free fatty acids
- Unique molecular structures (e.g. acylceramides)

Table 124.2 Factors affecting how stratum corneum lipids mediate barrier function.

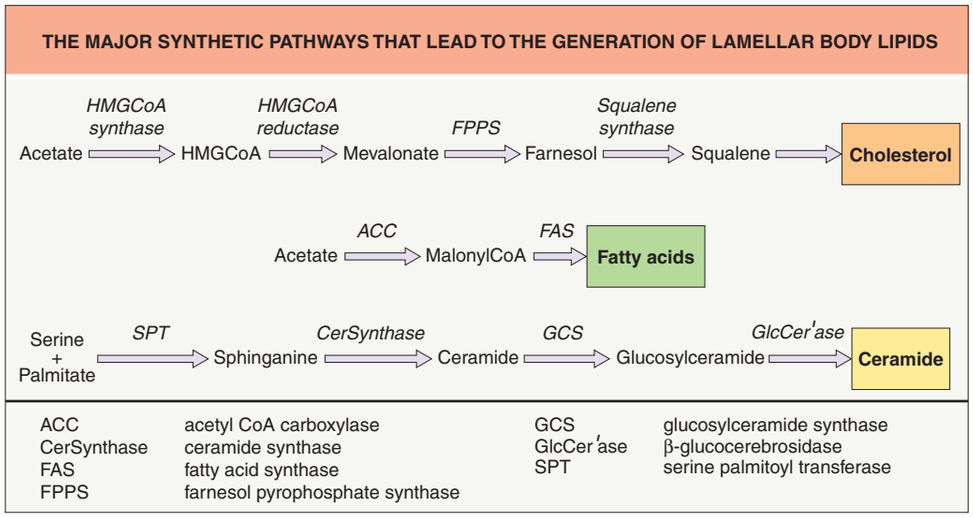

Fig. 124.3 The major synthetic pathways that lead to the generation of lamellar body lipids. The key enzymes in each pathway are shown. Applications of specific, conduritol-type inhibitors of β-glucocerebrosidase to intact skin lead to a progressive abnormality in barrier function. In both a transgenic murine model of Gaucher disease (GD) (produced by targeted disruption of the β-glucocerebrosidase gene) and in the severe, type 2 neuronopathic form of GD, infants present with a barrier abnormality. This is attributable to accumulation of glucosylceramides, depletion of ceramides, and persistence of immature lamellar bodies within the interstices of the stratum corneum.

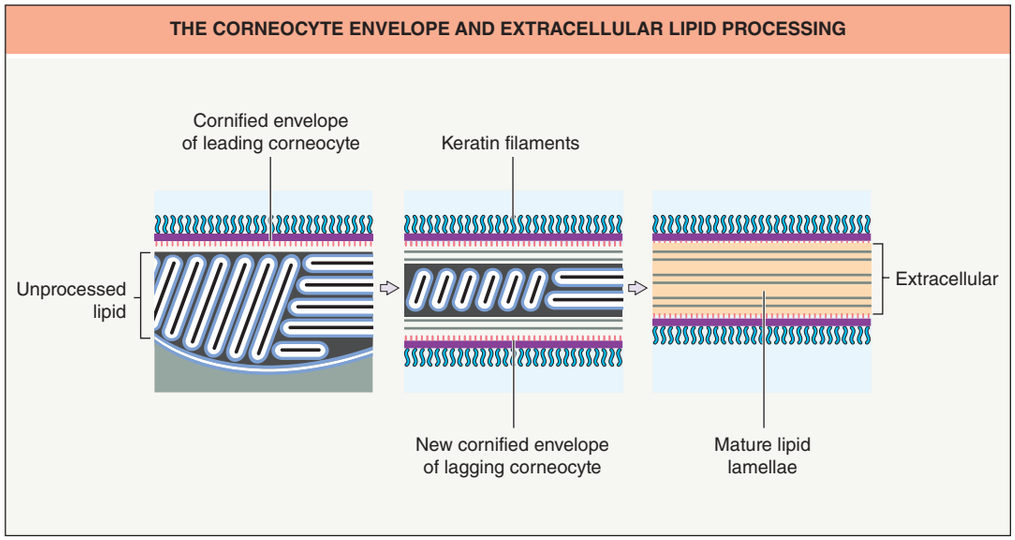

Fig. 124.4 The corneocyte envelope (CE) and extracellular lipid processing. After secretion of lamellar body contents into the extracellular space, lipolytic enzymes remove polar headgroups (indicated by blue outlines) to generate neutral lipids. These lipids align along the structured, hydrophobic template provided by the CE of the leading corneocyte, resulting in the formation of stacked, mature lipid lamellae. Meanwhile, transglutaminase 1 generates the CE on the lagging corneocyte, and ALOX12B, ALOXE3 and SDR9C7 catalyze oxidation reactions that precede anchoring and immobilization of the corneocyte lipid envelope (CLE; pink hatch marks) onto the CE. Dysfunction of these enzymes is seen in autosomal recessive congenital ichthyoses.

EPIDERMAL METABOLISM AND THE SKIN BARRIER

Biosynthetic Activities

Epidermal differentiation is a vectorial process that is accompanied by dramatic changes in lipid composition, including loss of triglycerides and phospholipids with the concomitant emergence of ceramides, cholesterol, and free fatty acids in the stratum corneum (see Fig. 124.2). Although epidermal lipid synthesis is both highly active and largely autonomous from systemic influences, it can be regulated by external influences, i.e. changes in the status of the permeability barrier[19]. Acute perturbations of the permeability barrier by environmental factors stimulate a characteristic recovery sequence that leads to restoration of normal function over about 72 hours in young skin (the cutaneous stress test)[20]. This metabolic sequence includes a rapid increase in cholesterol, free fatty acid, glucosylceramide, and ceramide synthesis that is restricted to the underlying epidermis; this is attributable to a prior increase in mRNA and enzyme activity/mass for each of the key synthetic enzymes (Fig. 124.3). Synthesis of each of these key lipids is required for normal barrier homeostasis, particularly in the context of barrier repair[12,19].

Lamellar Body Secretion

The unique two-compartment organization of the stratum corneum is attributable to the secretion of lamellar body-derived lipids and co-localized hydrolases at the stratum granulosum–stratum corneum interface[12]. Under basal conditions, lamellar body secretion is slow, but sufficient to provide for barrier integrity. Following acute barrier disruption, calcium is lost from the outer epidermis and much of the preformed pool of lamellar bodies in the outermost cells of the stratum granulosum is quickly secreted[20–22]. Calcium (Ca^{2+}) is an important regulator of lamellar body secretion, with the normally high levels of Ca^{2+} within the stratum granulosum restricting lamellar body secretion to low, maintenance levels[23,23a].

Extracellular Processing

Extrusion of the polar lipid contents of lamellar bodies at the stratum granulosum–stratum corneum interface is followed by the processing of those lipids into more hydrophobic species that form mature lamellar membranes (Fig. 124.4). The extracellular hydrolysis of glucosylceramides, phospholipids, and cholesterol sulfate due to the co-secretion of a set of hydrolytic enzymes results in the accumulation of their non-polar derivatives – ceramides, free fatty acids, and cholesterol within the stratum corneum interstices (see Fig. 124.2). Concurrently, the plasma membrane is replaced by the CE/CLE complex via the activity of transglutaminase 1 and lipoxidases, which catalyze cross-linking of the CE and CLE, respectively[24]. The CLE provides a highly structured, hydrophobic monolayer of protein-bound ω-OH-acylceramides, upon which processed lipids are organized into elongated mature lipid lamellae.

Extracellular processing of *glucosylceramides* by β-glucocerebrosidase plays a key role in barrier homeostasis (see legend to Fig. 124.3).

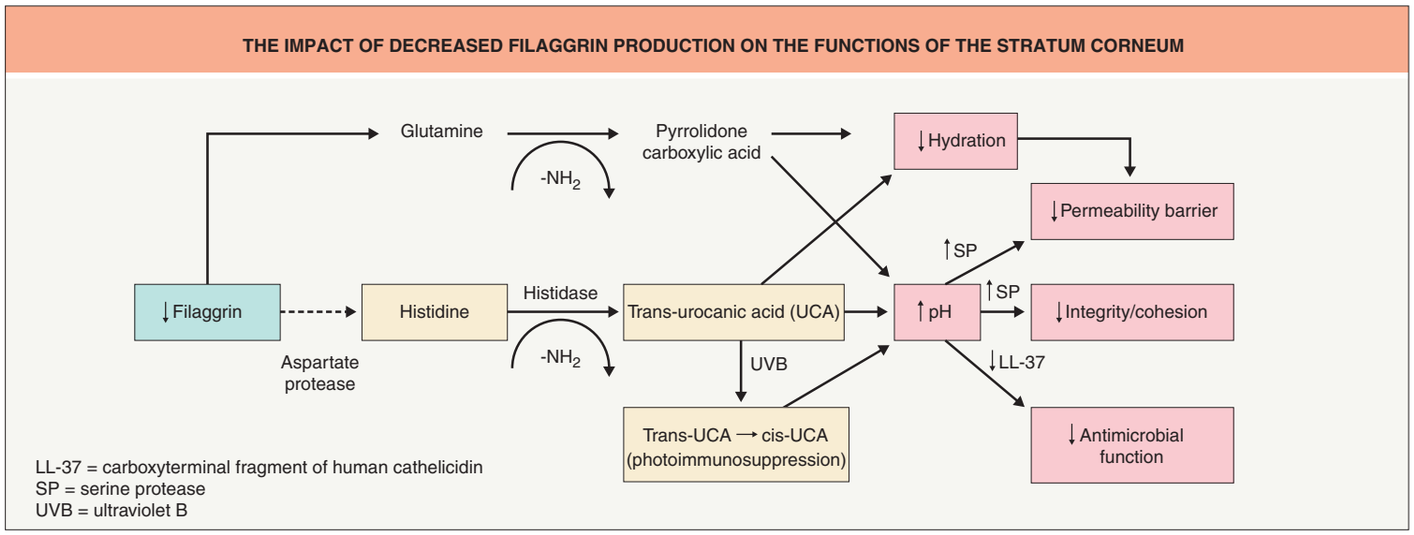

Fig. 124.5 The impact of decreased filaggrin production on the functions of the stratum corneum.

In addition, *phospholipid* hydrolysis, catalyzed by one or more secretory phospholipases (e.g. $sPLA_2$), generates a family of nonessential free fatty acids, which are also required for barrier homeostasis[25]. *Sphingomyelin* hydrolysis by acidic sphingomyelinase generates two of the nine ceramides required for normal barrier homeostasis (see Fig. 124.2). Sphingomyelinase is upregulated during epidermal injury, during which ceramide generation contributes to barrier recovery[26] as well as inflammation via its role as a second messenger in TNF receptor signaling[27]. The resultant epidermal disease represents an example of outside-in pathogenesis.

Finally, *cholesterol sulfate* is desulfated during passage from the inner to the outer stratum corneum[28]. Both cholesterol sulfate and its processing enzyme, steroid sulfatase, are concentrated in membrane domains of the stratum corneum. Of note, the content of cholesterol sulfate in these sites is increased by ~10-fold in X-linked ichthyosis (see Ch. 57). Excessive cholesterol sulfate increases the permeability of lamellar membranes, which together with decreased cholesterol content, lead to barrier dysfunction in X-linked ichthyosis[28] (see Fig. 124.2).

In addition to lipid precursors and lipolytic enzymes, lamellar bodies contain proteases and antiproteases that orchestrate the orderly digestion of corneodesmosomes, allowing corneocyte shedding or *desquamation*. By controlling the thickness of the stratum corneum, the rate of desquamation has a major impact on the barrier properties of skin. For example, while stratum corneum from palmoplantar skin is more permeable than in other sites, it is much thicker and therefore has a longer lag time for the penetration of topically applied drugs[1]. When stratum corneum permeability is increased in the setting of skin diseases such as psoriasis[29] and inherited ichthyoses[30], associated scale (due to abnormal desquamation and a thickened stratum corneum) provides partial compensation by mitigating barrier dysfunction.

Lamellar bodies also deliver antimicrobial peptides, including human β-defensin 2 and LL-37 (the carboxy-terminal fragment of human cathelicidin). In addition, corneocyte-derived peptide fragments[31], sebaceous gland-derived fatty acids, and free long-chain bases derived from ceramides exhibit antimicrobial activity[32]. Antimicrobial peptide levels and permeability barrier function are interdependent[33]. For example, topical agents that improve the skin barrier simultaneously enhance antimicrobial peptide production[34]. Emerging evidence supports a crosstalk between host immune effectors and cutaneous microorganism communities, i.e. the skin microbiome[35].

Acidification

The stratum corneum surface has an acidic pH ("acid mantle") which develops progressively within the extracellular space (whereas the interior of the corneocytes remains neutral). This pH gradient reflects an ~100-fold increase in the concentration of protons and forms over a span of ~10 microns[36]. Several processes contribute to the formation of the pH gradient: (1) extraepidermal mechanisms, including surface deposits of eccrine gland- and sebaceous gland-derived products as well as metabolites of microbial metabolism; (2) endogenous catabolic processes, e.g. phospholipid-to-free fatty acid hydrolysis, deamination of histidine to urocanic acid; and/or (3) local efflux of protons within the lower stratum corneum by sodium-proton antiporters [NHE_1] located in the apical plasma membrane of outer granular cells[36].

Because key extracellular processing enzymes, including β-glucocerebrosidase and acidic sphingomyelinase, exhibit optimal activity at an acidic pH, an acid mantle is critical for barrier generation. Loss of the pH gradient, leading to neutralization of the stratum corneum, is a common feature of skin diseases such as atopic dermatitis[37], in which it is thought to contribute to the pathogenesis of barrier dysfunction.

CUTANEOUS DISEASES AND BARRIER DYSFUNCTION

Abnormalities of the skin barrier are observed in both common and rare skin diseases. Causes of barrier dysfunction include (but are not limited to): mechanical trauma, exposure to detergents or solvents, seborrhea, prolonged water exposure, ultraviolet radiation, infection, inflammatory dermatoses, certain drugs, and genetic mutations and polymorphisms. Low humidity downregulates barrier competence while cold temperatures impair permeability barrier homeostasis[38]. Many disorders of cornification, including the ichthyoses, are due to pathogenic variants in genes that encode key components of the skin barrier, such as keratin and enzymes involved in extracellular lipid synthesis, among others[39].

Mutations and genetic polymorphisms in barrier-related genes also contribute to the pathogenesis of more common skin diseases, e.g. filaggrin in atopic dermatitis (see Ch. 12)[40,41] or cornified envelope proteins LCE3B and LCE3C in psoriasis[42]. Figure 124.5 depicts the impact of reduced filaggrin production on various functions of the stratum corneum. Aging skin also displays barrier abnormalities and increased susceptibility to xerotic eczema and pruritus due to age-associated declines in CE proteins and stratum corneum lipid content as well as elevated skin surface pH[43,44].

Barrier dysfunction induces a wide range of cellular responses in epidermal keratinocytes. Beyond controlling barrier recovery, they also affect epidermal proliferation (important in wound healing) and inflammation (outside-in link between barrier and inflammation)[45]. The latter is characterized by the production and release of epidermal cytokines involved in both innate immunity (e.g. TNF, IL-1α) and leukocyte recruitment and activation (e.g. IL-17, IL-22). When epidermal inflammation occurs on a large scale, it can have a local as well as a systemic impact via circulating cytokines[46,47]. This may explain in part the association between skin diseases with barrier dysfunction and disorders such as cardiovascular disease[46].

Inflammation can also initiate barrier dysfunction (inside-out link between inflammation and barrier) via two major mechanisms: (1) disruption of epidermal integrity (e.g. spongiotic, vesiculobullous, or ulcerative diseases), with defects in or loss of the stratum corneum; and (2) permeabilization of the stratum corneum interstices via changes in the lipid membranes. The first mechanism is relatively well characterized[48], with structural defects in the stratum corneum a rather straightforward explanation for impaired barrier function. The second mechanism typically involves a pronounced disorganization of stratum corneum lipid lamellae, as for example in psoriasis[47]. Psoriatic scale contains immature CEs[49,50] and CLEs (as assessed by covalently bound lipid composition) that make them fragile and less hydrophobic[51] than normal corneocytes, which could explain the failure to properly organize extracellular lipids into barrier-providing mature lipid lamellae. There are also changes in the composition of the extracellular lipids in some inflammatory skin diseases, particularly in the chain length of ceramides and fatty acids[52], which correlate with alterations in the lateral packing of lipid membranes and increased permeability. How inflammation induces these changes is an area of active investigation since the role of several inflammatory cytokines (e.g. IL-1, TNF) on epidermal homeostasis and barrier function remains unclear[53]. Finally, psychological stress disrupts permeability barrier homeostasis, impairs stratum corneum cohesion[54], and compromises epidermal innate immunity by increasing endogenous glucocorticoids[55,56].

TREATMENT OF SKIN BARRIER DYSFUNCTION

Therapies for barrier dysfunction are still limited. Semi-occlusive emollients, especially petrolatum[57], reduce transepidermal water loss, although less effectively than native stratum corneum lipids[58]. Impermeable and vapor-permeable dressings can provide nearly complete occlusion and are as effective as potent topical corticosteroids in the treatment of psoriasis[59], but are normally limited to small treatment areas. Moreover, these treatments are no substitute for the stratum corneum as a microbial barrier – they are applied on top of (superficial to) the microbiome, thereby providing an underlying moist environment that facilitates microbial growth and enhanced penetration. This explains why emollients and occlusive dressings increase the risk of skin infections[60]. Of note, topical probiotics can have beneficial effects on skin barrier homeostasis[61].

Targeted therapy of barrier dysfunction must address the underlying cause. While inflammation can be treated with anti-inflammatory and immunomodulatory drugs, a new class of therapeutic agents that addresses defects in lipid metabolism is emerging. For example, porokeratosis and CHILD syndrome, both resulting from defects in cholesterol synthesis, have been reported to improve following application of cholesterol plus lovastatin (the latter blocks accumulation of pathogenic lipid precursors)[62,63]. Ceramide-based, triple-lipid mixtures are employed to address defective barrier function. Increasing knowledge about the pathophysiology of skin barrier-driven diseases should offer major opportunities for novel therapies.

Parameters Affecting Skin Permeability *2211*
Strategies to Enhance Transdermal Drug Delivery *2213*

PARAMETERS AFFECTING SKIN PERMEABILITY

The skin is an attractive site for drug delivery, whether for *topical delivery* to locally treat cutaneous conditions or for *transdermal delivery* into the systemic circulation via absorption through the skin for other indications[64,65]. However, normal skin provides a significant barrier to drug absorption, whereas diseased skin can provide a lesser or greater barrier, depending on its associated epidermal changes[66]. While the most straightforward method of circumventing the stratum corneum barrier is an intradermal needle injection (e.g. the Mantoux technique)[67], this is often not practical for patients to perform on a routine basis.

Understanding the parameters that affect the permeability of this barrier is essential for achieving successful drug therapy via the skin without intradermal or subcutaneous injections. While local cutaneous effects are generally achieved by dissolving or suspending the drug in a vehicle that is applied topically as a semi-solid formulation (e.g. cream or ointment)[68], administration of systemic therapy via the skin is typically accomplished through the use of a patch. In either situation, drug is supplied at the surface of the skin for diffusion across the stratum corneum, with the goal of reaching therapeutic targets within the skin and/or systemic uptake via superficial dermal capillaries.

Parameters Controlling Absorption

Conventional transdermal drug delivery is a passive process governed by Fick's law, that is, the rate of absorption or flux (J) of any substance across a barrier is proportional to its concentration difference across that barrier[69,70]. For topically applied *drugs*, the concentration difference can be simplified as the concentration of drug in the vehicle, C_v, and the proportionality constant relating flux to concentration is the permeability coefficient, K_p (Eq. 1). K_p is composed of factors that relate to both drug and barrier, as well as their interaction. These factors are: D, the drug diffusion coefficient; K_m, the drug partition coefficient; and L, the length of the diffusion pathway across stratum corneum (Eq. 2). Thus, four factors control the kinetics of percutaneous drug absorption (Eq. 2); however, it is of great practical importance that two of the four (C_v, K_m) are highly dependent on one additional factor, the vehicle in which the drug is supplied to the skin.

$$J = K_p C_v \tag{1}$$

$$J = \left(\frac{DK_m}{L}\right) C_v \tag{2}$$

Role of the Vehicle

The vehicle is an important link between drug potency and therapeutic effectiveness, since extensive pharmaceutical research has shown that the composition of the vehicle can profoundly influence the rate and extent of absorption (bioavailability). As illustrated by the potency ranking scale for topical corticosteroids[71], the same drug appears

EFFECT OF VEHICLE ON CORTICOSTEROID POTENCY			
Corticosteroid*	**Potency class**	**Corticosteroid***	**Potency class**
Betamethasone dipropionate		**Fluocinonide**	
• Diprolene ointment 0.05%	1	• Lidex ointment 0.05%	2
• Diprolene gel 0.05%	1	• Lidex cream 0.05%	2
• Diprolene cream AF 0.05%	2	• Lidex gel 0.05%	2
• Diprosone ointment 0.05%	2	• Lidex solution 0.05%	2
• Diprosone cream 0.05%	3	• Lidex E cream 0.05%	3
• Diprosone lotion 0.05%	5		
Clobetasol propionate		**Triamcinolone acetonide**	
• Temovate ointment 0.05%	1	• Aristocort A ointment 0.1%	3
• Temovate cream 0.05%	1	• Kenalog cream 0.1%	4
• Temovate gel 0.05%	1	• Kenalog lotion 0.1%	5
• Temovate E cream 0.05%	1	• Aristocort cream 0.1%	6
• Olux foam 0.05%	1		
• Temovate Scalp Application 0.05%	2		
*Generic name in header, followed by trade names.			

Table 124.3 Effect of vehicle on corticosteroid potency. In this table, the potency class ranges from 1 (highest potency) to 6 (lowest potency).

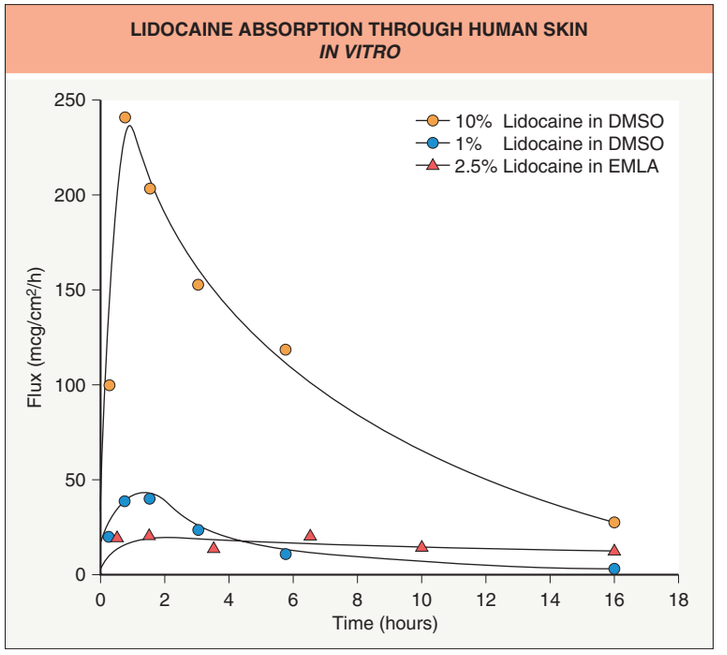

Fig. 124.6 Lidocaine absorption through human skin *in vitro*. Incorporation of DMSO as a co-solvent with ethanol results in both increased drug solubility (C_v) and partitioning (K_m). At 10% drug concentration, the maximum flux in the presence of DMSO is 10-fold greater than that achieved in an emulsion formulation without DMSO (eutectic mixture of lidocaine 2.5% and prilocaine 2.5% [EMLA]). At 1% drug concentration in DMSO, the maximum flux is two-fold greater than 2.5% drug in EMLA. *Reproduced from Mallory SB, et al. Topical lidocaine for anesthesia in patients undergoing pulsed dye laser treatment for vascular malformations. Pediatr Dermatol 1993;10:370–5.*

in different potency classes when formulated in different vehicles (Table 124.3). It was once axiomatic that ointments were more potent than creams. Though true for the early corticosteroid products, it is no longer generally applicable. Greater understanding of the science underlying topical formulations has allowed creams, gels, solutions, and foams to be specifically formulated equipotent to ointments (see Table 124.3).

In the rational design of dermatologic vehicles that maximize bioavailability, two factors are of critical importance: (1) solubilizing the drug in the vehicle (C_v); and (2) maximizing movement (partitioning) of drug from vehicle to stratum corneum (K_m). The partition coefficient describes the ability of a drug to escape from the vehicle and move into the outermost layer of the stratum corneum. It is defined as the equilibrium solubility of drug in the stratum corneum (sc) relative to its solubility in the vehicle ($K_m = C_{sc}/C_v$).

Drug Concentration

The driving force for percutaneous absorption is the concentration of *soluble* drug in the vehicle. Many older topical drug products were marketed with the expectation that higher concentrations were more potent. Although true for some products such as tretinoin gels and creams (0.01%–0.1%), in which the drug is completely solubilized at all concentrations, for others it is not the case. Hydrocortisone 1% and 2.5% in a cream formulation have been shown to be of equal potency, as have triamcinolone acetonide 0.025%, 0.1% and 0.5% creams[71]. One of the major advances in formulating glucocorticoids, as first shown with fluocinonide, came when it was discovered that the addition of propylene glycol to the vehicle could completely solubilize the drug, leading to corticosteroid products with greater potency.

Newer products are now tested during the development process to ensure that increased drug concentration results in increased bioavailability. However, excess non-dissolved drug can sometimes be advantageous, especially in transdermal patches worn for prolonged periods of time (e.g. up to a week). In this situation, as dissolved drug is absorbed into the body, non-dissolved drug can then become dissolved in order to maintain an equilibrium, thereby maintaining a constant dissolved drug concentration over time and providing a constant rate of delivery[72].

Partition Coefficient

In general, topically applied drugs are poorly absorbed because only a small fraction partitions into the stratum corneum. Most of the drug remains on the skin surface, subject to loss from a multitude of factors (exfoliation, sweating, wash-off, rub-off, adsorption onto clothing, and chemical or photochemical degradation). Even 10–12 hours following application, a drug that has not been lost by exfoliation or rub-off remains largely on the skin surface, and it is easily removed by a simple soap and water wash[73]. In the case of patches worn for several days, as much as half of the original amount of drug may still be present in the patch when it is removed, and this can pose a safety hazard upon disposal, especially with potentially dangerous drugs such as fentanyl[74].

A number of physical and chemical factors can improve partitioning. Hydration of the skin due to occlusion, either from a topical formulation or a patch, expands the reservoir volume available to drugs within the stratum corneum; this can increase absorption by as much as five- to ten-fold[75]. Common excipients such as ethanol and propylene glycol can also alter barrier structure so as to increase partitioning[76]. In addition, many excipients have good solvent properties and, as a result, positively affect C_v as well as K_m. The use of high concentrations of propylene glycol to maximize bioavailability has become pervasive among the super- and high-potency corticosteroids, but at a price. Adverse events such as burning and stinging are common when such preparations are applied to fissured or eroded skin, and contact dermatitis may occur.

A number of other compounds have been identified as enhancers. Dimethylsulfoxide (DMSO), the archetypical enhancer, exemplifies the effects that can be achieved (Fig. 124.6). As with ethanol and propylene glycol, both C_v and K_m are affected. Because DMSO is a superb solvent, higher drug concentrations can be achieved than with other solvents. In addition, DMSO expands the stratum corneum barrier, permitting increased drug uptake and possibly an increased rate of diffusion (D) through the barrier. However, the use of powerful enhancers such as DMSO is constrained by excessive skin irritation or toxicity[77].

Regional Variation

All body sites are not equally permeable[78]. Variations in stratum corneum thickness and lipid composition, the number of sebaceous glands, and hydration status can all affect absorption. Current data and clinical experience suggest that one can crudely rank regional permeability as follows: scrotum >> face/scalp > trunk/extremities > palm/sole >> nail.

STRATEGIES TO ENHANCE TRANSDERMAL DRUG DELIVERY

Despite the significant permeability barrier of the stratum corneum, drug delivery via the skin is a very attractive option and is widely employed for both local and systemic therapy (Table 124.4; Fig. 124.7)[64,65]. Topical treatment of cutaneous disorders obviously targets the site of disease, thereby minimizing adverse side effects elsewhere within the body. Delivery of systemic therapies via the skin avoids degradation of the medication within the gastrointestinal tract and from first-pass metabolism by the liver, both of which are associated with oral administration of drugs, in addition to evading the pain and safety issues associated with injections. Transdermal delivery of drugs, especially via long-acting patches, enables infrequent dosing and maintenance of steady-state drug levels.

Many dermatologic medications can be applied topically to the skin because the required dosage is often exceedingly small and therefore they can be effective even in the setting of highly inefficient absorption. In addition, a number of skin disorders are associated with compromised barrier function, which leads to an enhanced drug uptake in sites of involvement[79].

In contrast, systemic drug delivery via the skin typically requires administration of larger doses through normal skin. As a result, at the time of writing, fewer than two dozen drugs have been FDA-approved for transdermal administration. The drugs contained within these patches share several characteristics – they are low-molecular-weight (<400 Da), lipophilic (octanol–water partition coefficient up to 10 000), and relatively low-dose (typically <10 mg per day)[80] (Table 124.5).

Significant efforts have been expended on the development of new approaches to enhance transdermal drug delivery and thereby increase the number of drugs administered via this route (Fig. 124.8). These strategies can be broadly subdivided into chemical and physical approaches (Table 124.6).

TRANSDERMAL DRUG DELIVERY: THEORETICAL ADVANTAGES
• Drug delivery targeted to skin, i.e. for dermatologic indications • Improved patient adherence to therapy • Improved efficacy, i.e. continuous release • Reduced toxicity: (a) no "peaks" and (b) lower total absorbed dose • Bypass hepatic first-pass metabolism • Avoid local gastrointestinal side effects/metabolism • Decreased dosing frequency • Avoid painful injections • Reduced costs to patient due to decreased: (a) total dose and (b) dosing frequency (increased efficiency)

Table 124.4 Transdermal drug delivery: theoretical advantages.

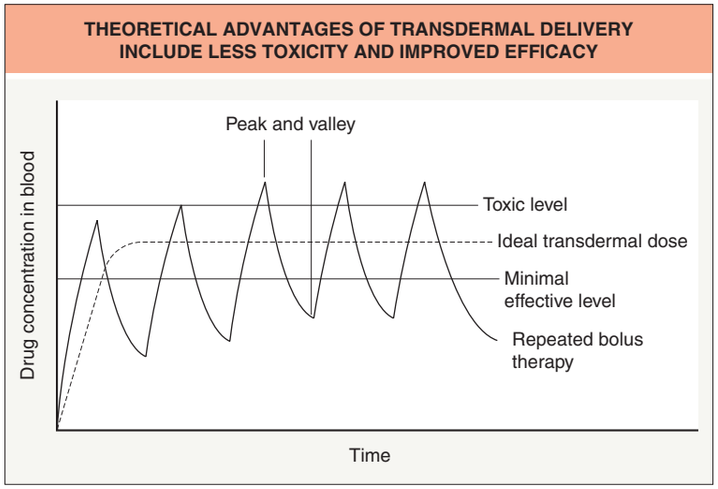

Fig. 124.7 Theoretical advantages of transdermal delivery include less toxicity and improved efficacy. This is due to a reduction in the "peaks" and "valleys" associated with repeated bolus therapy.

Chemical Enhancement

Chemical enhancers include compounds that interact with the lipid matrix of the stratum corneum to alter its nanostructure and thereby increase permeability[64,65,76]. The major advantages of chemical enhancers are that they are typically low cost, can be incorporated into a conventional patch or topical formulation, and do not require the complexity of a battery-powered device. The primary disadvantage of chemical enhancers is that they are often associated with skin irritation or toxicity when present at high concentrations and with long exposure times[77]. Thus, chemical enhancers have been employed principally to increase permeability to compounds that already cross the skin reasonably well, but they have generally been unable to significantly impact delivery of new classes of molecules (e.g. highly water-soluble drugs) or macromolecules such as proteins, gene-based medicines, and vaccines.

CONVENTIONAL TRANSDERMAL DRUG DELIVERY UTILIZING PATCHES
Ideal drug characteristics
• Low dosage (<10 mg/day) • Low molecular weight (<400 Da) • Moderately lipophilic
Examples of drugs available in transdermal patches
Buprenorphine, capsaicin, clonidine, estradiol, ethinyl estradiol, fentanyl, granisetron, glyceryl trinitrate (nitroglycerin), levonorgestrel, lidocaine, methylphenidate, methyl salicylate, nicotine, norelgestromin, norethindrone acetate, oxybutynin, rivastigmine, rotigotine, scopolamine, selegiline, sumatriptan, testosterone

Table 124.5 Conventional transdermal drug delivery utilizing patches.

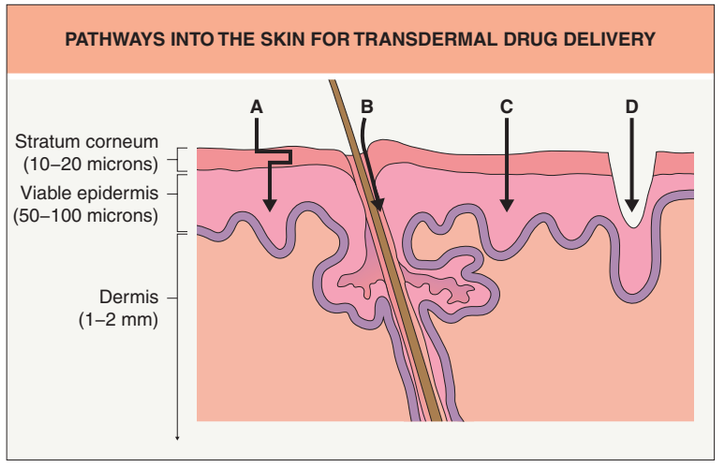

Fig. 124.8 Pathways into the skin for transdermal drug delivery. A Transdermal transport via a tortuous pathway largely within extracellular lipids. This pathway is utilized during drug absorption in association with chemical and some physical enhancers. **B** Transport through hair follicles and sweat ducts can be enhanced by iontophoresis and certain particulate formulations. **C** Transport directly across the stratum corneum is enabled by electroporation. **D** Stripping, ablation, abrasion, fractional photothermolysis, microneedles, and STAR particles remove or puncture stratum corneum to make micron-scale (or larger) pathways into the skin. *Reproduced with permission from Prausnitz MR, et al. Current status and future potential of transdermal drug delivery. Nat Rev Drug Discov 2004;3:115–24.*

STRATEGIES TO ENHANCE TRANSDERMAL DRUG DELIVERY	
Chemical	
• Ionic liquids • Liposomes/nanoparticles • Peptides	• Solvents • Surfactants/detergents • Water
Physical	
• Electroporation • Fractional photothermolysis • Iontophoresis • Mechanical abrasion • Microneedles	• STAR particles • Stripping • Thermal ablation • Ultrasound (cavitational) • Ultrasound (thermal)

Table 124.6 Strategies to enhance transdermal drug delivery. STAR particles, star-shaped particles.

The most common chemical enhancer is *water*, which leads to hydration of the stratum corneum when it accumulates during prolonged occlusion; the occlusion can result from a topical formulation or a patch[75]. Following 24–48 hours of occlusion, corneocytes swell, the intercellular spaces become distended, and the lacunar network becomes dilated. Distention of lacunae is thought to eventually lead to connections within an otherwise discontinuous system, creating "pores" in the stratum corneum interstices through which polar and non-polar substances can penetrate more readily.

Solvents, such as ethanol, methanol, chloroform and acetone, as well as *detergents* can extract barrier lipids and/or disrupt their bilayer structures, which then permeabilizes the stratum corneum[76,77]. Morphologic changes in human stratum corneum following exposure to solvents include phase separation and disruption of lamellar bilayers[81], in addition to the creation of defects in corneocyte membranes (with detergents). Moreover, *surfactants*, such as sodium dodecyl (lauryl) sulfate, and vehicles (e.g. propylene glycol) extract lipids and create extensive expansion of pre-existing lacunar domains. Furthermore, solvent-based penetration enhancers, such as azone, sulfoxides, urea and free fatty acids, not only extract extracellular lipids, but they also alter stratum corneum lipid organization (phase behavior), thereby increasing transdermal delivery and expanding intercellular domains (Fig. 124.9; see Fig. 124.6). More recent work suggests that combinations of particular chemical enhancers that adhere to specific, narrow-range compositions can be especially effective[82]. Topical medications have also been formulated as *ionic liquids*, which are drug salts paired with counterions that enable the drug to be in liquid form without the need for a solvent[83]. Certain peptides, such as polyarginine[84] and magainin[85], are believed to disrupt or penetrate stratum corneum lipids and thereby also increase transdermal drug delivery.

Finally, *liposomes* and *nanoparticles* represent additional "chemical" methods frequently employed to enhance delivery into the skin, especially in the case of cosmetics and moisturizers[86]. While intact liposomes typically do not penetrate the stratum corneum[87], they can be used to increase effective drug solubility in a vehicle (C_v) and facilitate partitioning into the skin (K_m). When nanoparticles contain drugs, this can result in an increase in drug concentrations on the skin surface, thereby increasing drug delivery into the skin, and, in some cases, nanoparticles enable slow release of drugs over time[88].

Physical Enhancement

There are a number of physical methods to increase drug delivery via the skin, many of which require the use of devices and some of which hold the promise to significantly expand the spectrum of drugs that can be administered transdermally to include water-soluble molecules and macromolecules[89,90].

Stripping is a simple technique used in research protocols to remove stratum corneum by sequential application of adhesive tape or cyanoacrylate glue[91]. Tape stripping removes both corneocytes and extracellular lipids, thereby reducing the elongated path length that drugs otherwise need to traverse, and it mechanically disrupts lamellar bilayers, even in the retained lower stratum corneum layers. Barrier disruption of human skin requires multiple strippings, which can lead to inflammation. More strippings are required to disrupt the barrier in subjects with skin phototypes V and VI (darkly pigmented) than with phototypes I and II (lightly pigmented)[92].

Fig. 124.9 Lipophilic agents (e.g. *n*-butanol) penetrate across the stratum corneum via the intercellular spaces. Note huge volume expansion of extracellular domains in this electron photomicrograph, representing the putative stratum corneum reservoir. *Method: n*-butanol precipitation *in situ* with osmium vapors. C, corneocyte.

Iontophoresis and electroporation represent electrically assisted, physical approaches to enhance delivery of drugs/macromolecules across the stratum corneum[93]. *Iontophoresis* uses low currents applied for minutes to hours from an externally placed electrode (with the same charge as the drug) in order to drive these molecules across the stratum corneum, primarily by electrophoresis[94]. As the rate of drug delivery is generally proportional to the applied current, iontophoresis offers an opportunity for programmable drug delivery, especially with the more recent development of miniaturized microprocessor systems. Clinically, iontophoresis has been employed to deliver: fentanyl and lidocaine for pain relief[95], pilocarpine to induce sweating (as a diagnostic test)[96], tap water to treat hyperhidrosis[97], and sumatriptan for migraine relief. Reverse iontophoresis has been used to extract glucose from the skin as a means of monitoring glucose levels in diabetic patients[98].

Electroporation (electropermeabilization) utilizes very short (microsecond to millisecond) and relatively high voltage (~100 V) electrical pulses to induce structural rearrangement of stratum corneum lipids, leading to pore formation[99,100]. Although currently at the research stage with regard to transdermal delivery, electroporation is being used to drive chemotherapeutic agents into superficial skin tumors by applying surface or penetrating electrodes[101].

While *ultrasound* is widely and safely employed in both medical diagnostics and physical therapy, this technology can also be used to enhance transdermal delivery. When ultrasound is utilized in a manner that resembles medical imaging, it is not very effective at increasing skin permeability. However, ultrasound administered in the context of heating deep tissues (as is done during physical therapy) has been shown to increase drug penetration into the skin, and this technique is actually used to increase local delivery of anti-inflammatory agents at the time of physical therapy[102]. With still different settings (in particular low frequencies such as <1 MHz), ultrasound can generate bubble activity, referred to as "*cavitation*", that can create microscopic defects in stratum corneum structure[103]. Cavitational ultrasound of the skin has been approved as a pretreatment prior to the application of lidocaine as a means of accelerating local anesthesia. In a related approach, pulsed laser beams have also been used to generate photomechanical shockwaves at the skin surface, which also increase skin permeability[104].

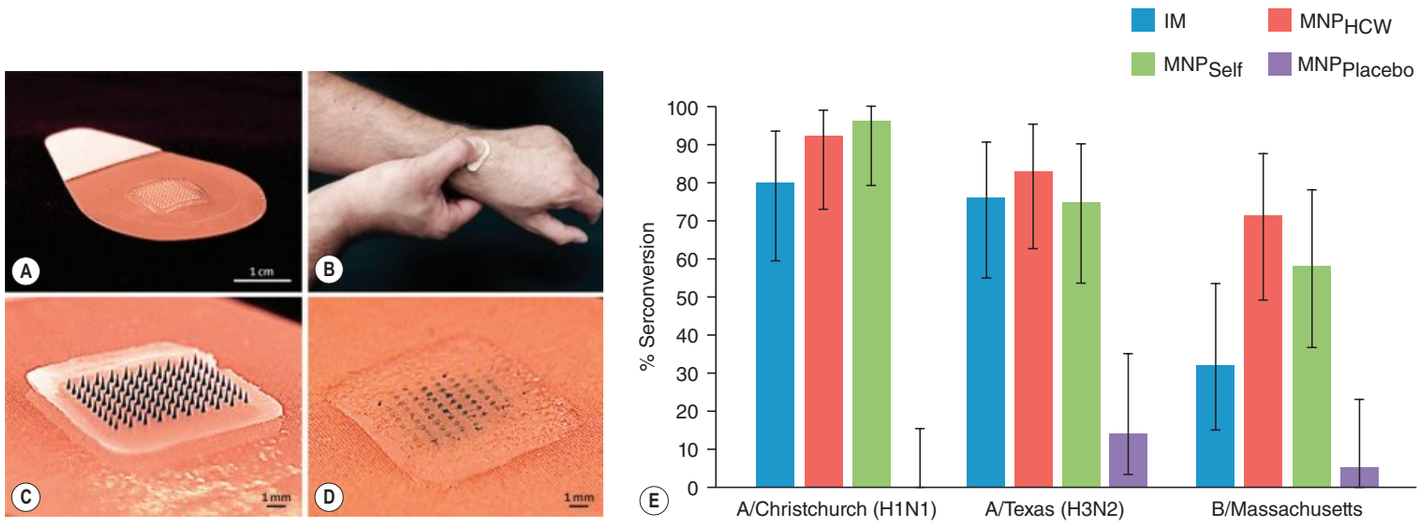

Fig. 124.10 Influenza vaccination of human subjects using a microneedle patch. A Microneedle patch. **B** Microneedle patch manually applied to the skin. Magnified view of 10 × 10 array of microneedles shown **C** before and **D** after application to skin. **E** Seroconversion against three influenza virus strains measured 28 days after influenza vaccination by intramuscular injection (IM) or microneedle patch (MNP$_{HCW}$) administered by a health care worker, microneedle patch self-administered by study subjects (MNP$_{self}$) and placebo microneedle patch containing no vaccine (MNP$_{placebo}$). *Reproduced with permission from Rouphael NG, et al. The safety, immunogenicity, and acceptability of inactivated influenza vaccine delivered by microneedle patch (TIV-MNP 2015): a randomised, partly blinded, placebo-controlled, phase 1 trial. Lancet 2017;390:649–58.*

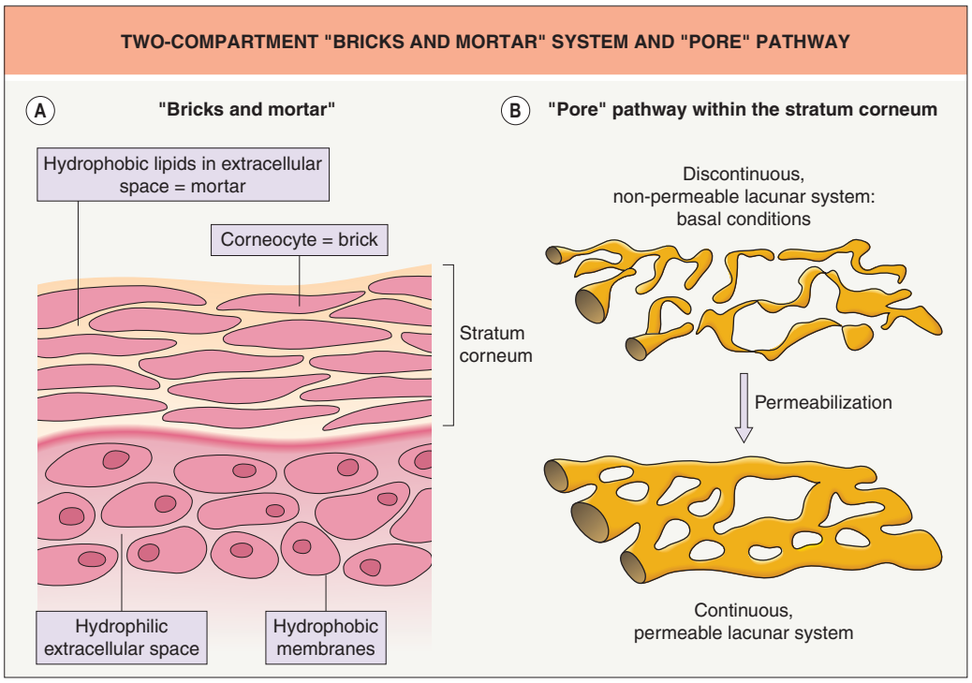
In addition to the methods described above that disrupt stratum corneum structure on a nanometer scale, there are methods for producing micron-scale holes across the stratum corneum. This enables delivery of much larger molecules with much greater fluxes into the skin. With *thermal ablation*, microsecond- to millisecond-long pulses of heat are applied utilizing electrical filaments, radiofrequency electrodes, or lasers which lead to micropores in the stratum corneum[105,106]. Because the pulses are so short, there is not enough time for heat to propagate deeply into the tissue, thereby localizing the ablation to the epidermis and minimizing pain; these latter effects have been demonstrated in clinical trials. An at least partial removal of the stratum corneum and an increase in skin permeability can be accomplished via sandpaper abrasion and microdermabrasion[107,108]. *Fractional photothermolysis* has also been used to create micron-scale holes in the skin (Chs. 136 & 137), as a means of enhancing delivery of several topical agents, including lidocaine, 5-aminolevulinic acid, and 5-fluorouracil[109].

Finally, *microneedles* represent another micron-scale approach to drug delivery via the skin and this technique has received significant attention in recent years[110]. Microneedles typically measure 0.2–1 mm in length; they can be solid or hollow and are manufactured by microfabrication tools adapted from those developed for the microelectronics industry. In clinical trials, *solid microneedles* have been used to punch microscopic holes into the skin prior to the application of drug-loaded patches such as those containing naltrexone[111]. Drug-coated solid microneedles, designed to undergo dissolution upon insertion into the skin, have also been tested, and the efficacy of zolmitriptan delivered in this manner for the treatment of migraine headaches has been demonstrated[112]. Fully water-soluble microneedles that encapsulate pharmaceutical compounds have also been developed, in particular for simplified vaccinations via patches that generate no sharps waste (Fig. 124.10)[113].

Microneedle technology has gained widespread use in the field of cosmetic dermatology. Initially, microneedles in a roller format were used to produce microinjuries to the skin in order to induce collagen formation and reduce the appearance of wrinkles[114]. More recently, water-soluble microneedles composed of hyaluronic acid have been employed for at-home delivery of dermal filler. Various microneedle designs have also been used to administer bioactive agents into the skin with claimed beneficial properties.

Hollow microneedles have been designed to enable simple and reliable intradermal injections. Clinical trials in patients with diabetes have shown accelerated pharmacokinetics of insulin after microneedle injections into the skin, when compared to conventional subcutaneous infusions[115]. Influenza vaccine that is approved for injection into the skin using a microneedle demonstrated increased immunogenicity in the elderly and a lower dose was effective in non-elderly adults[116]. This increased effectiveness of the vaccine is due to the highly immunoresponsive environment in the skin compared to muscle, the conventional site of vaccination.



A more recently developed microneedle technology is called *STAR particles*, which enable microneedle-based delivery over large areas of skin[117]. These millimeter-sized particles have sub-millimeter microneedles protruding from their surface. When mixed with a topical formulation and rubbed onto the skin, the STAR particles create microscopic pores that enable increased absorption of water-soluble drugs and macromolecules.

eFig. 124.1 Two-compartment "bricks and mortar" system and "pore" pathway. A The stratum corneum is a unique two-compartment system, analogous to a brick wall. Whereas lipids are sequestered extracellularly within the stratum corneum, the corneocyte is lipid-depleted but protein-enriched. **B** The degradation of corneodesmosomes results in discontinuous lacunar domains, which represent the likely aqueous "pore" pathway. These lacunae can enlarge and extend, forming a continuous but collapsible network under certain conditions, e.g. occlusion, prolonged hydration, sonophoresis.

eFig. 124.2 pH regulates sequential enzymatic steps that lead to formation of mature stratum corneum lamellar membranes. The process begins at the stratum granulosum–stratum corneum interface. Of note, in atopic dermatitis, a higher pH is observed.

Glucocorticoids 125

Courtney R. Schadt and Scott M. Jackson

Key features

- Glucocorticoids continue to be among the most commonly prescribed anti-inflammatory agents in dermatology and all of medicine, with a large number of disorders responding to these drugs
- Proper use of systemic glucocorticoids requires a working knowledge of the hypothalamic–pituitary–adrenal (HPA) axis
- Proper use of topical and intralesional glucocorticoids requires awareness of their various formulations and potencies
- Glucocorticoids have a broad range of potential adverse effects that can be minimized by a variety of strategies
- Clinical usage guidelines facilitate proper dosing and administration of glucocorticoids for both short- and long-term therapy

INTRODUCTION

The Nobel Prize in Medicine was awarded in 1950 to Hench and associates[1] for their initial work on the beneficial effects and toxicities of corticosteroids for rheumatic disorders. In 1951, Sulzberger and colleagues[2] first reported the use of systemic cortisone and adrenocorticotropic hormone (ACTH) as therapies for inflammatory skin diseases. One year later, Sulzberger and Witten successfully treated eczematous eruptions with topical hydrocortisone. A novel method of high-dose glucocorticoid therapy was introduced to dermatology in 1982 by Johnson and Lazarus[3], who used pulse intravenous therapy for pyoderma gangrenosum. During the past 40 years, a variety of other anti-inflammatory/immunomodulatory drugs have been developed, allowing for a "steroid-sparing" effect and minimization of risks from long-term therapy with systemic glucocorticoids.

PHARMACOLOGY AND MECHANISM OF ACTION

Structure and Metabolism

All steroids, including glucocorticoids, have the basic four-ring structure of cholesterol, with three hexane rings and one pentane ring. Fig. 125.1 shows the chemical structure of hydrocortisone (cortisol). Modifications in the basic four-ring structure of glucocorticoids result in systemic agents that have different potencies, mineralocorticoid effects, durations of action (biologic half-life), and metabolism; these agents are commonly referred to as corticosteroids, and this term is used elsewhere in the book. Table 125.1 lists the key pharmacologic properties of the major systemic agents used today. Similar changes in the basic structure of the glucocorticoid molecule have resulted in various topical agents with differing solubilities, lipophilic properties, degrees of percutaneous absorption, and glucocorticoid receptor-binding activities. Table 14.11 defines glucocorticoid structural classes relevant for allergic reactions and cross-reactivity among agents.

When examining the chemical structure of glucocorticoids, it is important to recognize that active agents such as hydrocortisone (see Fig. 125.1) have a hydroxyl group at the 11 position. The corresponding inactive drug, cortisone, has a ketone group at the 11 position and must undergo hepatic conversion to hydrocortisone for biologic activity. The same is true for prednisone, which must undergo the identical 11-hydroxylation by the liver to produce an active agent, prednisolone. Since conversion of the inactive drug to its active analogue is impaired in patients who have severe hepatic disease, it is best to treat such individuals with a medication such as prednisolone that does not require metabolic alteration to be of therapeutic benefit[4].

In addition to indicating equivalent glucocorticoid doses in milligrams, Table 125.1 shows that these agents differ in their relative mineralocorticoid as well as glucocorticoid potencies. Cortisone and hydrocortisone have fairly significant mineralocorticoid potency, whereas prednisone and prednisolone have slight mineralocorticoid effects. A drug that has no mineralocorticoid activity, such as methylprednisolone, would be most appropriate in situations where mineralocorticoid effects must be avoided[4].

Plasma half-lives of the various systemic glucocorticoids vary from about 1 to 5 hours, as seen in Table 125.1. However, the plasma half-life is a poor indicator of the duration of action (biologic activity) of each drug. Duration of biologic effect is best assessed by the period of suppression of ACTH secretion from the pituitary gland after the administration of a single dose of a particular glucocorticoid. As indicated in Table 125.1, short-acting glucocorticoids have an effect for 8–12 hours, intermediate-acting agents for 24–36 hours, and long-acting agents for more than 48 hours. Duration of biologic activity is a critical factor in choosing a glucocorticoid for alternate-day therapy. Intermediate-acting agents should be used for this purpose, with long-acting agents avoided because there would be no period for recovery of the hypothalamic–pituitary–adrenal (HPA) axis (see below)[4].

Absorption and Distribution

Oral glucocorticoids are absorbed in the jejunum, with peak plasma levels occurring 30–90 minutes after intake. Administration of these drugs with food may delay absorption but does not decrease the amount absorbed.

Once glucocorticoids reach the plasma, the primary carrier protein is corticosteroid-binding globulin (CBG), also known as transcortin. Most endogenous cortisol is bound to CBG, and low doses of exogenous glucocorticoids are primarily bound by this high-affinity, but low-capacity, carrier system. With higher glucocorticoid doses, some binding also occurs to albumin in a low-affinity fashion, but with a greater capacity because of the larger amount of albumin in plasma. The avidity with which exogenous glucocorticoids bind to these two carrier proteins is less than that of endogenous cortisol. As exogenous glucocorticoids fill CBG binding sites, an increase in low-affinity binding to albumin leads to a greater fraction of free (unbound) glucocorticoid. This free fraction is biologically active, entering cells and mediating glucocorticoid effects[5]. Disorders that result in decreased binding proteins in the plasma, such as hepatic or renal disease, increase the free fraction of exogenous glucocorticoids and thereby augment the therapeutic effects and toxicities of these drugs.

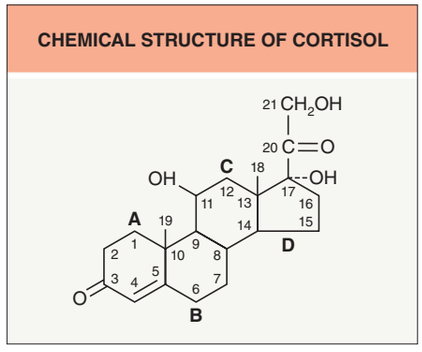

Fig. 125.1 Chemical structure of cortisol (hydrocortisone). Note the hydroxyl group at the 11 position.

PHARMACOLOGY OF SYSTEMIC GLUCOCORTICOIDS (GCs)					
	Equivalent GC *dose* (mg)	**GC *potency* (relative)**	**Mineralocorticoid potency (relative)**	**Duration of action (hours)***	**Plasma half-life (minutes)**
Short-acting					
Cortisone	25	0.8	1.0	8–12	60
Hydrocortisone	20	1	0.8	8–12	90
Intermediate-acting					
Prednisone	5	4	0.25	24–36	60
Prednisolone	5	4	0.25	24–36	200
Methylprednisolone	4	5	0	24–36	180
Triamcinolone	4	5	0	24–36	300
Long-acting					
Dexamethasone	0.75	25–30	0	36–54	200
Betamethasone	0.6	30–35	0	36–54	200

*Differs for intramuscular administration (see text).

Table 125.1 Pharmacology of systemic glucocorticoids (GCs). These agents are commonly referred to as corticosteroids, and this term is used elsewhere in the book.

The Hypothalamic–Pituitary–Adrenal (HPA) Axis

A working knowledge of the normal function of the HPA axis is required to understand glucocorticoid physiology. The hypothalamus produces corticotropin-releasing hormone, which is released in small pulses into the pituitary circulation. The anterior pituitary responds to corticotropin-releasing hormone with synthesis of ACTH and its subsequent pulsatile secretion into the peripheral circulation. ACTH is the hormone that stimulates the middle layer of the adrenal cortex to generate and release cortisol. Under basal conditions, the adrenals produce ~20–30 mg of cortisol (equivalent to 5–7.5 mg of prednisone) per day in an adult, but this may increase up to 10-fold under times of maximal stress. ACTH also has some role in stimulating adrenal androgen production, but it is not significantly involved in the production of the major mineralocorticoid, aldosterone. The major mineralocorticoid control mechanisms are the renin–angiotensin system and serum potassium levels.

There are three main control mechanisms for endogenous cortisol secretion[6]. The first is a negative feedback effect by plasma cortisol, which inhibits the secretion of corticotropin-releasing hormone and ACTH by the hypothalamus and pituitary, respectively. The second method of regulation is the pulsatile secretion of ACTH, which is based on a circadian cycle, with increasing pulses beginning several hours after the onset of sleep and reaching a maximum shortly before waking. From these ACTH pulses, the peak release of cortisol in a typical sleep cycle is at about 6–8 a.m. With other sleep cycles, the circadian pattern will adjust so that peak cortisol levels occur just prior to waking. The third form of control of endogenous cortisol production comes from neural effects on the HPA axis in response to various emotional or physical stresses. These neural stimuli include catecholamine production from the brainstem, corticotropin-releasing hormone from sites other than the hypothalamus, and vasopressin.

Molecular Mechanisms

As depicted in Fig. 125.2, the glucocorticoid free (unbound) fraction enters cells and exerts its effects by binding to a cytoplasmic glucocorticoid receptor, which is within a protein complex that includes heat shock proteins[5]. Binding of glucocorticoids to this receptor leads to their translocation into the nucleus and eventual release from the protein complex. In the nucleus, the glucocorticoid receptor forms a dimer that binds to glucocorticoid response elements in the promoter region of certain genes (see Fig. 125.2). Approximately 10–100 genes in each cell are regulated directly by glucocorticoids[7]. This binding affects the rate of transcription, inducing or (less often) repressing specific messenger RNA production and protein synthesis.

The glucocorticoid receptor also interacts with other transcription factors that have a central role in the inflammatory response as well as their coactivator molecules, such as cAMP response element binding protein (CREB)-binding protein. Nuclear factor-κB (NF-κB) is an important transcription factor that induces the expression of many genes that play a significant role in chronic inflammation, encoding various cytokines, adhesion molecules, inflammatory enzymes, and growth factors. By indirectly and directly inhibiting NF-κB, the glucocorticoid receptor can dramatically reduce the inflammatory process (see Fig. 125.2)[5]. The glucocorticoid receptor also has an inhibitory effect on activator protein 1 (AP-1), a heterodimeric transcription factor composed of proteins such as c-jun, c-fos, and activating transcription factor; this likewise controls expression of growth factor and cytokine genes. The key cytokines and other proinflammatory molecules that are inhibited by glucocorticoids and the effects of these drugs on inflammatory cells are summarized in Table 125.2[8,9].

CLINICAL INDICATIONS, DOSAGES, HPA-AXIS SUPPRESSION, TAPERING, AND CONTRAINDICATIONS

Table 125.3 lists major categories of dermatologic disease where systemic glucocorticoids are used. There are many more skin conditions for which topical and intralesional glucocorticoids can be helpful, such as eczematous and papulosquamous disorders and other localized inflammatory processes.

Oral Therapy

Dermatologists use glucocorticoids for short periods to treat acute conditions such as extensive allergic contact dermatitis and other acute eczematous disorders. Therapy is considered short-term if it is administered for ~3 weeks or less. If a skin disease requires a longer course of therapy (months to years), the addition of a glucocorticoid-sparing agent should be considered to assist in reducing the dosage and duration of glucocorticoid therapy. An oral agent with an intermediate duration of action, such as prednisone, is usually given in a single early-morning dose to achieve the least HPA axis suppression. In some severe acute dermatoses, the dose can be divided and administered twice daily for better initial control (versus more frequent intravenous administration), but conversion to a single early-morning dose should occur as soon as possible. Split-dose therapy results in parallel increases in efficacy and toxicity. The total number of milligrams given daily as a split dose is considered to be biologically equivalent to a slightly higher single morning dose. The daily dose of prednisone varies depending on the severity of the dermatosis, but for most moderate conditions, a common initial dose is 40–60 mg/day in average-weight adults or ~1 mg/kg/day in children.

Prednisone is often the intermediate-acting glucocorticoid of choice for both short- and long-term therapy. It is inexpensive and available

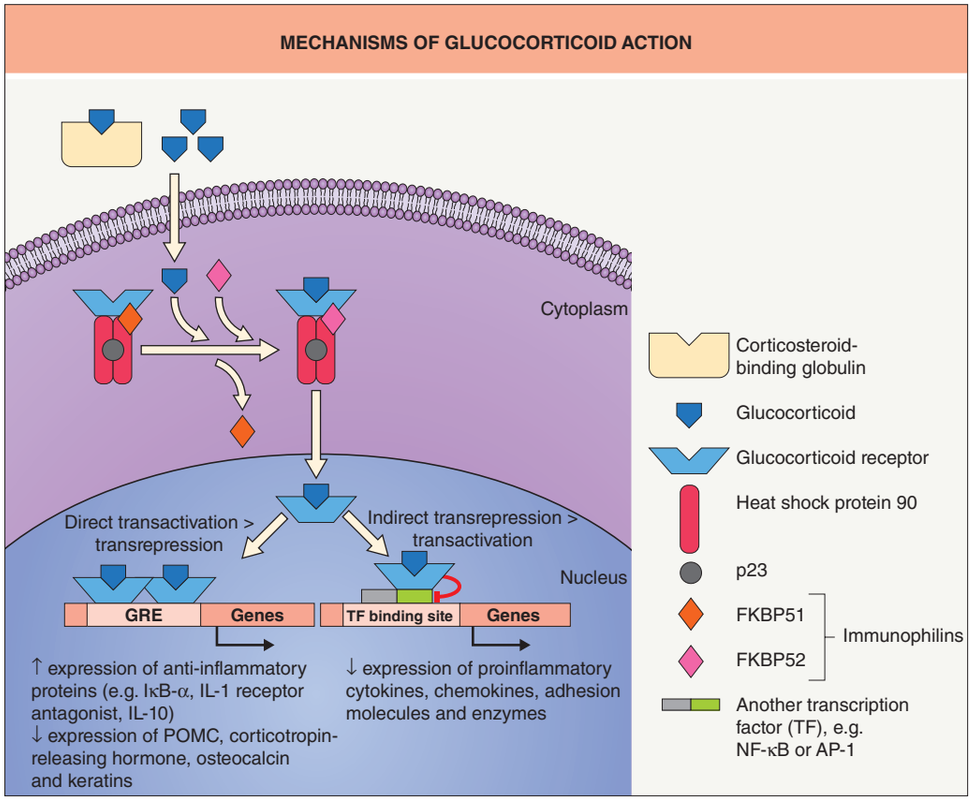

Fig. 125.2 Mechanisms of glucocorticoid action. "Free" glucocorticoid enters the cell and binds to the glucocorticoid receptor, which forms a complex that includes the 90 kDa heat shock protein and an immunophilin, FK506-binding protein 51 (FKBP51) in the cytoplasm. After glucocorticoid binding, FKBP52 replaces FKBP51 and facilitates nuclear translocation. In the nucleus, ligand-bound glucocorticoid receptor homodimers directly bind to glucocorticoid response elements (GREs) in the promoter regions of target genes, which leads to activation or (less often) repression of transcription. Glucocorticoid receptor monomers can also indirectly affect gene expression by interacting with and inhibiting other transcription factors such as nuclear factor-κB (NF-κB) or activator protein 1 (AP-1), resulting in decreased transcription of proinflammatory genes. IL, interleukin; IκB-α, inhibitor κB-α; POMC, proopiomelanocortin.

ANTI-INFLAMMATORY EFFECTS OF GLUCOCORTICOIDS
Decreased production of cytokines and other proinflammatory molecules
• Tumor necrosis factor • Granulocyte–macrophage colony-stimulating factor • Interleukin (IL)-1, IL-2, IL-6, and IL-8 • Intercellular adhesion molecule (ICAM)-1, E-selectin • Leukotrienes and prostaglandins (due to decreased phospholipase A_2 and cyclooxygenase activity)
Effects on inflammatory cells

• Neutrophils
  • Increased release from the bone marrow, resulting in neutrophilia due to a larger circulating pool
  • Decreased infiltration into sites of inflammation due to reduced expression of endothelial adhesion molecules and chemoattractants
  • Decreased apoptosis
  • Milder effects on phagocytosis and bactericidal function
• Lymphocytes
  • Redistribution of T cells to lymphoid depots, resulting in transient lymphopenia
  • Decreased activation and proliferation of effector (helper > cytotoxic) T cells, related to decreased IL-2 signaling and antigen presentation
  • Decreased B cell function and antibody production (at high doses)
  • Increased apoptosis
  • Increased regulatory T cell function
• Eosinophils
  • Decreased release from bone marrow and recruitment to sites of inflammation
  • Increased apoptosis
• Monocytes/macrophages
  • Decreased production, differentiation, and antigen presentation
• Mast cells
  • Decreased maturation, cytokine production, high-affinity IgE receptor (FcεRI) expression, and mediator release
• Erythrocytes
  • Decreased destruction due to reduced autohemolysis and erythrophagocytosis

Table 125.2 Anti-inflammatory effects of glucocorticoids.

MAJOR USES OF SYSTEMIC GLUCOCORTICOIDS IN DERMATOLOGY	
Severe dermatitis	
• Contact dermatitis (various forms) • Acute exacerbations of atopic dermatitis (risk rebound flare upon discontinuation)	• Photodermatitis • Exfoliative erythrodermas
Bullous dermatoses	
• Pemphigus (all forms) • Bullous pemphigoid • Mucous membrane (cicatricial) pemphigoid	• Linear IgA bullous dermatosis • Epidermolysis bullosa acquisita • Gestational pemphigoid • Erythema multiforme (major)
Vasculitis	
• Cutaneous (various types)	• Systemic (various types)
Autoimmune connective tissue diseases	
• Lupus erythematosus • Dermatomyositis • Systemic sclerosis (selected patients) • Eosinophilic fasciitis	• Morphea (severe generalized and linear variants) • Mixed connective tissue disease • Relapsing polychondritis
Neutrophilic dermatoses	
• Sweet syndrome (acute febrile neutrophilic dermatosis)	• Pyoderma gangrenosum • Behçet disease
Other disorders	
• Sarcoidosis • Lichen planus • Panniculitis (some types) • Urticaria/angioedema (acutely)	• Drug reaction with eosinophilia and systemic symptoms (DRESS) • Arthropod bites/stings

Table 125.3 Major uses of systemic glucocorticoids in dermatology.

ALTERNATE-MORNING GLUCOCORTICOID THERAPY

• "Off" days allow recovery of hypothalamic–pituitary–adrenal (HPA) axis
• Decreases risks of:
  • Growth suppression
  • Myopathy
  • Hypertension
  • Opportunistic infections
  • Electrolyte imbalances (e.g. hypokalemia, hypocalcemia)
• Does *not* substantially alter risks of osteoporosis or cataracts
• Fluctuations in glucose levels can make diabetes mellitus more difficult to manage

Table 125.4 Alternate-morning glucocorticoid therapy.

in many dosage forms[6]. Methylprednisolone can be used if there is a need to avoid any mineralocorticoid effects. Intermediate-acting drugs such as prednisone and methylprednisolone are also utilized for alternate-morning therapy, which allows the HPA axis to recover in the last 12 hours of the off-day of therapy. Other advantages of alternate-morning glucocorticoid therapy are listed in Table 125.4. Two important side effects of long-term glucocorticoid therapy that are not minimized by alternate-morning dosing are osteoporosis and cataracts (see below).

Intramuscular Therapy

Dermatologists occasionally use intramuscular administration of glucocorticoids for control of acute dermatoses[10]. Although some acute dermatoses respond very well to intramuscular glucocorticoid therapy, serious conditions such as pemphigus vulgaris or systemic lupus erythematosus (SLE) are best treated by other routes of systemic administration because of the initial need for higher daily doses and the requirement for more control over dosage changes. Advantages of intramuscular glucocorticoid therapy include guaranteed compliance due to physician administration and an assured steady release of glucocorticoids from the injected depot preparation. Critics of intramuscular therapy stress that oral morning doses are more physiologic, are absorbed more predictably, allow more precise tapering, and can be administered on alternate-morning schedules to decrease HPA axis suppression. There is also the possibility of lipoatrophy or a sterile abscess at an injection site, especially with triamcinolone, if the injection is not given deeply enough into the muscle. Intramuscular agents such as betamethasone and dexamethasone, which have a duration of action of less than 1 week, may be preferred in self-limited dermatoses. Longer-acting intramuscular agents that produce effects for about 3 weeks, such as triamcinolone acetonide and methylprednisolone acetate, should not be given more than about four to six times per year. The physician might be lulled into thinking that therapy is intermittent and relatively safe, while in fact it is continuous for ≥3 weeks per injection, necessitating time for HPA axis recovery.

Intravenous and Pulse Therapy

Intravenous doses of glucocorticoids may be necessary in life-threatening dermatologic conditions. A total daily dose of 2 mg/kg or more of methylprednisolone is given initially in divided doses every 6–8 hours in these acute and critical situations. Another method of dosing glucocorticoids in severe dermatologic disease is intravenous pulse therapy[11]. With this method, methylprednisolone is given intravenously in doses of 0.5–1 g over 2 hours daily for 1–5 days. This therapy was formerly given in an inpatient setting with cardiac monitoring because arrhythmias and rare cases of sudden death are possible if rapid administration results in acute electrolyte shifts. However, coadministration of potassium helps to avoid this problem, and slow infusion of the methylprednisolone over 2 hours usually prevents cardiac effects, allowing use of this therapy in an outpatient setting. Pulse therapy allows for a dramatic acute effect in severe dermatoses and is usually followed by maintenance therapy with oral glucocorticoids.

Topical Therapy

For topical glucocorticoid therapy, there are many different medications available in a wide range of potencies and a variety of vehicles. Topical glucocorticoids have been categorized by the WHO into four major potency groups that span seven classes, ranging from the ultra high potency agents in class 1 to the very low potency agents in class 7. These classes have been developed based on vasoconstrictor assays and double-blind clinical studies. Investigators graded the intensity of cutaneous vasoconstriction within normal skin of control subjects after overnight application of various agents and found significant correlation between degree of vasoconstriction and clinical efficacy (response of psoriatic lesions treated for 2–3 weeks)[12]. A list of topical preparations in each class is shown in Table 125.5. The vehicle can greatly influence the percutaneous absorption and therapeutic efficacy of a particular glucocorticoid. In some instances, brand-name and generic formulations of the same agent, concentration, and vehicle type may have different potencies (see Table 124.3). Limited insurance coverage and generic substitutions may result in patients receiving a different formulation than was intended by the clinician, with potential consequences on the effectiveness of therapy.

An ointment formulation is often more potent than the same molecule in a cream or lotion base because occlusive vehicles enhance percutaneous absorption through increased hydration of the stratum corneum. Gel preparations also tend to be readily absorbed. In selecting a topical glucocorticoid preparation for clinical use, one must first choose the desired potency based on the type, location, thickness, and extent of lesions. Next, one must select the proper vehicle based on the need for hydration or a drying effect, location on the body, and potential for irritation or sensitization by components of the vehicle. Lotions are elegant for the face, creams rub in well, ointments are advantageous for dry lesions, and gels or foams are more useful in hairy areas or for a drying effect (see Fig. 129.3). For the face and body folds, high potency glucocorticoid preparations should be avoided if possible due to the risks of skin atrophy in both locations and steroid rosacea/perioral dermatitis on the face. "Pulse dosing" (e.g. twice daily on the weekends only) may reduce the risk of epidermal atrophy with more potent glucocorticoids. Beyond decreasing the potency or the frequency of application of a topical glucocorticoid, it is not certain that any other modification reduces the risk of cutaneous atrophy or steroid rosacea/perioral dermatitis.

Certain topical glucocorticoids such as mometasone furoate and fluticasone propionate have low percutaneous absorption and are rapidly metabolized in the liver, minimizing their systemic bioavailability[13]. The latter agent is also highly lipophilic and has high affinity for the glucocorticoid receptor without significant binding to androgen, progesterone, estrogen, or mineralocorticoid receptors.

Commonly prescribed ophthalmic glucocorticoid preparations are listed in Table 125.6.

Intralesional Therapy

For many localized disorders, especially when topical therapy is not beneficial and systemic therapy is best avoided, intralesional glucocorticoid therapy can be very effective. A triamcinolone acetonide suspension is diluted to the desired concentration, which depends on the condition and the location to be treated; it is then injected in small amounts into the lesion(s), usually with a 30-gauge needle. With thick dermal lesions such as keloids, concentrations as high as 20–40 mg/ml of triamcinolone may be injected, as the desired result is to decrease the excessive connective tissue. However, with other disorders, atrophy of the dermis or fat can occur as a side effect, and a more dilute concentration (as low as 2 mg/ml of triamcinolone acetonide) should be used. This method of administration allows the clinician to bypass the barrier of a thickened stratum corneum and/or to treat a dermal or perifollicular inflammatory process (e.g. granuloma annulare, nodulocystic acne, alopecia areata) directly with higher concentrations of glucocorticoid at the site of the pathology, reducing the risk of epidermal atrophy.

HPA Axis Suppression

Exogenous glucocorticoids can induce a secondary type of adrenal insufficiency that is related to both the dose and duration of treatment. Adrenal suppression usually occurs after 4 weeks of systemic treatment with doses just above physiologic levels and earlier with higher doses[14]. This effect is lessened by administering the glucocorticoid in a single morning dose and decreased even more by using an intermediate-acting agent on alternate mornings.

POTENCY RANKING OF SOME COMMONLY USED TOPICAL GLUCOCORTICOIDS		
WHO potency group	**Class**	**Topical glucocorticoid agent and formulation**
Ultra high (super-potent)	1	Betamethasone dipropionate ointment* and gel* 0.05% Clobetasol propionate ointment, cream, gel, lotion, foam, solution ("scalp application")†, spray, and shampoo 0.05% Desoximetasone spray 0.25% Diflorasone diacetate ointment* 0.05% Fluocinonide cream 0.1% Flurandrenolide tape 4 mcg/cm^2 Halobetasol propionate ointment, cream, lotion, and foam 0.05%

Table 125.5 Potency ranking of some commonly used topical glucocorticoids. Note different concentrations for betamethasone valerate, clobetasol, desoximetasone, fluocinolone, halobetasol, and triamcinolone acetonide,

The entire HPA axis is affected by exogenous glucocorticoids. The hypothalamus is the first to be suppressed and the quickest to recover, whereas the adrenals are the last of the three glands to be suppressed and the slowest to recover. After high-dose therapy for months to years, ACTH levels may not return to normal for several months. Full recovery of the adrenal glands with normal serum cortisol levels may take even longer, sometimes up to 1 year[6]. There can be altered stress responsiveness in situations such as infection or surgery. Symptoms of weakness, fatigue, anorexia, nausea, and fever may occur, and patients may even rarely develop hypotension or shock. Small doses of intravenous glucocorticoids may be needed prior to physically stressful situations such as major surgical procedures. Minor surgical procedures under local anesthesia do not require replacement therapy. Endocrinologic consultation should be obtained if the rare addisonian crisis occurs.

Even in the absence of overt adrenal insufficiency, a *glucocorticoid withdrawal syndrome* presenting with arthralgias, myalgias, headache, mood changes, fatigue, nausea, and decreased appetite can also occur upon rapid tapering of long-term glucocorticoid therapy. Low intracellular glucocorticoid levels are thought to be the cause, and a return to previous doses with slower tapering alleviates this syndrome.

With regard to HPA axis suppression, the primary screening test for basal function of the entire axis is the morning serum cortisol level. The morning glucocorticoid dose should be omitted on the day the

OPHTHALMIC GLUCOCORTICOIDS
Maximum strength
Loteprednol suspension 0.5% Prednisolone suspension and solution 1% Rimexolone suspension 1%

Table 125.6 Ophthalmic glucocorticoids.

cortisol level is checked between 6 and 8 a.m. Impaired basal HPA axis function is suggested by serum cortisol levels below 10 mcg/dl. Adrenal function alone can be tested by using the more specific ACTH stimulation test, in which serum cortisol levels are measured at baseline and then 30 and/or 60 minutes after intravenous or intramuscular administration of 250 mcg (standard-dose test; can be adjusted for weight in young children) or 1 mcg (low-dose test, which may be more sensitive) of ACTH (cosyntropin)[15]. If it is necessary to test stress responsiveness of the HPA axis or the adrenal glands in greater detail, endocrinologic consultation should be obtained for the ACTH stimulation test or for other evaluations including the corticotropin-releasing factor test, the insulin hypoglycemia test, or the metyrapone test.

Tapering Systemic Glucocorticoids

There is a paucity of high-quality studies examining systemic glucocorticoid tapering regimens for chronic medical conditions, including dermatologic diseases[14]. Some endocrinologic organizations advise tapering following oral administration of: (1) 40 mg of prednisone or the equivalent daily for more than one week; (2) any glucocorticoid dose daily for more than three weeks; (3) repeated glucocorticoid doses in the evenings; and (4) a glucocorticoid course within one year of stopping long-term therapy or in patients with other risks factors for adrenal insufficiency[14]. However, there is little evidence supporting these recommendations. As noted above, oral glucocorticoids should be taken as a single dose in the morning when possible to reduce the risk of adrenal insufficiency[16]. If the disease flares during the taper, the last glucocorticoid dose at which the condition was controlled should be resumed, with subsequent slower dose reduction.

Other factors that may impact the glucocorticoid regimen include the severity and chronicity of the underlying skin disease, time of onset of effectiveness of a coadministered steroid-sparing agent, and the patient's age and comorbidities (e.g. diabetes mellitus, psychiatric disease, hypertension, osteoporosis). Acute skin conditions (e.g. allergic contact dermatitis) of moderate severity can generally be treated with a 2- to 3-week glucocorticoid course. However, more serious chronic skin conditions, such as pyoderma gangrenosum, SLE, dermatomyositis, and vasculitis typically require longer courses with slow tapering over 6–8 or more weeks. As the dose of prednisone is decreased, the taper should be slowed.

In general, a course of systemic glucocorticoids longer than 3–4 weeks can be tapered as follows, with close monitoring of disease activity: prednisone (or equivalent) >40 mg/day – decrease by 5–10 mg weekly; 20–40 mg/day – decrease by 5 mg weekly; 10–20 mg/day – decrease by 2.5 mg weekly; and 5–10 mg/day – decrease by 1 mg every 2–3 weeks. Another method of glucocorticoid dosage tapering is to convert from daily to alternate-day therapy once the prednisone dose is about 20–30 mg/day[4]. The simplest way to convert is to multiply the previous daily dose by 2–2.5 times for the on-day dose, and taper therapy rapidly on the off-day. An alternative method is to increase the on-day dose by 5 mg increments and decrease the off-day dose by a similar amount, until therapy is eventually doubled on the on-day and stopped on the off-day. Finally, simultaneous tapering and alternate-morning conversion can be accomplished by decreasing the dose by 5 mg on the alternate morning, with the patient eventually taking the same dose every other morning as they were taking daily.

SIDE EFFECTS OF SHORT-TERM SYSTEMIC GLUCOCORTICOID THERAPY
• Mood changes, anxiety, insomnia • Gastrointestinal intolerance (e.g. nausea, vomiting) • Hyperglycemia • Fluid/sodium retention • Increased appetite, weight gain • Acneiform eruptions • Increased infections • Amenorrhea • Muscular weakness, muscle effects • Impaired wound healing

Table 125.7 Side effects of short-term systemic glucocorticoid therapy.

Contraindications

There are several contraindications to systemic or local glucocorticoid therapy[6]. Herpes simplex keratitis is considered a contraindication to local glucocorticoid treatment of the eye, whereas active tuberculosis and systemic fungal infections are usually considered as contraindications to systemic glucocorticoid therapy. Previous history of hypersensitivity to an intravenous preparation, which is rare, should preclude further use of that particular drug. Relative contraindications to systemic glucocorticoid therapy include active peptic ulcer disease, severe depression or psychosis, and an extensive chronic dermatosis (e.g. psoriasis) likely to flare after rapid glucocorticoid taper. In such situations, systemic glucocorticoid treatment should be used only when the benefits clearly outweigh the risks.

MAJOR SIDE EFFECTS

Short-term glucocorticoid therapy is usually extremely safe for self-limited and acute dermatoses. When side effects do occur with short courses of systemic therapy, those listed in Table 125.7 are most common. With long-term systemic glucocorticoid therapy at supraphysiologic doses, there is an increased incidence of more serious effects. Table 125.8 lists the major categories of complications and major adverse effects in each category. Most of these side effects are dose-related. As shown in Table 125.9, some patients have a higher risk of side effects from glucocorticoids[6]. The following discussion highlights selected toxicities of glucocorticoid therapy.

Osteoporosis

Osteoporosis is one of the most prevalent side effects in patients receiving long-term systemic glucocorticoid therapy. Without preventative measures, osteoporosis develops in 30%–50% of all patients treated chronically with glucocorticoids[17]. A rapid decline in bone mineral density occurs within the first 3 months of usage, and the rate of loss peaks at 6 months[18]. Postmenopausal White women are at highest risk for complications such as fractures, because they have the lowest bone mass before beginning therapy. The greatest amount of bone loss is usually observed in young men, because they have the highest pretreatment bone mass. The development of osteopenia and osteoporosis is not avoided by alternate-morning treatment schedules.

Trabecular bone, which is present in the axial skeleton (vertebrae, ribs), has a metabolic turnover rate eight times that of cortical bone (long bones), making trabecular bone much more prone to demineralization[19]. Although many patients with osteoporosis have no symptoms, more advanced disease can produce bone pain, fractures, and vertebral collapse. The mechanism of glucocorticoid-induced bone loss includes both direct and indirect effects[20]. Glucocorticoids *directly* reduce the proliferation and function of osteoblasts, increase apoptosis of osteoblasts, and promote proliferation of osteoclasts. They act *indirectly* by increasing urinary calcium excretion and reducing intestinal absorption of calcium. This decreases serum calcium and stimulates parathyroid hormone release, which drives osteoclasts to resorb bone.

MAJOR SIDE EFFECTS OF LONG-TERM SYSTEMIC GLUCOCORTICOID THERAPY	
Musculoskeletal	
Osteoporosis	Muscle atrophy
Osteonecrosis (e.g. hip)	Myopathy
Growth retardation	
Ophthalmologic	
Cataracts	Hemorrhage
Glaucoma	Exophthalmos
Infection	
Gastrointestinal	
Nausea, vomiting	Intestinal perforation
Gastroesophageal reflux	Pancreatitis
Peptic ulcer disease	Esophagitis (reflux or candidal)
Metabolic	
Hyperglycemia	Hypocalcemia
Hyperlipidemia	Hypokalemic alkalosis
Obesity	
Cardiovascular	
Hypertension	Atherosclerosis
Peripheral edema	
Gynecologic, obstetric	
Amenorrhea	Fetal effects (rare adrenal insufficiency; cleft palate in animal studies)
Hematologic, cellular	
Leukocytosis	Eosinopenia
Lymphopenia	Immunosuppression with increased risk of infections
Nervous system	
Mood, personality changes	Pseudotumor cerebri
Psychiatric problems, psychosis	Peripheral neuropathy
Seizures	Epidural lipomatosis
Cutaneous	
Atrophy, striae, telangiectasia	Hirsutism
Vascular fragility, purpura	Infections
Acne, acneiform eruptions	
Hypothalamic–pituitary–adrenal (HPA) axis	
Suppression	Adrenal (addisonian) crisis
Withdrawal syndrome	

Table 125.8 Major side effects of long-term systemic glucocorticoid therapy.

PATIENTS AT HIGHER RISK FOR TOXICITY FROM GLUCOCORTICOID THERAPY	
Patient group	**Concerns**
Female patients	• Slower metabolism/clearance of GCs due to estrogen • Lower baseline bone density • Often given a higher dose per kg when not adjusted based on weight
Postmenopausal women, elderly patients	• Increased risk of osteoporosis, especially if limited physical activity
Pediatric patients	• Temporary retardation of growth • Increased likelihood of striae distensae in adolescents
Patients with SLE, dermato/polymyositis or rheumatoid arthritis	• Long-term use associated with a higher risk of aseptic necrosis of bone, muscle atrophy or osteoporosis, respectively
Patients with hepatic disease (e.g. secondary to alcoholism)	• Decreased metabolism of GCs and lipids, leading to high serum triglyceride levels
Patients with hypoalbuminemia	• Increased free fraction of GCs results in greater side effects
Patients who smoke and/or have high alcohol intake	• Increased risk of osteoporosis and peptic ulcer disease

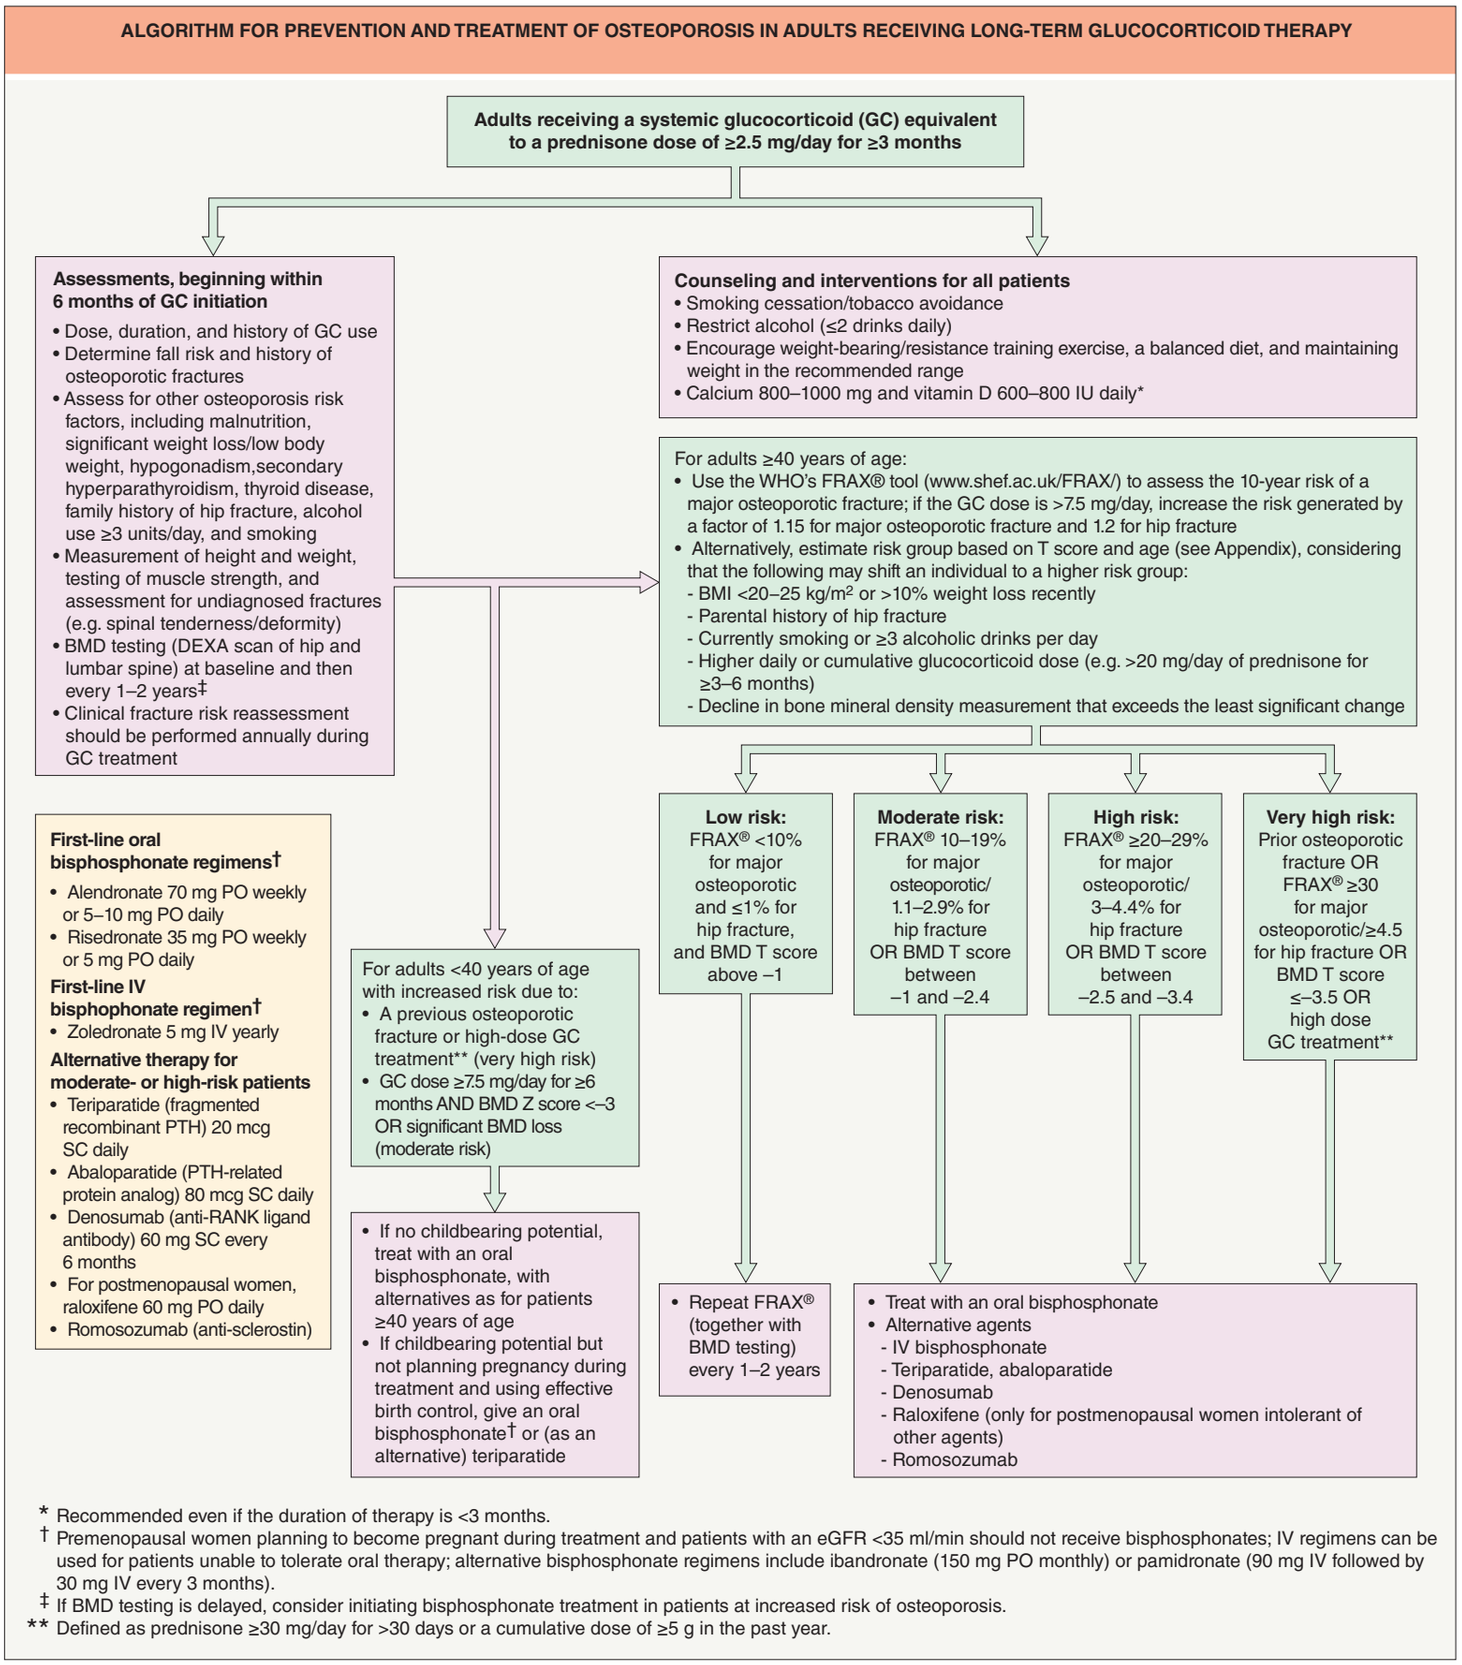

Table 125.9 Patients at higher risk for toxicity from glucocorticoid (GC) therapy. SLE, systemic lupus erythematosus.

Fig. 125.3 Radiograph of the spine showing severe demineralization. This is indicative of advanced osteoporosis.

Although routine radiographs can detect vertebral compression fractures, these plain X-ray studies are not sensitive enough to detect osteoporosis until 20%–60% of bone mass is lost (Fig. 125.3). Currently, the best measurement of osteoporosis is quantification of bone mineral density with dual-energy X-ray absorptiometry (DEXA), which is preferred because of its sensitivity, reproducibility, and low radiation exposure. Ideally, patients on long-term glucocorticoids should have a baseline DEXA examination of the hip and lumbar spine, with a repeat study performed every 1–3 years at the same sites. In densitometry reports, T scores are used to connote a standard deviation from the mean of a healthy control population. Osteopenia is defined as a T score between −1 and −2.5 standard deviations below the mean, with a T score less than −2.5 (i.e. −2.6 or below) defining osteoporosis[17]. For patients beginning long-term glucocorticoid therapy, risk factors for decreased bone density should be assessed and guidelines for the prevention and treatment of osteoporosis followed (Fig. 125.4)[18,21]. Endocrinologic consultation should be obtained in patients who develop significant osteopenia or osteoporosis. Further information on recommended regimens for osteoporosis prevention and treatment in patients receiving long-term glucocorticoid therapy is provided in Fig. 125.4[22].

In general, experts agree that patients with a history of low-impact fractures and adults with moderate to high fracture risk, especially postmenopausal women and men ≥50–65 years of age, should begin concomitant *bisphosphonate* therapy when initiating a glucocorticoid treatment course lasting ≥3 months (see Fig. 125.4). Since the largest reduction in bone mass occurs during the first 6 months of glucocorticoid therapy, it is important to initiate this and other preventative measures promptly[18]. Alendronate and risedronate are first-line oral agents given daily or weekly. They should be taken on an empty stomach, only with water, upon arising in the morning; patients should remain upright for at least 30–60 minutes after administration. Although generally well tolerated, gastrointestinal side effects can occur and, if severe, may necessitate changing to a different agent. Intravenous bisphosphonates such as zoledronate 4–5 mg IV once yearly or pamidronate 30 mg IV

* Recommended even if the duration of therapy is <3 months.
† Premenopausal women planning to become pregnant during treatment and patients with an eGFR <35 ml/min should not receive bisphosphonates; IV regimens can be used for patients unable to tolerate oral therapy; alternative bisphosphonate regimens include ibandronate (150 mg PO monthly) or pamidronate (90 mg IV followed by 30 mg IV every 3 months).
‡ If BMD testing is delayed, consider initiating bisphosphonate treatment in patients at increased risk of osteoporosis.
** Defined as prednisone ≥30 mg/day for >30 days or a cumulative dose of ≥5 g in the past year.

Fig. 125.4 Algorithm for prevention and treatment of osteoporosis in adults receiving long-term glucocorticoid therapy. Based on the American College of Rheumatology 2023 recommendations (www.rheumatology.org/glucocorticoid-induced-osteoporosis-guideline). Recommendations for children receiving glucocorticoid therapy for ≥3 months include: (1) clinical fracture risk assessment within 6 months of beginning therapy and then annually; (2) for those 4–17 years of age, calcium 1 g and vitamin D 600 IU daily; and (3) for those with history of an osteoporotic fracture and a glucocorticoid dose of ≥0.1 mg/kg/day, treatment with an oral bisphosphonate. Androgen-deprivation therapy in men and (especially in women) rheumatoid arthritis represent additional risk factors for osteoporosis. BMD, bone mineral density; BMI, body mass index; DEXA, dual-energy X-ray absorptiometry; IV, intravenously; PO, per os; PTH, parathyroid hormone; SC, subcutaneously.

every 3 months are alternatives. Osteonecrosis of the jaw represents a potential complication of bisphosphonate therapy, occurring most often with high-dose intravenous administration in patients with an underlying malignancy (e.g. multiple myeloma) and occasionally in association with invasive dental work[23]. Several case reports and small series have described atypical fractures of the subtrochanteric or diaphyseal femur in patients receiving long-term bisphosphonate therapy, but larger studies have demonstrated a very low absolute risk[23,24]. All bisphosphonates, especially those with long half-lives (e.g. ibandronate), should be avoided in premenopausal women who might become pregnant, as these agents cross the placenta and produce teratogenicity, including fetal skeletal abnormalities. Furthermore, bisphosphonates should not be administered to patients with an estimated glomerular filtration rate (eGFR) of <35 ml/minute.

Several other agents that can reduce bone resorption or increase bone formation represent options to prevent and treat glucocorticoid-induced osteoporosis in high-risk patients or those who do not tolerate bisphosphonates. *Teriparatide* (a fragment of human parathyroid hormone [PTH]) and *abaloparatide* (a PTH-related protein analogue) are additional options that increase bone formation. *Denosumab* is a monoclonal antibody directed against RANKL (receptor activator of NF-κB ligand) that blocks osteoclast maturation and thereby leads to decreased bone resorption. It is not cleared by the kidney and can be used in patients with eGFR <35 ml/minute. Potential side effects include hypocalcemia, dermatitis, osteonecrosis of the jaw, increased risk of infections, and fetal harm. *Raloxifene* is a selective estrogen receptor modulator (SERM) with less anti-resorptive potency than bisphosphonates; it represents an alternative for selected postmenopausal women (e.g. those with a high risk of invasive breast cancer), but increased risk of cardiovascular disease and thrombosis limit its use. Of note, estrogen/progestin therapy is no longer a first-line treatment for osteoporosis in postmenopausal women due to increased risk of breast cancer, stroke, myocardial infarction, and venous thromboembolism[25]. *Romosozumab*, a monoclonal antibody that increases bone density by targeting sclerostin, is likewise not a first-line agent due to the associated risk of cardiovascular disease and thrombosis. Because discontinuation of denosumab, teriparatide, abaloparatide, or romosozumab may lead to rapid bone loss and increased fracture risk, sequential therapy with a bisphosphonate for at least one year is recommended.

Osteonecrosis

Osteonecrosis (also known as aseptic necrosis or avascular necrosis) has numerous causes, and it is an uncommon but serious complication of glucocorticoid treatment[26]. Additional risk factors include physical trauma, sickle cell disease, alcohol abuse, cigarette smoking, HIV infection, and elevated serum triglycerides. The incidence of glucocorticoid-related osteonecrosis is higher in renal transplant recipients and patients with SLE, altered lipid metabolism, fatty degeneration of the liver, or alcoholism.

Localized bone pain during activity is the usual initial symptom of osteonecrosis, with the pain eventually occurring at rest and requiring analgesics for relief. The proximal femur is the most common site, although the distal femur or humeral head may be affected. Most patients who develop osteonecrosis while on glucocorticoids have been treated for at least 6–12 months, paralleling the time needed to induce changes in bone marrow fat deposition.

The mechanism of this condition is not completely understood, although intraosseous hypertension secondary to fat cell enlargement may compromise terminal arterioles at certain sites. Some investigators believe that fat emboli can originate from fatty deposits in the liver or from serum triglycerides, whereas others believe that only bone-derived fat emboli produce arterial occlusion with subsequent infarction.

Signs of osteonecrosis may not be evident on standard X-rays for as long as 6 months after bone pain begins (Fig. 125.5A). Therefore, early MRI, the most specific and sensitive radiologic examination, is recommended for confirmation of diagnosis (Fig. 125.5B). Initial medical treatment is conservative and consists of trauma prevention, rest, and modified weight bearing with the use of crutches[27]. More advanced cases in young patients may require hip salvaging procedures such as core decompression to reduce intraosseous pressure, vascularized fibular grafting, or electric stimulation. Eventual total joint arthroplasty is often unavoidable.

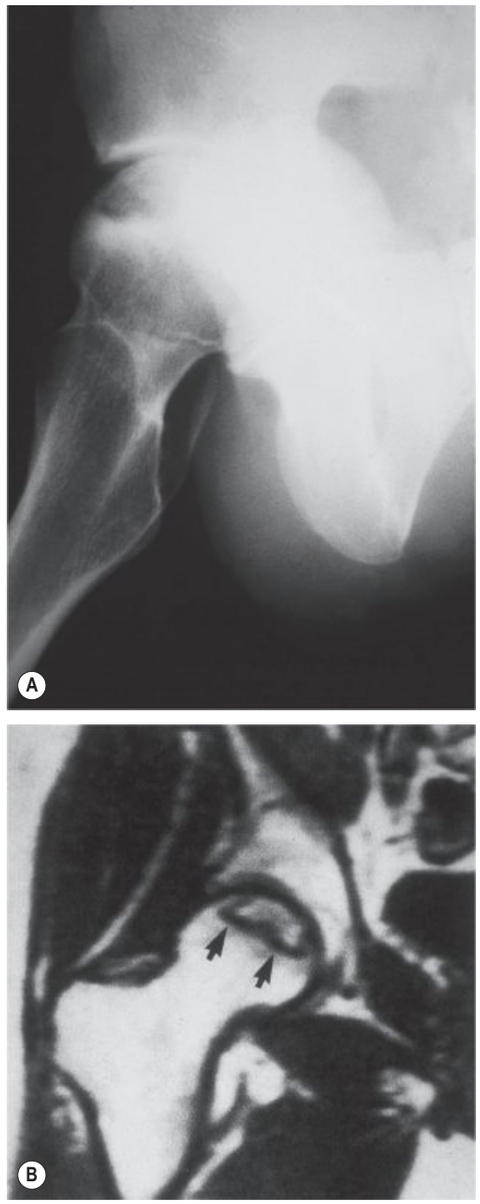

Fig. 125.5 Osteonecrosis of the femoral head. **A** Radiograph fails to demonstrate early stages of osteonecrosis. **B** In contrast, osteonecrosis is clearly evident on an MRI of the hip in the same patient (arrows).

Growth Suppression

The doses of systemic glucocorticoids required to produce growth suppression are not much higher than physiologic doses. Alternate-morning therapy can minimize this effect but does not eliminate it completely[28]. Glucocorticoid therapy via inhalants or extensive, chronic use of topical agents may also rarely produce growth suppression. Once the glucocorticoid therapy is discontinued, there is often a compensatory growth spurt with normal development of height. If chronic glucocorticoid therapy is given just before or during early puberty, the expected pubertal growth spurt is often delayed; with continued glucocorticoid administration, compensatory growth may occasionally be prevented by epiphyseal closure.

Glucocorticoids can suppress growth by several mechanisms, including interference with nitrogen and mineral retention; inhibition of collagen and protein matrix synthesis; and decreased release and signaling of growth hormone[28]. Growth monitoring should be done every 3–6 months, and growth hormone therapy may be considered in certain situations to restore linear growth and reverse other catabolic effects.

Myopathy

Myopathy is an uncommon complication of glucocorticoid therapy. The classic (chronic) form presents as painless, symmetrical proximal muscle weakness, most often of the lower extremities. It typically begins

FEATURES THAT DISTINGUISH GLUCOCORTICOID (GC)-RELATED MYOPATHY FROM MYOSITIS		
Feature	**Glucocorticoid-related myopathy**	**Myositis**
Clinical setting	• More likely with a high GC dose • Improves within 3–4 weeks when the GC dose is decreased	• Less likely with a high GC dose • Worsens when the GC dose is decreased
Clinical presentation	• Weakness, usually without myalgias	• Weakness, often associated with myalgias
Laboratory findings	• Usually normal serum creatine kinase • Elevated urine creatine*, which decreases as the GC dose is decreased	• Elevated serum creatine kinase • Elevated urine creatine*, which increases as the GC dose is decreased
EMG findings	• Normal	• Abnormal
MRI findings	• Signs of muscle atrophy	• Signs of muscle inflammation/edema
Muscle biopsy findings	• Atrophy	• Inflammation and necrosis

*Percent creatinuria can be calculated as creatine (mg) / [creatine + creatinine (mg)] in a 24-hour urine sample; however, elevated levels (>10%) are not specific to myopathy.

Table 125.10 Features that distinguish glucocorticoid (GC)-related myopathy from myositis. The myopathy is also referred to as corticosteroid-induced myopathy or simply steroid myopathy. EMG, electromyography; MRI, magnetic resonance imaging.

many weeks to months after systemic therapy is initiated, usually in patients treated with doses equivalent to >40 mg/day of prednisone. Although possibly more common with fluorinated glucocorticoids (e.g. dexamethasone, betamethasone, triamcinolone), the condition can occur with any agent[29]. Alternate-morning therapy might decrease its incidence. Diagnosis of myopathy may be difficult, as serum muscle enzyme levels and electromyographic studies tend to be normal. Muscle biopsy findings are relatively nonspecific, with variable muscle fiber diameters and atrophy of type II fibers but no substantial inflammation or necrosis. Increased urinary creatine excretion can be a clue to the diagnosis. Gradual reduction of the glucocorticoid dose along with physical therapy is useful in managing this complication, although muscle function may not return to normal for many months.

With inflammatory muscle diseases such as dermatomyositis, the glucocorticoids used to treat the disorder may actually increase the tendency for muscle atrophy. Steroid-sparing agents are often utilized after initial control with glucocorticoids, especially if glucocorticoid tapering is not occurring at an acceptable rate[4] (see Ch. 42). Findings that help to distinguish glucocorticoid-related myopathy from myositis are presented in Table 125.10.

Cataracts

The cumulative dosage and duration of therapy are the most important factors in the development of posterior subcapsular cataracts in patients receiving systemic glucocorticoid therapy. This adverse effect has been noted in patients receiving as little as 10 mg/day of prednisone for 1 year. Cataract development is not reduced by alternate-morning schedules, although patients on continuous therapy are at higher risk than those receiving intermittent treatment. While there may be some individual susceptibility factors, children are at greatest risk, developing cataracts with lower doses and shorter treatment durations compared to adults. Cataracts that occur as a manifestation of atopic keratoconjunctivitis in patients with atopic dermatitis are often anterior subcapsular lesions, but cataracts may also occur in a posterior location and be indistinguishable from those associated with glucocorticoids.

Ophthalmologic examinations are recommended every 6–12 months for patients on long-term systemic glucocorticoid therapy. Progression of cataracts can still occur despite decreasing or discontinuing glucocorticoid therapy, but discontinuing the glucocorticoids occasionally deters further cataract formation or reverses lens opacification[30].

Metabolic Effects

Glucocorticoids produce *hyperglycemia* by affecting glucose metabolism through enhanced hepatic gluconeogenesis and decreased peripheral insulin-mediated glucose uptake. Relative insulin resistance is produced by decreasing the affinity of cellular receptors for insulin. Although worsening of pre-existing or subclinical glucose intolerance is common, new-onset diabetes mellitus usually occurs only with high-dose therapy, and ketoacidosis is rare. Most patients will revert to their prior glucose status within a few months of discontinuing glucocorticoid therapy. Blood glucose levels should be assessed periodically during high-dose or long-term glucocorticoid therapy. Diabetic patients require closer monitoring, and they may need to be switched from oral antidiabetic agents to insulin or given higher insulin doses due to glucocorticoid-induced insulin resistance. Alternate-morning glucocorticoid schedules are usually not possible in diabetic patients because of the resulting fluctuations in insulin requirements.

Hyperlipidemia is a common side effect of glucocorticoid therapy, especially in patients with prior lipid abnormalities. Elevation of triglycerides is most frequently observed, but elevations of high- or low-density lipoproteins occur in some patients. The mechanism of hypertriglyceridemia is likely related to relative insulin insufficiency. A diet low in saturated fat and calories should be instituted in patients on long-term glucocorticoids.

Chronic glucocorticoid therapy often leads to weight gain with central redistribution of fat, including the classic "buffalo hump" and "moon facies". Other potential metabolic effects include hypokalemic alkalosis associated with high-dose therapy, especially with agents that have a substantial mineralocorticoid effect, and uncommonly the development of hypocalcemia, which may rarely lead to tetany in children on high-dose therapy. Potassium supplementation may be necessary, and adequate calcium intake is mandatory.

Cardiovascular Effects

Although the majority of patients with endogenous glucocorticoid excess (Cushing syndrome) have hypertension, administration of exogenous glucocorticoids produces hypertension in only about 20% of patients, because of the lower mineralocorticoid effect of these agents. Glucocorticoid therapy-associated hypertension is more common in patients with pre-existing hypertension or decreased renal function, in the elderly, and when glucocorticoids with greater mineralocorticoid activity are used[27]. Because glucocorticoids rarely affect blood pressure during the first 2 weeks of therapy, short courses of glucocorticoids in hypertensive patients almost never produce problems. When such patients receive long-term therapy, sodium restriction is important along with the possible institution of a thiazide diuretic. Alternate-morning therapy may reduce blood pressure elevation. The pathogenesis of glucocorticoid-induced hypertension is not totally understood, but it is likely related to vasoconstriction from potentiation of catecholamines and inhibition of vasodilators; sodium retention related to mineralocorticoid activity; and intravascular volume expansion.

Accelerated atherosclerosis occasionally develops in association with long-term systemic glucocorticoid therapy, especially in patients with SLE, rheumatoid arthritis, and renal transplants. This adverse effect has also been observed in children treated with glucocorticoids, and it has long been noted in patients with Cushing syndrome from chronic endogenous glucocorticoid excess. Instances of thromboembolic complications and atrioventricular conduction problems have also been reported with glucocorticoid therapy.

Gastrointestinal Effects

The relationship between systemic glucocorticoid therapy and peptic ulcer disease (PUD) is controversial, with varying results in different published case series. There does seem to be an increased incidence of PUD in patients (such as those with rheumatoid arthritis) treated concomitantly with glucocorticoids and NSAIDs or aspirin[31]. Other additive risk factors include smoking, alcohol use, and a history of PUD. When PUD occurs in patients receiving glucocorticoids, it is more likely to be gastric than duodenal, with milder pain symptoms and a greater chance of a major complication such as hemorrhage or perforation. This is related to the tendency of glucocorticoids to mask

signs and symptoms of inflammation and to inhibit wound healing. A possible mechanism of ulceration in these situations is decreased mucus production and mucosal cell renewal. The administration of oral glucocorticoids with food, as well as the use of H2 receptor antagonists or proton pump inhibitors in higher-risk settings, decreases the likelihood of PUD in patients on glucocorticoids.

Glucocorticoid-related nausea, vomiting, and gastroesophageal reflux are also minimized by administration with food and/or taking acid-suppressing medications. Candidal esophagitis, which can occur in patients with an erosive oral mucosal disease such as pemphigus vulgaris, requires treatment with oral antifungals (e.g. fluconazole). Other gastrointestinal side effects of glucocorticoids include pancreatitis in association with hypertriglyceridemia, fatty liver changes, and (rarely) intestinal perforation.

Infection

Patients receiving systemic glucocorticoids have an increased susceptibility to many bacterial, viral, fungal, and parasitic infections. Cutaneous staphylococcal and superficial fungal infections are common. Fever and signs of inflammation may be masked in patients taking glucocorticoids, making early recognition of infection difficult. Alternate-morning therapy and doses equivalent to <10 mg/day of prednisone reduce the chance of opportunistic infection.

Reactivation of tuberculosis represents a potential concern in patients on chronic glucocorticoid therapy. In addition to assessing risk of exposure, a tuberculosis history should be taken and, if negative or uncertain, a tuberculin skin test or interferon-γ release assay performed prior to beginning therapy. A chest radiograph should be obtained for patients with a positive tuberculin reaction (≥5 mm of induration in individuals receiving the equivalent of ≥15 mg/day of prednisone for a month or more) or interferon-γ release assay, a history of tuberculosis, or other risk factors (e.g. pre-existing immunosuppression). A 9-month course of isoniazid is recommended for those with an untreated latent tuberculosis infection.

An increased risk of *Pneumocystis jirovecii* pneumonia has been observed in patients receiving glucocorticoid therapy at a dose equivalent to ≥20 mg/day of prednisone for longer than a month who also have another cause of immunocompromise. Susceptible individuals include those with systemic inflammatory disorders such as granulomatosis with polyangiitis or SLE, especially if they are receiving additional immunosuppressive agents and/or have complications such as pulmonary disease or lymphopenia[32]. These high-risk patients should receive prophylaxis, typically with trimethoprim–sulfamethoxazole (TMP-SMX; e.g. one double-strength tablet three times weekly or daily)[33]. While HIV-positive patients with $CD4^+$ counts <200/mm^3 routinely receive TMP-SMX prophylaxis, it should also be considered in HIV-positive individuals with $CD4^+$ counts >200/mm^3 who are receiving systemic glucocorticoid therapy.

Patients receiving chronic glucocorticoid therapy at supraphysiologic doses may have inadequate antibody responses to immunizations. Live-virus vaccines (see Table 128.8) should not be given to children or adults during or (if treated for ≥2 weeks) within a month after discontinuing glucocorticoid therapy at a dose equivalent to ≥20 mg/day of prednisone or ≥2 mg/kg/day in children weighing <10 kg[34].

Obstetric and Gynecologic Effects

An increased incidence of cleft palate has been noted in rodents exposed to very large doses of glucocorticoids early in gestation; therefore, the safety of glucocorticoids during the first trimester of pregnancy has been debated. However, clinical experience and several clinical trials have shown minimal effects in the offspring of women treated with glucocorticoids during pregnancy[35] (see Ch. 27). Only small amounts of prednisone reach the fetus in an active form, because a placental enzyme, 11-hydroxysteroid dehydrogenase type 2, inactivates most prednisolone crossing into the fetal circulation. This enzyme has a limited ability to metabolize fluorinated glucocorticoids (e.g. betamethasone, dexamethasone), so greater amounts of these agents reach the fetus. Pregnant patients on glucocorticoids do have a slightly increased risk of both hypertension, which might account for smaller fetal gestational size, and gestational glucose intolerance, which is relatively common with moderate to high glucocorticoid doses. When large glucocorticoid doses are used near the time of delivery, fetal HPA axis suppression occasionally occurs, resulting in a pseudo-addisonian neonate. Even though glucocorticoids are secreted into breast milk, the American Academy of Pediatrics has determined that prednisone therapy is compatible with breastfeeding; if possible, nursing should be delayed for ~4 hours after prednisone administration.

In non-pregnant women, amenorrhea may occur from systemic therapy with glucocorticoids, most frequently with intramuscular injections. To prevent unnecessary concern, premenopausal women receiving systemic glucocorticoids should be alerted to this possibility. Decreased sperm counts have also been reported in men receiving systemic glucocorticoids.

Nervous System Effects

The potentially misleading term "steroid psychosis" has been utilized for the broad spectrum of neuropsychiatric effects of systemic glucocorticoids. Glucocorticoids can impact behavior, affect, and cognition in multiple ways, with only a small portion of affected individuals experiencing delusions or other psychotic symptoms[36]. Mood changes range from euphoria, irritability, and mania to hopelessness and depression. Attention, memory, psychomotor speed, and sleep may also be affected. Depression tends to develop with longer-term glucocorticoid use, while manic symptoms are more often associated with short-term or pulsed administration[36].

Neuropsychiatric effects most frequently occur in patients receiving doses >40 mg/day of prednisone or the equivalent and arise within the first few weeks of therapy[36,37]. However, symptoms can also develop upon glucocorticoid tapering. Blood–brain barrier damage and hypoalbuminemia increase the likelihood of neuropsychiatric complications; other possible risk factors include female sex, older age, use of a longer-acting glucocorticoid, and a previous primary psychiatric condition or neuropsychiatric reaction to glucocorticoids[36].

To manage neuropsychiatric complications, the glucocorticoid should be discontinued or tapered to ≤40 mg/day prednisone or the equivalent if possible. Consultation with a psychiatrist may be necessary. Low-dose olanzapine can be helpful in the treatment of both psychotic and affective symptoms[36].

Pseudotumor cerebri is another possible complication of high-dose or long-term glucocorticoid therapy and presents with headache, nausea, vomiting, visual changes, and papilledema. It typically develops after rapid tapering or discontinuation of the glucocorticoid, so returning to a higher dose followed by more gradual tapering is recommended. Although the condition is reversible, there is potential for visual loss.

Seizures occur uncommonly, primarily affecting seizure-prone patients on high glucocorticoid doses. Other infrequent neurologic complications include electroencephalographic changes, enhancement of tremor, peripheral neuropathy, and epidural lipomatosis.

Cutaneous Effects

Patients receiving systemic glucocorticoids can develop a broad range of cutaneous effects, many of which are similar to those associated with endogenous Cushing syndrome. These include purpura, telangiectasias, atrophy, striae (Fig. 125.6), pseudoscars, acneiform or rosacea-like eruptions, and facial plethora. In one study, almost half of patients developed skin changes after 3 months of treatment with a mean prednisone dosage of 30 mg/day[38]. Localized development of telangiectasias, atrophy, and hypopigmentation can also result from chronic use of topical glucocorticoids, especially long-term daily application of potent agents or use under occlusion, and from intralesional glucocorticoid therapy (Figs. 125.7 & 125.8). Intralesional administration occasionally leads to these findings in a linear pattern along pathways of lymphatic drainage (see Fig. 66.28).

Systemic glucocorticoid-induced acne or folliculitis characteristically presents with monomorphic papulopustules on the chest and back (Fig. 125.9). Acne vulgaris itself is also frequently worsened by continuous glucocorticoid therapy, although inflammatory and cystic acne lesions may be temporarily improved by very short intermittent courses of systemic glucocorticoids, or by intralesional injections of cysts (see Ch. 36). An acneiform or rosacea-like perioral, perinasal, or periorbital eruption can also occur secondary to use of inhaled glucocorticoids or application of topical glucocorticoids (especially more potent agents) to

Fig. 125.6 Extensive striae in a patient on chronic oral prednisone therapy. *Courtesy Julie V. Schaffer, MD.*

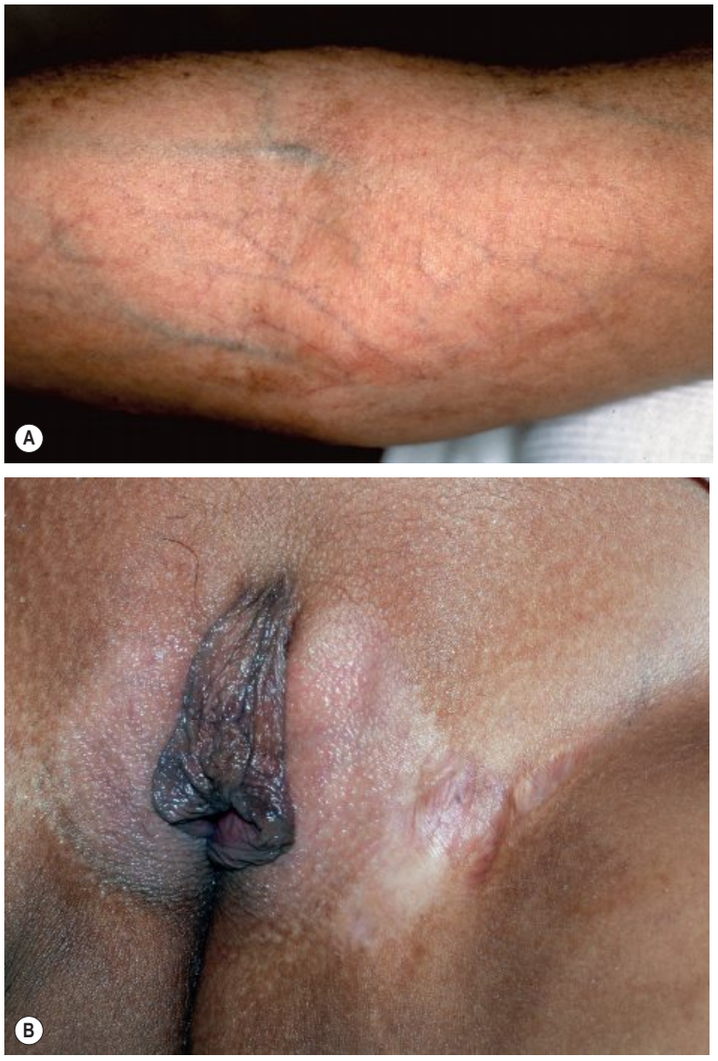

Fig. 125.7 Cutaneous atrophy due to chronic daily application of topical glucocorticoids. A Note the prominent vascular pattern on the arm. **B** This 10-year-old girl's seborrheic dermatitis had been treated with a mid-potency topical glucocorticoid on a daily basis for several years, resulting in striae and hypopigmentation. *B, Courtesy Julie V. Schaffer, MD.*

the face (Fig. 125.10). In addition, long-term continuous use of potent topical glucocorticoids on the face or in the groin can lead to erythema, edema, papulopustules, and a burning sensation upon their discontinuation, referred to as "topical steroid addiction" in social media[39].

Fig. 125.8 Local side effects of intralesional glucocorticoids. Telangiectasias, dermal and subcutaneous atrophy, and yellow–white deposits of triamcinolone acetonide (arrow). *Courtesy Jean L. Bolognia, MD.*

Fig. 125.9 Systemic glucocorticoid-induced acne. Note the monomorphic pink papulopustules in a characteristic location on the upper trunk.

Other cutaneous effects from systemic glucocorticoids include acanthosis nigricans, telogen effluvium, hirsutism, and hypertrichosis. Localized hypertrichosis can also develop in areas of topical glucocorticoid application. In addition, systemic and topical glucocorticoid therapy may impair wound healing by inhibiting fibroblast function and collagen production. This can result in decreased angiogenesis, extrafibrillar matrix ("ground substance") production, and wound re-epithelialization[4].

INTERACTIONS AND DOSE ALTERATIONS

Considerations regarding interactions between glucocorticoids and other medications as well as medical conditions that may require alteration of the glucocorticoid regimen are presented in Table 125.11.

Acknowledgment

The authors wish to acknowledge the late Lee T Nesbitt Jr, MD, for his valuable contribution to this chapter in the previous editions.

GLUCOCORTICOID (GC) THERAPY: DOSING AND SIDE-EFFECT CONSIDERATIONS RELATED TO DRUG INTERACTONS AND MEDICAL CONDITIONS	
Increased dose of GC required	Induction of cytochrome P450 metabolism* (particularly CYP3A4; see Table 131.8) • Phenytoin • Phenobarbital • Rifampin Decreased GI absorption, increased hepatic clearance, and lower prednisolone : prednisone ratio • Hyperthyroidism
Decreased dose of GC required	Inhibition of cytochrome P450 metabolism (particularly CYP3A4; see Table 131.8) • Ketoconazole > other azole antifungals • Erythromycin > clarithromycin Altered protein binding and decreased hepatic metabolism (e.g. via competitive inhibition) • Estrogens/oral contraceptives Increased free (unbound) fraction of GC • Hypoalbuminemia Renal function impaired Liver function impaired†
Specific side effect potentiated	Risk of GI side effects/peptic ulcer disease • NSAIDs Risk of infections • Other immunosuppressive agents Risk of hypokalemia • Potassium-depleting diuretics • Amphotericin B
Decreased levels/ increased dose requirements of other drugs	• Insulin, oral hypoglycemic agents (due to GC-related insulin resistance) • Isoniazid • Salicylates • Warfarin (variable; GC can also increase vascular fragility)
Increased levels/ decreased dose requirements of other drugs	• β-carotene • Cyclosporine

*Of note, dexamethasone itself may act as a CYP3A4 inducer.
†In patients with severe hepatic disease, conversion of prednisone to its active form (prednisolone) may be decreased.

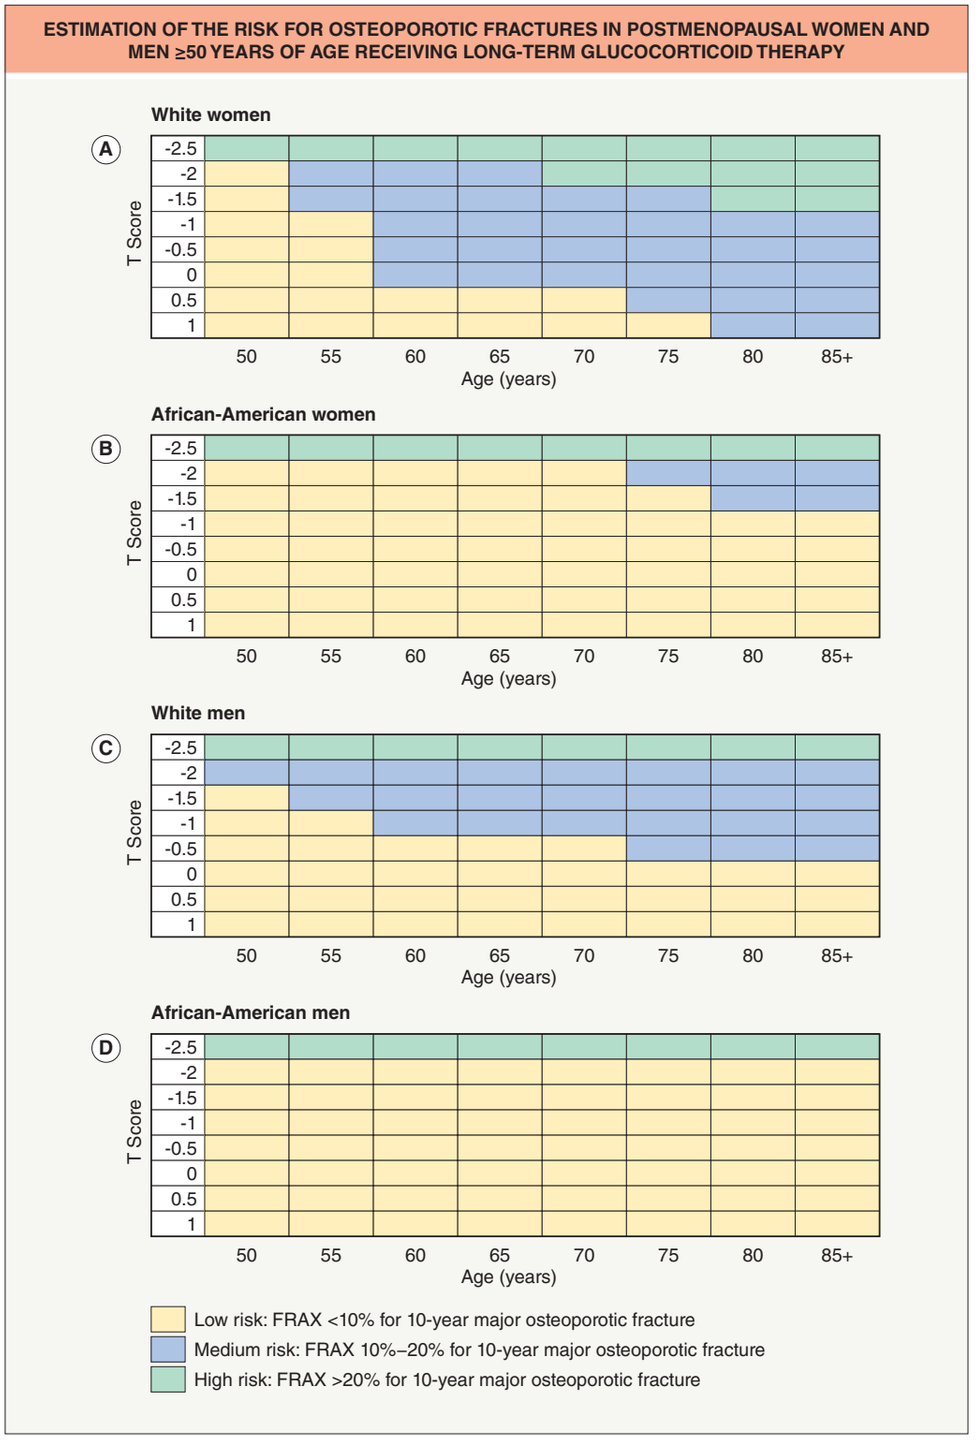

Table 125.11 Glucocorticoid (GC) therapy: dosing and side-effect considerations related to drug interactions and medical conditions. GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs.

126 Retinoids

Jean-Hilaire Saurat and Olivier Sorg

Key features

- Retinoids are structural and functional analogues of vitamin A that exert multiple effects on cellular differentiation and proliferation, the immune system, and embryonic development
- Retinoic acid receptors (RARs) and retinoid X receptors (RXRs) are ligand-dependent transcription factors belonging to the steroid–thyroid hormone nuclear receptor superfamily
- *Topical* retinoids are used to treat a number of conditions including acne, photoaging, and psoriasis; the limiting factor is dose-related skin irritation, and teratogenicity risk is very low to non-existent
- *Oral* retinoids are the most effective drugs available for severe acne (isotretinoin) and many disorders of cornification (acitretin and isotretinoin). They are also helpful in the management of psoriasis, especially pustular and erythrodermic forms (acitretin > isotretinoin), pityriasis rubra pilaris (acitretin and isotretinoin), cutaneous T cell lymphoma (bexarotene), and chronic hand eczema (alitretinoin)
- Systemic retinoid therapy requires careful patient selection and monitoring due to associated teratogenicity and other potential toxicities; laboratory abnormalities (e.g. hypertriglyceridemia, elevated transaminases); ocular, musculoskeletal, and (primarily for bexarotene) endocrinological or hematologic adverse effects

INTRODUCTION

Vitamin A (retinol) and related compounds with either structural (retinol derivative) or functional (vitamin A activity) similarities are known as retinoids (Fig. 126.1). The importance of retinoids in cutaneous biology was first appreciated early in the twentieth century by Wolbach, who observed that vitamin A-deficient animals manifested altered keratinization, such as epidermal hyperkeratosis and squamous metaplasia of mucous membranes. The anti-keratinizing properties of vitamin A led von Stuettgen and Bollag to administer topical and systemic retinoids to treat disorders of cornification. In initial clinical trials with oral vitamin A, tolerable doses were ineffective but higher, potentially effective doses were too toxic. Because of this narrow therapeutic window, a program was launched to engineer synthetic retinoids with higher therapeutic activity and lower toxicity. Parallel to efforts with systemic agents, a growing interest in topical retinoids emerged.

All-*trans*-retinoic acid (a*t*-RA; tretinoin), a naturally occurring metabolite of retinol (see Fig. 126.1), was the first retinoid to be synthesized. Orally, it did not have significant advantages over vitamin A, and, as a result, the primary dermatologic focus became its topical use, especially for acne vulgaris and photoaging.

Initially synthesized in 1955, 13-*cis*-retinoic acid (13-*cis*-RA; isotretinoin) was first studied clinically almost two decades later. Its use was delayed by concerns regarding its teratogenicity, which were amplified because of the thalidomide tragedy. Results of isotretinoin treatment of psoriasis were equivocal, and etretinate was subsequently found to be more effective. In the mid to late 1970s, Peck and colleagues described the effectiveness of oral isotretinoin in the treatment of lamellar ichthyosis and other disorders of cornification as well as its ability to produce complete responses with prolonged remissions in patients with treatment-resistant nodulocystic acne[1,2]. Topical isotretinoin has also been formulated and has efficacy similar to that of topical tretinoin for acne. In 1999, the US Food and Drug Administration (FDA) approved 9-*cis*-retinoic acid (9-*cis*-RA; alitretinoin) 0.1% gel for the topical treatment of cutaneous Kaposi sarcoma. To date, oral alitretinoin has been approved outside of the US to treat severe, recalcitrant hand eczema.

In 1972, Bollag developed two aromatic retinoids: etretinate and its free acid metabolite, acitretin. Both had a therapeutic index ten times more favorable than that of tretinoin in the chemically induced rodent papilloma test model. Etretinate and acitretin represent second-generation retinoids, and their development constituted a breakthrough in the systemic treatment of psoriasis and disorders of cornification.

A major advance in understanding the molecular pharmacologic features and mechanisms of action of retinoids came with the discovery of nuclear receptors known as retinoic acid receptors (RARs) and retinoid X receptors (RXRs). This allowed the development of new retinoids that target specific retinoid receptors. FDA-approved third- and fourth-generation retinoids include topical adapalene (acne), topical tazarotene (psoriasis and acne), topical trifarotene (acne), and oral as well as topical bexarotene (cutaneous T cell lymphoma [CTCL]). Lastly, topical precursors of retinoic acid such as retinyl esters, retinol and retinaldehyde are included in cosmeceutical products.

MECHANISM OF ACTION

Retinoids are involved in the regulation of diverse biologic functions (Table 126.1). They can: (1) affect cellular growth, differentiation and morphogenesis; (2) inhibit tumor promotion and malignant cell growth; (3) exert immunomodulatory actions; and (4) alter cellular cohesiveness[3].

Vitamin A Metabolism

Vitamin A (retinol) must be acquired through the diet as retinyl esters and provitamin A carotenoids; of the latter, β-carotene is particularly efficient in its ability to be converted to vitamin A. Within the intestinal lumen, retinyl esters are hydrolyzed to retinol, which is then absorbed and stored in the liver in the ester form (especially retinyl palmitate; Fig. 126.2). Retinol and its esters represent the main dietary source, as well as transport and storage form, of vitamin A. Once inside the bloodstream, after release of the retinyl ester (storage form) from the liver, retinol is transported bound to a complex of retinol-binding protein (RBP) and transthyretin. The uptake of retinol from the RBP–transthyretin complex to target cells is mediated by STRA6 (stimulated by retinoic acid 6), a dimeric transmembrane protein that acts as an RBP–retinol receptor[4,5] (see Fig. 126.2).

The cellular pathway leading to conversion of retinol to a*t*-RA, the biologically active ligand that binds to nuclear RARs, consists of a two-step process. Retinol (vitamin A alcohol) is first reversibly oxidized to retinaldehyde (vitamin A aldehyde), which is then irreversibly converted to retinoic acid (vitamin A acid). Cellular RBP (CRBP-I) facilitates these enzymatic reactions by delivering retinol to appropriate enzymes (see Fig. 126.2).

Two additional intracellular carriers, cellular retinoic acid-binding proteins (CRABP-I and CRABP-II), are thought to transport retinoic acid to the nucleus and buffer the level of free a*t*-RA in the cell. The latter is accomplished by sequestering a*t*-RA and by promoting metabolism of a*t*-RA by cytochrome P450 enzymes belonging to the CYP26 family (e.g. CYP26A1). CRABP-I regulates the metabolic fate of its ligands by directly affecting the activities of RA-metabolizing cytochrome P450 enzymes, while CRABP-II markedly stimulates the RA-induced transcriptional activity of RAR through protein–protein interactions[6].

Intracellularly, retinoic acid is found in both all-*trans* and 9-*cis* configurations (see Fig. 126.2). Physiologically, a*t*-RA (tretinoin) is the predominant retinoic acid form, and only a small fraction is isomerized (enzymatically or non-enzymatically) into 13-*cis*-RA (isotretinoin) or converted to polar metabolites with unknown biologic activity. a*t*-RA is the primary active ligand that binds to the three known nuclear RARs,

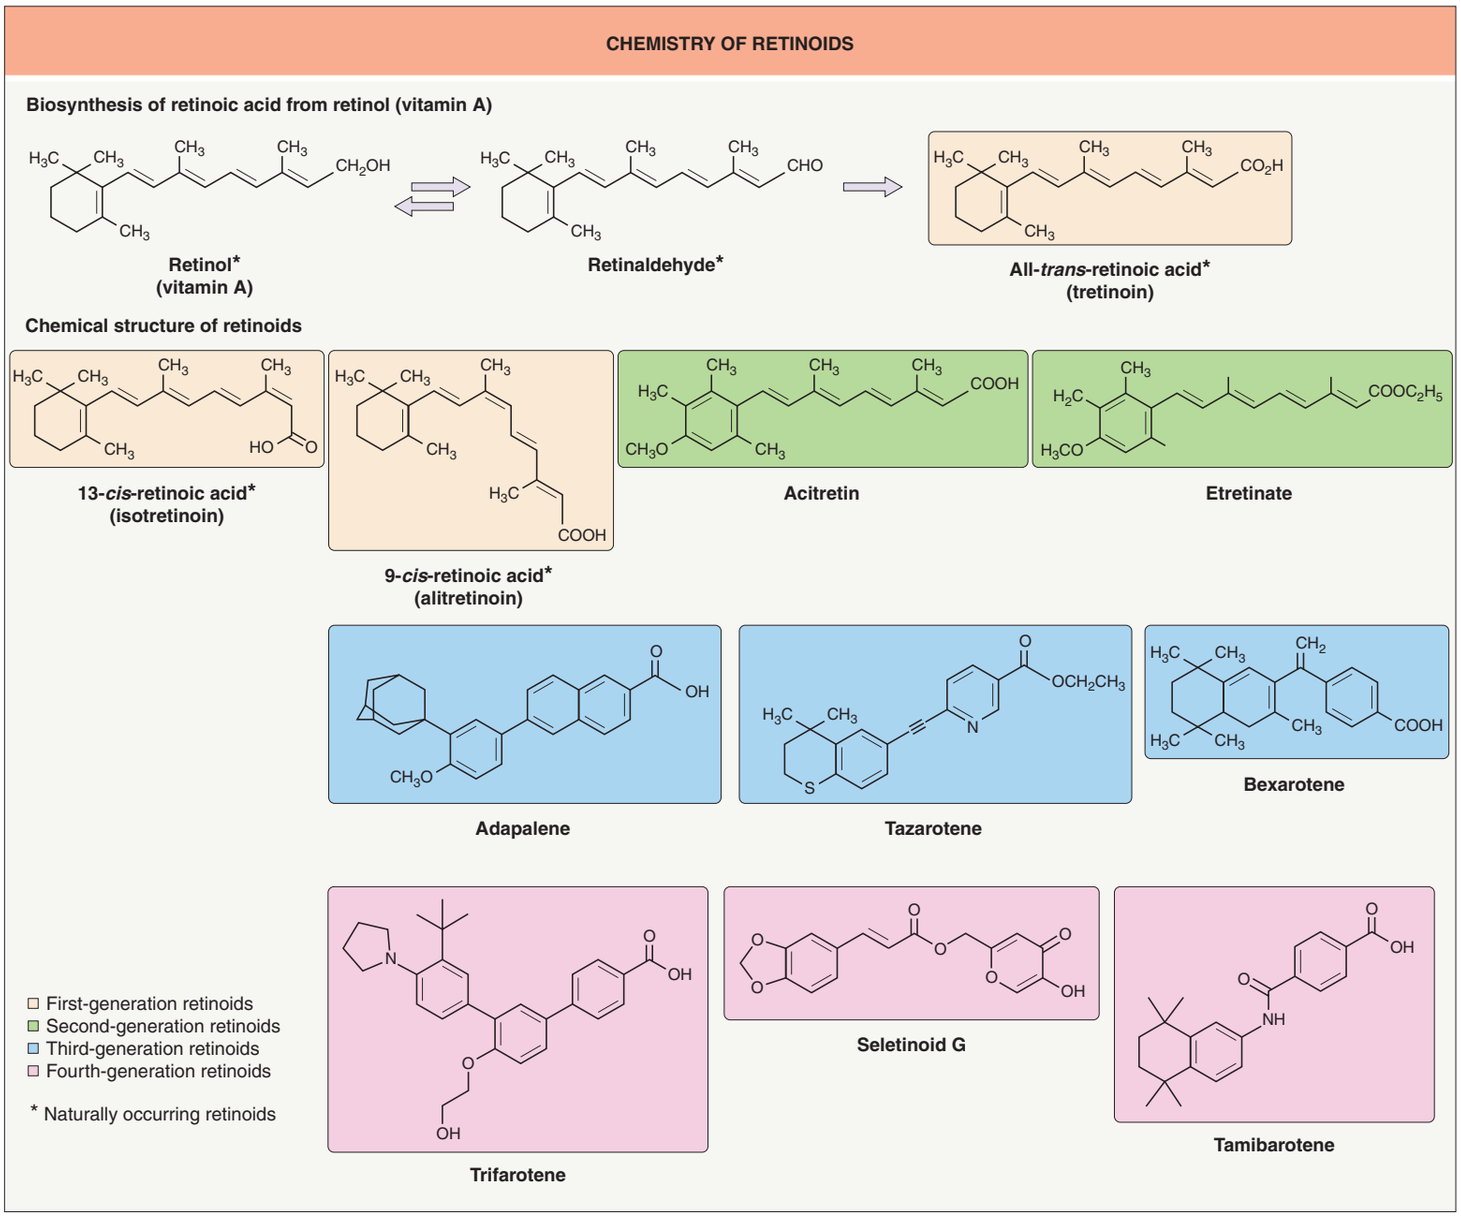

Fig. 126.1 Chemical structure of natural and synthetic retinoids. Motretinide is an additional second-generation retinoid.

BIOLOGIC FUNCTIONS OF RETINOIDS
Functions of vitamin A (retinol)*
• Embryonic growth • Morphogenesis • Differentiation and maintenance of epithelial tissues • Reproduction (retinol) • Visual function (retinaldehyde)
Biologic effects of retinoids
• Modulation of proliferation and differentiation • Anti-keratinization • Alteration of cellular cohesiveness • Anti-acne and anti-seborrheic effects • Immunologic and anti-inflammatory effects • Tumor prevention and therapy • Induction of apoptosis • Effects on extracellular matrix components
*Retinoic acid can substitute for retinol with regard to growth, morphogenesis, and epithelial differentiation; it cannot substitute completely for retinol in reproductive function, nor can it replace retinaldehyde in the visual system.

Table 126.1 Biologic functions of retinoids.

which mediate, at least in part, the molecular and cellular effects of retinoic acid. Although the biosynthesis of 9-*cis*-RA (alitretinoin) is not well-defined, it might be produced from all-*trans*-retinol via 9-*cis*-retinol and 9-*cis*-retinaldehyde.

Retinoid Receptors

Retinoids exert most of their physiologic effects on DNA transcription by binding to two distinct families of nuclear receptors, RARs and RXRs (see Fig. 126.2). These receptor families belong to a superfamily of nuclear receptors that act as ligand-activated transcription factors and include the steroid, vitamin D_3, and thyroid hormone receptors as well as peroxisome proliferator-activated receptors (PPARs). The RAR and RXR receptor families each contain three receptor isotypes (α, β and γ) encoded by different genes. *at*-RA (tretinoin) binds only to RARs, whereas 9-*cis*-RA (alitretinoin) binds both to RARs and RXRs (Table 126.2).

RARs function as heterodimers with RXRs, whereas RXRs may also act as homodimers or participate in the formation of heterodimers with a variety of other nuclear receptors, including vitamin D_3, thyroid hormone, and PPARs. Such heterodimers provide a mechanism for cross-talk between nuclear hormone signaling pathways.

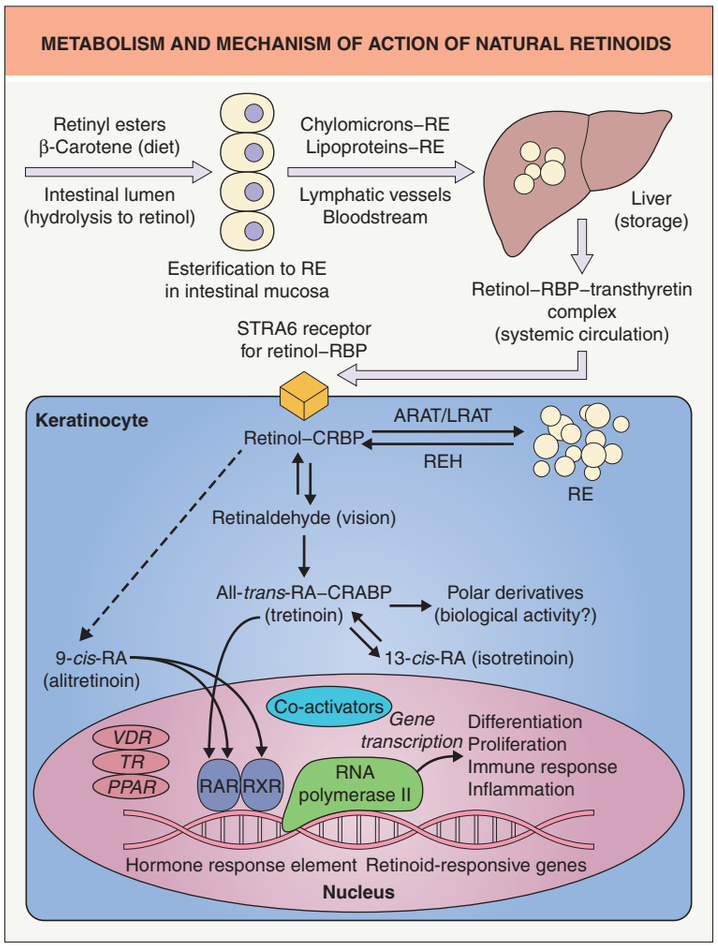

Fig. 126.2 Metabolism and mechanism of action of natural retinoids. ARAT, acyl-CoA:retinol acyl transferase; CRABP, cellular retinoic acid-binding protein; CRBP, cellular retinol-binding protein; LRAT, lecithin:retinol acyl transferase; PPAR, peroxisome proliferator-activated receptor; RA, retinoic acid; RAR, retinoic acid receptor; RBP, retinol-binding protein; RE, retinyl esters; REH, retinyl ester hydrolase; RXR, retinoid X receptor; STRA6, stimulated by retinoic acid 6; TR, thyroid receptor; VDR, vitamin D_3 receptor.

Dimers of retinoid receptors (RAR/RXR or RXR/RXR) are localized to the nucleus and bind, even in the unliganded state, to specific DNA regulatory sequences called retinoid hormone response elements (RAREs) in the promoter regions of retinoid-responsive genes (see Fig. 126.2). Unliganded receptors bind to co-repressor molecules and repress transcription. However, when the receptor binds its ligand, it undergoes a conformational change resulting in the release of co-repressors and recruitment of co-activators. These molecules include histone acetylases that change the conformation of chromatin and allow access to DNA by transcriptional machinery. The retinoid–receptor complex thereby modulates the transcription of specific sets of genes, and it is likely that many of the differentiation-inducing actions of retinoids are mediated by this mechanism.

In addition to *direct upregulation* of gene transcription via binding of retinoid–receptor complexes to RAREs, retinoids can have *indirect* effects on gene transcription that result from the *downregulation* of genes that do not contain RAREs in their promoter region. The retinoid–receptor complex is thought to antagonize transcription factors such as activator protein-1 (AP1) and nuclear factor-interleukin-6 (NF-IL6) by competing for the same set of required co-activator proteins, thereby leading to decreased expression of AP1 and NF-IL6-responsive genes; expression of the latter genes promotes cellular proliferation and inflammation. The antiproliferative and anti-inflammatory actions of retinoids are believed to be mediated by this type of indirect negative gene regulation. In particular, retinoic acid has important roles in inhibiting IL-6-driven induction of proinflammatory Th17 cells and in promoting differentiation of anti-inflammatory regulatory T cells (see Ch. 4). The anti-inflammatory effects of *at*-RA (tretinoin) have also been associated with its ability to regulate the expression and activation of Toll-like receptors (TLRs), especially TLR2. The biologic relevance of non-genomic effects of retinoids (e.g. cross-talk with extracellular protein/peptide signals acting via membrane receptors with downstream phosphorylation) remains under investigation.

The existence of several types and varied distributions of receptors, dimers, hormone response elements, and regulatory proteins shows that retinoid action is mediated via multiple pathways and results in a complex process of activation or inhibition of a large set of coordinately regulated genes. However, the exact mechanism of retinoid action in many dermatologic conditions is still unknown, and, so far, the nuclear receptor concept does not fully explain the biologic diversity of retinoid effects.

Retinoids in the Skin

Vitamin A and its bioactive metabolites play a major role in promoting the keratinocyte differentiation that occurs from the epidermal basal layer to the stratum corneum[7]. Retinyl esters and retinol are the major retinoids found in the skin, with the former reaching a concentration of >1000 pmol/g in the epidermis. Epidermal retinoids can absorb UVB radiation and have ~2%–3% of the UVB-filtering capacity of the melanin in phototype II/III skin[7,8]. The UVB absorption process results in dramatic depletion of epidermal retinoids[9], which can be prevented by application of topical retinoids[10]. Nutritional deficiency, aging, and oxidative stress can also lead to lowered retinoid levels in the skin[7]. There has been ongoing debate regarding possible generation of reactive oxygen species upon the interaction of UVA radiation with retinyl esters (e.g. retinyl palmitate) present in cosmetics and sunscreens, but the theoretical potential for photocarcinogenicity has not been shown to be clinically relevant.

Synthetic Retinoids

There are now four generations of retinoids (see Fig. 126.1). The *first-generation* non-aromatic retinoids (tretinoin, isotretinoin, alitretinoin) are synthesized by chemically modifying the polar end group and the polyene side chain of vitamin A. *Second-generation* mono-aromatic retinoids (etretinate, acitretin, motretinide) are formed by replacing the cyclic moiety of vitamin A with different substituted and unsubstituted ring systems. *Third-generation* polyaromatic retinoids (adapalene, bexarotene, tazarotene), called arotinoids, are produced by cyclization of the polyene side chain. *Fourth-generation* polyaromatic retinoids (trifarotene, seletinoid G, tamibarotene) were designed to have increased selectivity of binding.

Commercially available retinoids differ not only in their spectrum of clinical efficacy but also in their observed toxicity and pharmacokinetics. Each retinoid should be investigated as a unique drug, and the lack of disease response to one retinoid does not necessarily signify unresponsiveness to other retinoids.

The oral bioavailability of retinoids is considerably enhanced when administrated with food, especially with a fatty meal, due to their lipophilic properties. More recently, a lidose–isotretinoin formulation with enhanced absorption when taken without food was developed. Retinoid metabolism is predominantly hepatic; it involves oxidation and chain shortening to biologically inactive and polar metabolites, facilitating biliary and/or renal elimination. The oxidative metabolism is induced by the retinoids themselves and possibly also by other agents known to stimulate hepatic cytochrome P450 isoforms. Table 126.2 summarizes the key pharmacologic features and nuclear binding profiles of retinoids used in dermatology.

First-generation retinoids

Tretinoin (all-*trans*-retinoic acid)

Tretinoin, the predominant physiologic form of retinoic acid, was the first topical retinoid to be utilized for the treatment of acne and photoaging. It binds to cellular retinoic acid-binding proteins (CRABPs) and non-selectively to nuclear RARs (see above), resulting in modulation of keratinocyte proliferation and differentiation, inflammation, and extracellular matrix production. Because the standard tretinoin formulation is photolabile, night-time application is recommended to prevent degradation.

KEY PHARMACOLOGIC FEATURES AND NUCLEAR BINDING PROFILES OF RETINOIDS											
Retinoid	**Type**	**Systemic absorption or bioavailability* (% dose)**	**Elimination half-life**	**Metabolism**	**Excretion**	**Nuclear receptor binding affinity**					
						RAR			RXR		
						α	β	γ	α	β	γ
Topical retinoids*											
Tretinoin† (all-*trans*-retinoic acid)	Natural (1st generation)	<2% in normal skin	Normally present in the skin	Isomerization to 13-*cis*-RA (epidermis)	Desquamation, biliary	+	+	+	–	–	–
Alitretinoin (9-*cis*-retinoic acid)	Natural (1st generation)	Minimal	Normally present in the skin	Main metabolite: 4-oxo-9-*cis*-RA	Desquamation, biliary	+	+	+	+	+	+
Adapalene	3rd generation	Minimal	Unknown	Minimal biotransformation due to chemical rigidity	Desquamation, biliary	±	+	+	–	–	–
Tazarotene	3rd generation	<1%–6% in normal skin	16 hours (tazarotenic acid)	Rapid (within 20 minutes) ester hydrolysis within the skin to form its active metabolite, tazarotenic acid; excreted metabolites: sulfoxides, sulfones	Desquamation, renal (within 3 days), biliary (within 7 days)	±	+	+	–	–	–
Trifarotene	4th generation	≤10 pmol/L	2–9 hours	Hepatic	Biliary	–	–	+	–	–	–
Systemic retinoids											
Tretinoin†	Natural (1st generation)	50%	1 hour	Hepatic; main metabolites: *cis*- and *trans*-4-oxo derivatives	Biliary, renal	+	+	+	–	–	–
Isotretinoin (13-*cis*-RA)	Natural (1st generation)	25%	20 hours	Hepatic, endogenous concentration reached within 2 weeks; main metabolite: 4-oxo-isotretinoin	Biliary, renal	–	–	–	–	–	–
Alitretinoin	Natural (1st generation)	Unknown	2–10 hours	Hepatic; main metabolite: 4-oxo-alitretinoin	Renal, biliary	+	+	+	+	+	+
Acitretin (and etretinate)	2nd generation	60%	2 days	Hepatic, re-esterification to etretinate indirectly increased by alcohol consumption; main metabolite: *cis*-acitretin	Biliary, renal	+‡	+‡	+‡	–	–	–
Bexarotene¶	3rd generation	Unknown	7–9 hours	Hepatic	Biliary	–	–	–	+	+	+
Tamibarotene	4th generation	NA	2–3 hours	Hepatic	NA	+	+	–	±	±	±

*Topical formulations have limited propensity for distribution to systemic tissues; oral bioavailability is highly variable and increases when administered with food.
†Also binds the cellular retinoic acid-binding protein (CRABP).
‡Activate RARs despite binding poorly to them.
¶Also available in a topical form.

Table 126.2 Key pharmacologic features and nuclear binding profile of retinoids. NA, not available; RA, retinoic acid; RAR, retinoic acid receptor; RXR, retinoid X receptor.

Isotretinoin (13-*cis*-retinoic acid)

Isotretinoin is a naturally occurring retinoid resulting from the metabolism of vitamin A (see Fig. 126.2)[11]. 13-*cis*-RA and a*t*-RA are two physiologically interconvertible isomers that differ in their elimination half-lives: approximately 20 hours and 1 hour, respectively. Isotretinoin undergoes first-pass metabolism in the liver and subsequent enterohepatic recycling. In plasma, more than 99% of isotretinoin is protein-bound, mainly to albumin. There is neither liver nor adipose tissue storage, in contrast to vitamin A. The major metabolite of isotretinoin, 4-oxo-isotretinoin, is produced by oxidation. Isotretinoin and its metabolites are excreted in the urine and feces. After discontinuation of isotretinoin, *physiologic* concentrations of the drug and its major metabolites are reached within 2 weeks, ranging from 2 days for a*t*-RA to 10 days for 4-oxo-isotretinoin. Therefore, 1 month of post-therapy contraception provides an adequate safety margin to avoid teratogenicity.

Among natural and synthetic retinoids, only oral isotretinoin and its 4-oxo-isotretinoin metabolite significantly suppress sebum production, which explains their dramatic effects on acne. Isotretinoin-induced seboatrophy is unlikely to be RAR/RXR-mediated since isotretinoin has no clear affinity for any known retinoid receptor[12], and potent RAR/RXR ligands such as tretinoin and alitretinoin do not lead to seboatrophy. The mechanism of isotretinoin-induced seboatrophy is thought to involve sebocyte apoptosis[13], but inhibition of either sebocyte progenitor differentiation or the genes encoding sebogenic enzymes represent two other possible pathomechanisms.

Alitretinoin (9-*cis*-retinoic acid)

Alitretinoin is a naturally occurring pan-agonist retinoid that binds to both RARs and RXRs[14], representing the endogenous ligand for the latter. Topical alitretinoin 0.1% gel is FDA-approved for the treatment of cutaneous Kaposi sarcoma, and oral alitretinoin therapy is currently utilized outside the US for refractory chronic hand eczema. The absorption of oral alitretinoin from the gastrointestinal tract is variable and dose-proportional over the therapeutic range of 10–30 mg daily; the absolute bioavailability of alitretinoin has not been determined. Alitretinoin is metabolized via oxidation by CYP3A4 enzymes of the liver into 4-oxo-alitretinoin, and both the parent drug and its metabolite also undergo isomerization into a*t*-RA and 4-oxo-a*t*-RA, respectively. Elimination is primarily renal, with the half-life of unchanged alitretinoin ranging between 2 and 10 hours. Alitretinoin concentrations return to normal within 1–3 days after treatment cessation.

The mechanism of action of alitretinoin in chronic hand eczema is unknown, although downregulated expression of RARs and RXRs in lesional skin was recently described[15]. Alitretinoin has immunomodulatory and anti-inflammatory effects that include suppressing the expansion of cytokine-activated leukocyte subsets and antigen-presenting cells.

Second-generation retinoids

Acitretin

Acitretin is the major metabolite and the pharmacologically active form of etretinate[16]. Although acitretin and etretinate are equally effective, acitretin has much more rapid elimination. Etretinate is approximately 50 times more lipophilic than acitretin and binds strongly to plasma proteins, particularly lipoproteins and albumin. Etretinate is stored in adipose tissue (including subcutaneous fat), from which it is released slowly, with a long terminal half-life of up to 120 days. Under identical conditions, acitretin carries a negatively charged group that makes it much less lipophilic than etretinate. As a result, acitretin does not accumulate in adipose tissue and is eliminated from the body more rapidly, with a half-life of 2 days.

The major serious adverse effect of oral retinoids is teratogenicity, and, therefore, the length of time that these drugs are present in the body is of great importance. Re-esterification of acitretin to etretinate may occur when acitretin is taken simultaneously with alcohol[17,18]. This finding prompted the manufacturer to extend the time of contraception for female patients with childbearing potential taking acitretin to 2 years after its discontinuation, as it is for etretinate. The FDA advises a contraceptive period of at least 3 years for acitretin, based on the pharmacokinetics of acitretin and etretinate observed in clinical trials and on previous safety experience with etretinate. However, acitretin retains its shorter half-life in women who strictly avoid alcohol during treatment and for 2 months thereafter.[16] Because of its improved risk–benefit ratio, acitretin was approved by the FDA in 1996 as a substitute for etretinate, which is no longer commercially available[16].

Acitretin's mechanism of action is still not clearly understood. Paradoxically, it activates all three RAR subtypes despite binding poorly to them. Evidence supports a normalization of differentiation and proliferation as well as a modification of inflammatory responses and neutrophil function.

Third-generation retinoids

Adapalene

Adapalene is a photostable, rigid, and highly lipophilic synthetic retinoid with higher affinity for RAR-β/γ than for RAR-α. Since RAR-β is not expressed in keratinocytes, RAR-γ is the primary target receptor for adapalene in the epidermis. Adapalene does not bind to cellular retinoic acid-binding proteins (CRABPs) but does induce expression of CRABP-II. Its lipophilic properties may contribute to better pilosebaceous uptake and anti-acne activity. Given its negligible transdermal absorption, the teratogenic risks of topical adapalene appear to be minimal. Adapalene affects the cellular differentiation, keratinization, and inflammatory processes that are abnormal in acne. Although adapalene has not been shown to be sebostatic *in vivo* in humans, it was found to inhibit triacylglycerol biosynthesis and lipid droplet accumulation *in vitro* in hamster sebocytes[19].

Tazarotene

Tazarotene is a prodrug that is rapidly converted by cutaneous esterases to its free carboxylic acid (tazarotenic acid), which is the active metabolite. It has a higher affinity for RAR-β/γ than RAR-α and no affinity for RXR[20]. Because of its rapid metabolism, systemic exposure is low. Tazarotene appears to modulate the pathogenesis of psoriasis by regulating expression of retinoid responsive genes, including those involved in cell proliferation, cell differentiation, and inflammation[21].

Bexarotene

Bexarotene, an RXR-selective retinoid (rexinoid), is FDA-approved in oral (1999) and topical (2000) forms for treatment of CTCL. This compound is about 100-fold more potent at binding to RXRs than to RARs. In plasma, bexarotene is highly bound (>99%) to various proteins that have yet to be characterized. Bexarotene has a clearance profile similar to that of isotretinoin, with a terminal half-life of between 7 and 9 hours[22]. Bexarotene is metabolized by CYP3A4 and generates its own oxidative metabolites via hepatic CYP3A4 induction. Neither bexarotene nor its metabolites are excreted in the urine; their elimination is thought to occur primarily via the hepatobiliary system[22]. The exact mechanism of action of bexarotene in CTCL is still unknown, but it probably acts through regulation of cellular differentiation and proliferation, as well as via induction of apoptosis[23].

Fourth-generation retinoids

Trifarotene

Trifarotene, a fourth-generation retinoid with 20-fold higher affinity for RAR-γ than RAR-α/β, was FDA-approved in 2019 as a topical acne treatment for individuals ≥9 years of age[24]. This agent was designed to be stable in keratinocytes but rapidly metabolized in hepatic microsomes, thereby minimizing systemic drug levels. In addition to effects on known retinoid-mediated pathways, gene expression profiling has shown that trifarotene modulates proteolysis, reduces intercellular adhesion, and activates transporters involved in skin hydration[25].

Retinoic acid metabolism blocking agents

*R*etinoic *a*cid *m*etabolism *b*locking *a*gents (RAMBAs) inhibit catabolism of *a*t-RA by P450 enzymes in the CYP26 family, thereby raising the intracellular levels of endogenous *a*t-RA in the skin and other targeted tissues[26]. This limits systemic exposure and the potential for toxicity, and *a*t-RA levels return to the physiologic range within 24 hours of discontinuing these medications. Liarozole, an imidazole derivative without antifungal properties, is a RAMBA with low isoenzyme specificity that also inhibits P450-mediated pathways of steroid biosynthesis whereas talarozole, a triazole derivative, is a more selective and highly active CYP26 enzyme inhibitor. DX314, a CYP26B1-selective RAMBA that may protect epidermal barrier integrity, is also under investigation[27]. Liarozole has been granted orphan drug status for congenital ichthyosis by the European Commission and the FDA. In a randomized, placebo-controlled phase II/III trial in 64 patients with moderate-to-severe lamellar ichthyosis, a 41%–50% response rate was observed in patients receiving liarozole, compared to 11% with placebo, with borderline statistical significance ($p=0.056$)[26].

INDICATIONS (TABLE 126.3)

Topical Retinoids

The most important element in topical retinoid therapy is patient education. Local skin irritation can be expected, and noticeable beneficial effects often take weeks or months to appear. Administration of topical retinoids should be titrated depending on cutaneous irritation, which may mean decreasing the concentration or the frequency of application. It is generally wise to begin with a low-strength formulation and then increase the concentration as tolerance builds. Another tactic is to start by applying a given concentration every other day. Daytime moisturizers with sunscreen are important components of any topical retinoid regimen.

Acne

Topical retinoids, of which tretinoin is the prototype, are mainstays in the treatment of comedonal and inflammatory acne vulgaris[28]. The primary mode of action in acne is thought to be the normalization of differentiation and proliferation of the follicular epithelium (see Ch. 36), which leads to the loosening and unseating of microcomedones, thereby preventing obstruction of the pilosebaceous unit. In addition, topical retinoids may have anti-inflammatory activity. The mechanism of action of topical isotretinoin (not available in the US) is similar to that of topical tretinoin because of intraepithelial isomerization of isotretinoin to tretinoin (see Fig. 126.2). In contrast to oral isotretinoin, topical isotretinoin fails to suppress sebum production; it is less irritating and probably also somewhat less effective than tretinoin. The topical synthetic retinoids adapalene, tazarotene, and trifarotene have comparable or (for adapalene) improved tolerability while maintaining efficacy similar to that of topical tretinoin[29,30].

Topical retinoids should be applied to the entire face or all acne-prone areas once a day as tolerated, with tretinoin applied in the evening to prevent inactivation by UV light. Application of these medications to dry skin may reduce skin irritation by minimizing dermal absorption. Patients should be advised that beneficial effects do not typically become evident for 6–8 weeks or longer. An apparent exacerbation may occur during the first month of therapy, representing the externalization of deeper-seated acne lesions as the follicular epithelium is loosening. With the exception of mild, primarily comedonal acne, topical retinoids are typically used concomitantly with benzoyl peroxide products and antibiotics (oral or topical) that target *Cutibacterium acnes* and inflammatory processes that contribute to acne (see Ch. 36).

CLINICAL INDICATIONS FOR RETINOIDS IN DERMATOLOGY		
Topical retinoids		
FDA-approved indications	Acne vulgaris (tretinoin, adapalene, tazarotene, trifarotene) Photoaging, e.g. fine facial wrinkling, mottled pigmentation, facial roughness (tretinoin, tazarotene) Psoriasis, <20% of body surface area (tazarotene*) Cutaneous T cell lymphoma (bexarotene) Kaposi sarcoma (alitretinoin)	
Selected non-FDA-approved indications	Some disorders of cornification (ichthyoses) Darier disease Pityriasis rubra pilaris Rosacea Pigmentary disorders, e.g. melasma, postinflammatory hyperpigmentation Lentigines Actinic keratoses Striae Wound healing Lichen planus (oral and cutaneous) Verrucae planae (flat warts) Corticosteroid-induced atrophy Therapy and prevention of skin cancer (basal cell carcinoma; xeroderma pigmentosum)	
Systemic retinoids		
FDA-approved indications	Psoriasis (acitretin)	Pustular psoriasis (localized and von Zumbusch) Erythrodermic psoriasis Severe and recalcitrant plaque-type psoriasis*
	Acne (isotretinoin)	Nodulocystic acne Recalcitrant acne with tendency for scarring
	Cutaneous T cell lymphoma (bexarotene)	Resistant to at least one systemic therapy
Selected non-FDA-approved indications	Rosacea and acne-related disorders	Hidradenitis suppurativa Eosinophilic pustular folliculitis (Ofuji disease) AIDS-associated eosinophilic folliculitis Pyoderma faciale (rosacea fulminans) Acne with solid facial edema Dissecting cellulitis of the scalp
	Disorders of cornification and related conditions	Ichthyoses, various forms (see Ch. 57) Darier disease Keratoderma Papillon–Lefèvre syndrome
	Inflammatory disorders	Chronic hand eczema (alitretinoin, acitretin) Pityriasis rubra pilaris Lupus erythematosus Lichen planus

*Combination therapy, e.g. with a topical corticosteroid or photo(chemo)therapy, is often required.

Table 126.3 Clinical indications for retinoids in dermatology. Of note, the oral form of tretinoin (all-*trans*-retinoic acid; *at*-RA) is FDA-approved for the treatment of acute promyelocytic leukemia (APL). Tamibarotene, a fourth-generation retinoid, is currently approved in Japan for the treatment of APL.

Psoriasis

Topical application of tretinoin or isotretinoin has limited efficacy in psoriasis. Although topical tazarotene was shown to be effective in treating mild to moderate plaque-type psoriasis affecting ≤20% of the body surface area, irritation limits its use as monotherapy. A combination of tazarotene and a mid- to high-potency topical corticosteroid can improve efficacy and reduce the likelihood of both irritation and corticosteroid-induced atrophy.

Photoaging

Several controlled studies have demonstrated that topical retinoids, including tretinoin and tazarotene creams, can improve fine wrinkling and lighten uneven pigmentation[31]. It generally takes 3–6 months of daily application to see significant clinical improvement. Cutaneous irritation is usually the limiting factor. Retinaldehyde was found to be as effective as tretinoin in treating photodamage in less extensive trials[32], and it had a better tolerance profile that may reflect more controlled delivery of retinoic acid to target cells. Seletinoid G, a fourth-generation polyaromatic retinoid with RAR-γ selectivity designed to produce less skin irritation, is under investigation as a treatment for photoaging.[33]

Photoaging is the consequence of UVR-induced damage to the skin, which is characterized by decreased vitamin A content[7] as well as lower expression of RXR-α and RAR-γ (the major retinoid receptors in keratinocytes)[34] in the acute setting and then later by upregulation of AP1-driven matrix metalloproteinases (MMPs). Topical retinoids promote cellular differentiation and extracellular matrix synthesis, including an increase in hyaluronic acid via a CD44-mediated mechanism in addition to decreased MMP production[35]. Histologic findings after repeated topical application of tretinoin include compaction of the stratum corneum, epidermal hyperplasia (acanthosis), correction of atypia (e.g. actinic keratoses), dispersion of melanin granules, increased dermal collagen synthesis, and angiogenesis. These findings explain reported observations of smoother skin, a rosy glow, decreased blotchy pigmentation, and diminished fine lines and wrinkles following topical retinoid treatment[36].

Other indications

Other FDA-approved indications for topical retinoids include alitretinoin 0.1% gel for cutaneous Kaposi sarcoma and bexarotene 1% gel for CTCL[37]. There are also numerous "off-label" uses for topical retinoids (see Table 126.3).

Systemic Retinoids

Psoriasis

Several randomized, controlled, multicenter trials have been performed to ascertain the efficacy of acitretin in plaque-type and pustular psoriasis, with similar results to prior studies of etretinate[38]. Guidelines for use of acitretin in psoriasis are summarized in Tables 8.13 and 8.14. The best results have been obtained in acral or generalized (von Zumbusch) pustular psoriasis, in which acitretin is considered to be a first-line therapy. The various forms of pustular psoriasis, as well as erythrodermic psoriasis, tend to clear relatively rapidly with acitretin monotherapy. Rebound does not usually occur after stopping treatment, and reintroduction produces a beneficial response.

Plaque-type psoriasis responds variably to acitretin. Although complete clearance of plaques is achieved in only about 30% of treated patients, substantial improvement is obtained in an additional 50%. The mean decrease in the Psoriasis Area and Severity Index (PASI) score is ~60%–70%, depending on the dosage and duration of treatment. Many of the plaques may remain, but they are thinner with less scale and erythema.

An initial worsening with increased erythema and/or extent of involvement of plaque-type psoriasis may occur within a few days of starting acitretin therapy at a dosage of 0.5–1 mg/kg per day (~25–70 mg/day in adults). Utilization of a lower dose (10 mg/day) initially, followed by a progressive increase, helps to avoid this complication.

Total clearance of psoriatic plaques usually requires that oral retinoids be combined with other treatments such as topical corticosteroids, topical vitamin D derivatives, anthralin (dithranol), or photo(chemo) therapy (narrowband UVB or psoralen plus UVA [PUVA])[39,40]. The "Re-PUVA" combination, in which retinoids are given for 14 days before starting PUVA, can produce an accelerated response rate and resolution of lesions that would not clear with a retinoid or PUVA alone (Fig. 126.3). The cumulative UVA exposure required to produce a remission is also significantly lower with Re-PUVA, reducing the risk of UVA-induced carcinogenesis. Oral retinoids can also be combined with bath PUVA. Lastly, the combination of acitretin with UVB phototherapy has been shown to be more effective than retinoid or UVB phototherapy alone in patients with psoriasis[41,42].

Isotretinoin is less effective than acitretin for psoriasis, although some efficacy has been shown in combination with PUVA[43]. Isotretinoin is still occasionally used in women of childbearing age with psoriasis who need a systemic retinoid to avoid the long post-acitretin contraception period.

Acne

The introduction of oral isotretinoin was a key advance in acne therapy and it still remains the most effective medication. With the possible exception of hormonal acne, isotretinoin has been shown to induce long-term remissions and even "cure" acne. It is the only medication that affects, albeit not to the same degree or permanently, all the major etiologic factors implicated in acne: sebum production, comedogenesis, and colonization with *C. acnes* (Fig. 126.4; see Ch. 36). Among natural and synthetic retinoids studied in humans, only isotretinoin has been found to suppress sebum production (see above).

In the early 1980s, oral isotretinoin use was restricted to patients suffering from severe nodulocystic acne. With increasing experience, however, its use has been extended to patients with less severe disease who have responded unsatisfactorily to conventional therapies such as topical retinoids plus oral antibiotics. Patients with moderate acne that shows signs of scarring also represent candidates for oral isotretinoin therapy.

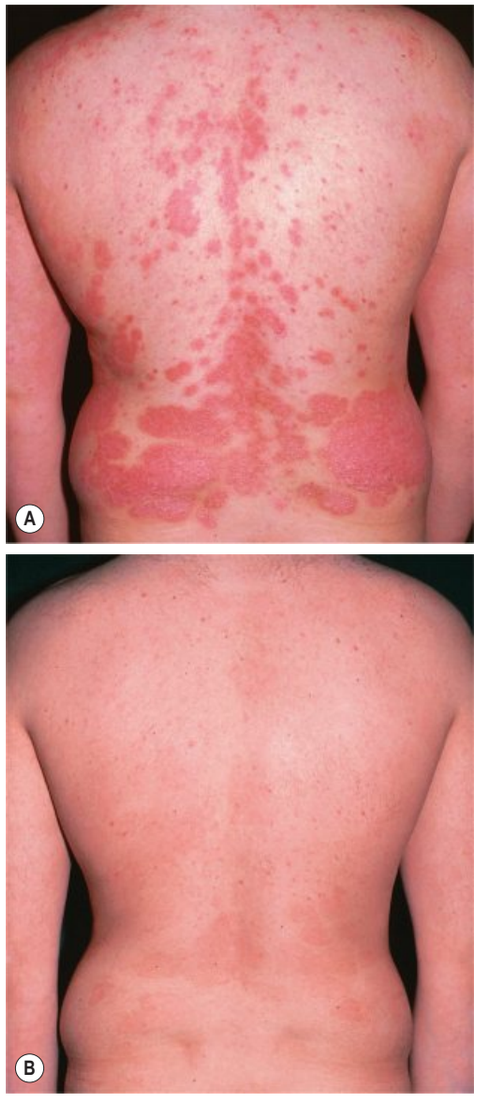

Fig. 126.3 Chronic plaque-type psoriasis. Before (**A**) and after (**B**) treatment with a combination of acitretin and PUVA.

Fig. 126.4 Severe acne vulgaris. Before (**A**) and after (**B**) treatment with oral isotretinoin. *Courtesy Ángela Hernández-Martín, MD.*

Acne morbidity extends beyond the aesthetics of physical appearance. Psychosocial consequences of acne range from depression and anxiety to interpersonal and work-related difficulties. Quality-of-life studies have shown that isotretinoin treatment significantly improves sociability and self-esteem.

It was initially considered that optimal benefit would be achieved with an isotretinoin dose of 1 mg/kg per day. However, this can induce undesirable dose-dependent effects, and similar short-term therapeutic results have been obtained with doses below 0.5 mg/kg per day. In order to avoid the higher incidence of relapses associated with lower-dose isotretinoin, treatment can be continued for a longer period of time in order to reach a critical cumulative dose threshold. The cumulative dose was first recognized to be important in isotretinoin therapy for acne by Harms et al. in 1989[44]; it refers to the total amount of oral isotretinoin taken by the patient over the entire course, divided by the body weight (mg/kg body weight). For example, a patient weighing 50 kg and receiving 25 mg/day of isotretinoin for 100 days would have received a cumulative dose of 50 mg/kg (25 mg × 100 = 2500 mg, divided by 50 kg = 50 mg/kg). Data from several studies indicated that post-therapy relapse is minimized by a treatment course amounting to a total of at least 120 mg/kg, with minimal further therapeutic gain beyond about 150 mg/kg[45]. However, a 6-month course of low-dose isotretinoin (20 mg/day; mean cumulative dose = 70 mg/kg) was also found to be effective in the treatment of moderate acne, with a low incidence of severe side effects and a reduced cost compared with higher doses[46].

A lag period of 1–3 months may occur before the onset of the therapeutic effect. Approximately one-third of patients with acne require a second course of isotretinoin therapy, either for persistent disease or for relapse. A major predictive factor for resistance to isotretinoin treatment is closed comedonal and microcystic acne. Hyperandrogenemia due to ovarian or adrenal dysfunction should be excluded in women with a history of acne that is either refractory to isotretinoin or has relapsed following appropriate courses of isotretinoin.

A flare of disease during the first few weeks of treatment, sometimes with an acne fulminans-like presentation and subsequent evolution of acne cysts into lesions resembling pyogenic granulomas, is occasionally observed with isotretinoin treatment (see Fig. 36.17). The incidence of this side effect may be reduced by using lower doses of isotretinoin during the first 3–4 weeks of therapy[47]. Because oral isotretinoin is a potent teratogen, prevention of pregnancy in female patients with childbearing potential is critical, with a need for continuous effective contraception from 1 month prior to initiating therapy until 1 month after the last dose (see below)[47].

Isotretinoin has a more limited effect on hidradenitis suppurativa and dissecting cellulitis of the scalp, which can occur together with acne conglobata as components of the follicular occlusion tetrad[48]. Some clinicians recommend oral isotretinoin during the weeks or months preceding surgery for hidradenitis suppurativa, and sometimes also during the postoperative period, while others avoid isotretinoin perioperatively because of reports of enhanced scarring (see below).

Cutaneous T cell lymphoma

Isotretinoin and acitretin are somewhat effective and are considered to be of equal potency in the treatment of mycosis fungoides (MF). Retinoids can be used in combination with PUVA, interferon, or systemic chemotherapy (see Ch. 120). Despite initial improvement of the various stages of MF, it is often impossible to maintain remissions with these retinoids as monotherapy.

Both oral and topical bexarotene can produce clinical responses in CTCL. Two multicenter clinical trials of oral bexarotene were conducted in patients with stage I–IIA (early) disease (n = 58) or stage IIB–IVB (advanced) disease (n = 94)[23]. Patients in the early-stage study randomly assigned to a low-dose arm of 6.5 mg/m^2 per day had a 20% response rate, in contrast to 54% and 67% for patients receiving starting doses of 300 mg/m^2 per day and 650 mg/m^2 per day (then decreased to 500 mg/m^2 per day), respectively[41]. However, dose-dependent toxicity was a significant problem. Response rates were ~50% for the patients with advanced CTCL, who all received doses of 300–650 mg/m^2 per day[23,37].

Bexarotene is FDA-approved as oral therapy for CTCL that has been refractory to at least one systemic agent, and as a topical gel formulation for refractory early-stage CTCL. Given the high incidence of side effects, in particular hyperlipidemia (see below), a commonly recommended starting dose for oral bexarotene is 150 mg/m^2 per day (Table 126.4). Combination therapies utilizing bexarotene together with PUVA, narrowband UVB, methotrexate, interferon-α, or denileukin diftitox have also been evaluated in clinical trials and case series[49].

Chronic hand eczema

In a randomized, double-blind, placebo-controlled, multicenter study, 1032 adults with severe chronic hand eczema were treated with 30 mg or 10 mg of oral alitretinoin versus placebo once daily for 12–24 weeks. Responses, defined as clear or almost clear hands, were achieved in 48%, 28%, and 17% of the patients in the three groups, respectively. Treatment was well tolerated, with dose-dependent adverse events including headache, mucocutaneous side effects, hyperlipidemia, and hypothyroidism. Improvement typically began to develop after ~4 weeks of treatment, and the median time to relapse, defined as recurrence of 75% of initial signs and symptoms, was 6 months in the absence of any further therapy[50]. Oral alitretinoin (currently not available in the US) therefore represents a therapeutic option for adults with severe, recalcitrant chronic hand eczema, with the possibility of using intermittent courses to induce intermediate-term remissions[51].

Other "off-label" clinical uses

The multiple effects of retinoids explain their role in treating a broad spectrum of cutaneous diseases. Although many skin disorders respond to retinoids (see Table 126.3), benefit has been established in controlled studies for relatively few conditions.

Ichthyosis

Acitretin and isotretinoin can be of benefit in patients with non-syndromic autosomal recessive congenital ichthyoses (Fig. 126.5; see Ch. 57)[52]. Good results have also been observed in patients with X-linked recessive ichthyosis and ichthyosis vulgaris; however, these diseases tend to be less severe and do not usually require systemic retinoid therapy. Given the lifelong duration of heritable ichthyoses, intermittent retinoid courses are sometimes prescribed.

Darier disease

Severe forms of Darier disease are often treated with systemic retinoids. Therapy should be started with a low dose (e.g. acitretin 10 mg/day,

APPROACH TO ORAL BEXAROTENE THERAPY FOR CUTANEOUS T-CELL LYMPHOMA			
	Bexarotene administration	**Monitoring**	**Management of side effects**
Prior to treatment		Baseline CBC, basic metabolic panel, hepatic panel, TSH, free T4, fasting lipid panel, CK Determine if patient takes medications that inhibit or induce CYP3A4 (see Ch. 131)	Dietary and lifestyle modifications to minimize risk of hyperlipidemia If pre-existing laboratory abnormalities, administer: • Levothyroxine to achieve normal free T4 levels • A fibrate (e.g. fenofibrate)* to achieve triglyceride level <200 mg/dl and HDL level >50 mg/dl • A statin† to achieve LDL level <160 mg/dl
Day –7			Start fibrate (e.g. fenofibrate 145–200 mg daily)*
Day 0	Start bexarotene 150 mg/m^2 daily		Start levothyroxine 0.05 mg daily
Days 7 to 28		Free T4‡ & fasting lipid panel every 1–2 weeks	Adjust levothyroxine and fibrate doses and/or add statin† as required to keep laboratory values in target ranges above
Day 28¶	Increase to bexarotene 300 mg/m^2 daily		
Day 29 onward	Adjust bexarotene dose as needed depending on disease response	Free T4‡ & fasting lipid panel • Every 1–2 weeks until in target range and after subsequent dose changes • Otherwise every 1–2 months CBC every 1–2 months	As above; a triglyceride level <400 mg/dl may be a more realistic target for some patients

*Reduce dose for patients with decreased creatinine clearance; because gemfibrozil raises bexarotene levels, these medications should ***not*** be administered concomitantly.
†Niacin represents another option for patients with combined hyperlipidemia; patients receiving a fibrate and statin concomitantly may be at increased risk of rhabdomyolysis.
‡Monitor free T4 as indicator of hypothyroidism; bexarotene lowers TSH levels (central hypothyroidism).
¶May increase dose as early as day 14 or, if more time is required to normalize lipid and free T4 levels, after day 28.

Table 126.4 Approach to initiating oral bexarotene therapy for cutaneous T cell lymphoma. CBC, complete blood count; CK, creatine kinase; HDL, high-density lipoprotein; LDL, low-density lipoprotein; T4, thyroxine; TSH, thyroid-stimulating hormone.

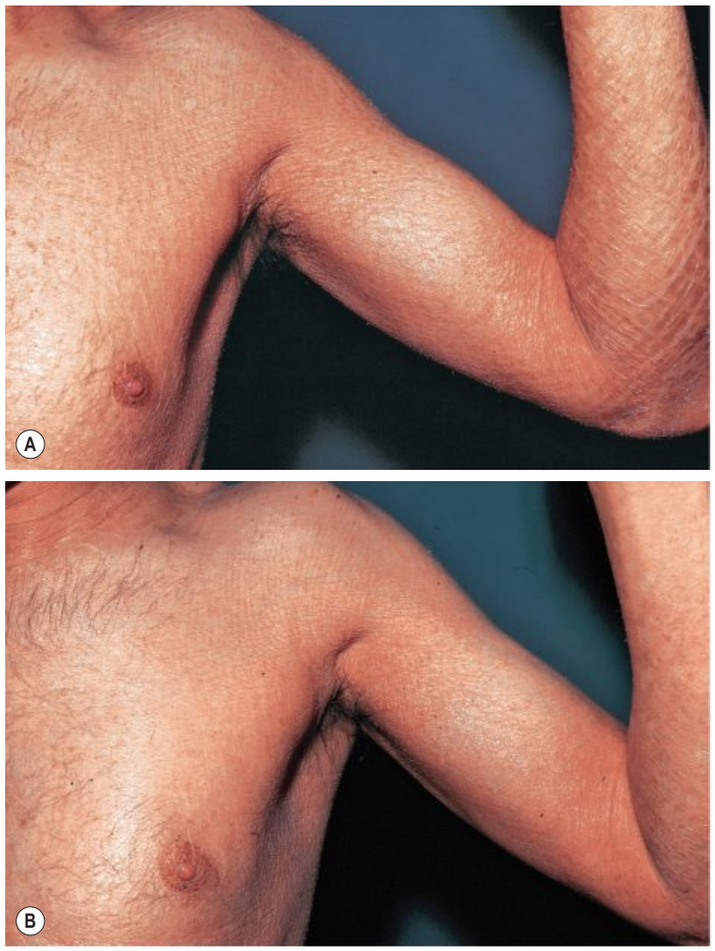

Fig. 126.5 Lamellar ichthyosis. Before (**A**) and after (**B**) treatment with acitretin.

isotretinoin 20 mg/day) in order to prevent an initial exacerbation of the disease; 20 mg/day of acitretin is usually sufficient for significant improvement.

Pityriasis rubra pilaris

Treatment with an oral retinoid (acitretin, isotretinoin, or alitretinoin) can lead to clearance of pityriasis rubra pilaris (PRP) (Fig. 126.6; see Ch. 9). In extensive cases, concomitant use of methotrexate may be advantageous, but with attention to possible liver toxicity.[53]

Rosacea

In severe or treatment-resistant rosacea, isotretinoin typically has a greater effect on inflammatory lesions than on vascular manifestations[54]. A low daily dose (10 mg) is often sufficient, although higher-dose acne vulgaris regimens are sometimes used for severe disease.

Premalignant and malignant skin lesions

Acitretin has been shown to be effective in the treatment of premalignant skin lesions, including human papillomavirus-induced neoplasia and actinic keratoses. In patients with basal cell nevus syndrome and xeroderma pigmentosum as well as solid organ transplant recipients, it may reduce the development of keratinocyte carcinomas (see Ch. 108). A prospective, open, randomized crossover study demonstrated that acitretin (25 mg/day for 12 months) prevented the development of squamous cell carcinoma in renal transplant recipients[55].

Lupus erythematosus

Both isotretinoin and acitretin have been used successfully in patients with various forms of lupus erythematosus (LE), including hypertrophic LE.[56] Recommended doses range from 0.2–1.0 mg/kg/day. Recurrence after completion of treatment is a limiting factor. Comparable therapeutic efficacy has been observed for acitretin and hydroxychloroquine in chronic and subacute cutaneous LE[57].

DOSAGE

The different formulations, strengths, and standard dosage ranges of topical and systemic retinoids currently available for use in dermatology are outlined in Table 126.5.

CONTRAINDICATIONS

Topical Retinoids

Topical retinoids should be avoided during pregnancy and nursing, due primarily to medicolegal issues raised by the teratogenicity of

Fig. 126.6 Pityriasis rubra pilaris. Before (**A**) and after (**B**) treatment with acitretin.

oral retinoids. Use of irritating topical products (e.g. abrasive cleansers, astringents) and hair removal via waxing should be avoided in areas being treated with a topical retinoid.

Systemic Retinoids

The absolute contraindications are pregnancy, women contemplating becoming pregnant or non-compliant with contraception, breastfeeding, and hypersensitivity to medication components. Relative contraindications include moderate to severe hypercholesterolemia or hypertriglyceridemia, significant hepatic dysfunction (especially for bexarotene), hypothyroidism (especially for bexarotene and alitretinoin), suicidal ideation, and pseudotumor cerebri. Patients should be advised not to take vitamin A supplements in excess.

MAJOR SIDE EFFECTS

Topical Retinoids

By far the most common side effect of topical retinoids is skin irritation characterized by erythema and peeling (Table 126.6). "Retinoid dermatitis" typically occurs during the first month of treatment and tends

ADVERSE EFFECTS OF TOPICAL RETINOIDS	
Skin irritation (retinoid dermatitis)	Erythema Peeling, scaling Dryness Burning Pruritus Photosensitivity
Uncommon	Hypo- or hyperpigmentation Ectropion Allergic contact dermatitis Sticky skin

Table 126.6 Adverse effects of topical retinoids.

FORMULATIONS OF TOPICAL AND SYSTEMIC RETINOIDS				
Retinoid	**Route**	**Formulations**	**Standard dosage range**	**Major indications**
Retinol	Topical	Various (0.15%, 0.3%)		Cosmeceutical products
Retinaldehyde	Topical	Various (0.05%–0.1%)		
Tretinoin†	Topical	Gel, cream, solution (0.1%, 0.08%, 0.06%, 0.05%, 0.04%, 0.025%, 0.02%, 0.01%)		Acne vulgaris Photoaging
	Oral	10 mg capsules	45 mg/m^2/day	Acute promyelocytic leukemia
Tazarotene‡	Topical	Gel, cream, lotion, foam (0.045%, 0.05%, 0.1%)		Acne vulgaris Plaque-type psoriasis Photoaging
Adapalene¶	Topical	Gel, cream, lotion (0.1%, 0.3%)		Acne vulgaris
Trifarotene	Topical	Cream (0.005%)		Acne vulgaris
Isotretinoin	Topical§	Gel (0.05%)		Acne vulgaris*
	Oral	8, 10, 16, 20, 24, 25, 30, 35, 40 mg capsules	0.5–2 mg/kg/day	Severe, recalcitrant acne; related dermatoses*
Acitretin	Oral	10, 17.5, 22.5, 25 mg capsules	25–50 mg/day	Psoriasis Disorders of cornification*
Bexarotene	Topical	Gel (1%)		Cutaneous T cell lymphoma
	Oral	75 mg capsules	300 mg/m^2/day	
Alitretinoin	Topical	Gel (0.1%)		Kaposi sarcoma
	Oral§	10, 30 mg capsules	10–30 mg/day	Chronic hand eczema*

*Not an FDA-approved indication.
†Tretinoin is also available in combination with clindamycin phosphate 1.2% for acne or with fluocinolone acetonide 0.01% plus hydroquinone 4% for melasma.
‡Tazarotene 0.045% is also available in combination with halobetasol propionate 0.01% for plaque psoriasis.
¶Adapalene 0.1% is available over the counter and adapalene 0.1% and 0.3% are also available in combination with benzoyl peroxide 2.5% for acne.
§Currently not available in the US.

Table 126.5 Formulations of topical and systemic retinoids. Systemic retinoids are teratogenic and therefore contraindicated during pregnancy. Although topical retinoids have very low levels of systemic absorption, their use during pregnancy is not recommended and per the FDA, topical tazarotene and bexarotene are contraindicated during pregnancy. Topical tretinoin may be oxidized and inactivated by benzoyl peroxide, so it is recommended that these medications be applied at different times.

to recede thereafter. It usually responds to a temporary reduction in the frequency, amount, or duration (e.g. "short contact" therapy) of retinoid application and to the use of moisturizers. Desquamation and peeling correspond to the hyperproliferative response of the epidermis to tretinoin mediated by RARs, but the erythema does not seem to be receptor-mediated. The perioral area of the face is most sensitive to peeling, and retinoid use in this region can be limited or avoided.

Although no photoallergic or phototoxic reactions have been proven for topical retinoids, some patients note a decreased tolerance to UVR. Erythema tends to develop shortly after sun exposure and is often accompanied by a sensation of heat, raising the question of involvement of infrared irradiation. The potential for teratogenicity from use of topical retinoids is very low to non-existent. Systemic absorption of topically applied retinoids has been inconsequential in both animal and human studies[58–60], and there is no evidence that topical application of tretinoin during pregnancy causes congenital disorders. Temporary worsening of acne may occur within the first weeks of therapy. Uncommon side effects include transient hypo- or hyperpigmentation, koebnerization of psoriasis (especially with tazarotene), allergic contact dermatitis, and rarely ectropion. Of note, topical retinoids have been used to treat ectropion in patients with ichthyosis.

Systemic Retinoids

Teratogenicity is the most concerning adverse effect of oral retinoids (Table 126.7). The side-effect profile of systemic retinoids (Table 126.8) resembles the toxic effects of vitamin A or hypervitaminosis A syndrome. Acute retinoid toxicity can include mucocutaneous (most common) and laboratory abnormalities, while chronic retinoid toxicity may occasionally produce bony changes.

Teratogenicity

Systemic retinoids are potent teratogens, and fetal deformities are the major concern in treating fertile women with oral retinoids. So far, with regard to teratogenicity, no safe minimal dose during pregnancy has been established. The defects seen in retinoid embryopathy can include craniofacial (microtia/anotia, micrognathia), cardiovascular, thymic, and central nervous system (CNS; hydrocephalus, microcephaly) abnormalities (see Table 126.7)[58,61]. These malformations may lead to spontaneous abortion, premature birth, or fetal death. The putative mechanism involves toxic effects on neural crest cells, particularly with exposure during the fourth week of gestation. No typical retinoid embryopathy malformations have been reported in pregnancies where only the male partner was taking acitretin or isotretinoin at the time of conception. Although it is often recommended that men who are actively trying to father children avoid systemic retinoid therapy due to

RETINOID EMBRYOPATHY
Craniofacial
• Atresia of the ear canal, microtia, anotia • Microphthalmia • Asymmetry of the face • Cleft palate • Micrognathia
Cardiovascular (especially conotruncal and aortic arch defects)
• Transposition of the great vessels • Tetralogy of Fallot • Truncus arteriosus • Supracristal ventricular septal defect • Interrupted aortic arch • Retroesophageal right subclavian artery • Hypoplastic aorta
Central nervous system
• Hydrocephalus • Microcephaly • Cortical agenesis • Cerebellar hypoplasia • Mental retardation • Difficulty with visual motor integration
Third and fourth pharyngeal pouches
• Thymic hypoplasia • Parathyroid hypoplasia
Other
• Limb anomalies • Anal and vaginal atresia

Table 126.7 Retinoid embryopathy.

ADVERSE EFFECTS OF SYSTEMIC RETINOIDS	
Acute effects	
Mucocutaneous	Xerosis with pruritus* Cheilitis* Dry mucosa*: mouth, nose (epistaxis), eyes (see below) Skin fragility* Retinoid dermatitis (see Table 126.6)* Palmoplantar peeling* Photosensitivity Sticky sensation (palms, soles) Granulation tissue with pyogenic granuloma-like lesions (e.g. at sites of acne cysts, periungual) Intertriginous erosions with exuberant granulation tissue Nail fragility with softening, onycholysis, paronychia Facial swelling *Staphylococcus aureus* infection Telogen effluvium, hair thinning
Ocular	Xerophthalmia* Blepharoconjunctivitis Reduced night vision Blurred vision, photophobia, keratitis, corneal ulceration (rare)
Systemic	Myalgias Arthralgias Anorexia, nausea, diarrhea, abdominal pain Headache, pseudotumor cerebri (rare) Fatigue, lethargy, irritability Depression, suicidal ideation (rare and controversial) Toxic hepatitis (rare) Clinical signs of hypothyroidism (with bexarotene*) Pancreatitis secondary to hypertriglyceridemia (rare) Hyperuricemia with gout (rare)
Laboratory	Elevated liver function tests (usually transient, minor): AST, ALT, alkaline phosphatase, LDH, bilirubin Hyperlipidemia: hypertriglyceridemia*; increased cholesterol, VLDL and LDL; decreased HDL Decreased free thyroxine (T4) (with bexarotene*) Elevated creatine kinase Leukopenia (with bexarotene) Agranulocytosis (with bexarotene) Thrombocytosis, thrombocytopenia Hypercalcemia (rare)
Chronic effects	
Mucocutaneous	Alopecia (rare) Dry eyes, corneal opacities (rare)
Systemic	DISH syndrome-like bone changes Osteophyte and bony bridge formation, especially of vertebrae (rarely clinically significant at dosages for acne) Anterior > posterior spinal ligament calcification Extraspinal tendon and ligament calcification Osteoporotic changes in long bones (rare, with possible exception of long-term etretinate) Premature epiphyseal closure (rare) Periosteal thickening Myopathy (rare)
*Common adverse effects.	

Table 126.8 Adverse effects of systemic retinoids. See Table 126.7 for teratogenicity. ALT, alanine aminotransferase; AST, aspartate aminotransferase; DISH, diffuse idiopathic skeletal hyperostosis; HDL, high-density lipoprotein; LDH, lactate dehydrogenase; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

the presence of the drug in semen, only ~0.0001%–0.0005% of a typical oral dose would be delivered to a female partner (https://dailymed.nlm.nih.gov/).

In the US, physicians, patients (female or, to prevent sharing of medication, male), and pharmacies must register with a pregnancy risk reduction program (iPLEDGE™) in order for isotretinoin to be prescribed. The program requires female patients with childbearing potential to review an educational booklet, receive monthly counseling, take monthly comprehension and pregnancy tests (as well as two pregnancy tests prior to instituting therapy), and pledge to use two forms of effective contraception (or abstinence) continuously for 1 month before, during, and for 1 month after isotretinoin treatment[62,63]. Patients taking systemic retinoids should not donate blood while on therapy and for 1 month or 3 years after the last dose of isotretinoin or acitretin, respectively.

Skin and mucous membrane adverse effects

Dose-dependent mucocutaneous toxicity is the most commonly observed side effect of oral retinoids, and it reflects decreased production of sebum, reduced stratum corneum thickness, and altered skin barrier function (Fig. 126.7). Dry lips or cheilitis is the earliest and the most frequent finding (Fig. 126.8). Dryness of the mouth, nasal mucosa (associated with fragility and epistaxis), and eyes (see below) are other potential manifestations.

Xerosis of the skin and associated pruritus, peeling (especially of the palms and soles), and fissuring (particularly of the fingertips) are frequent side effects. Exacerbations of atopic dermatitis may occur. Photosensitivity is occasionally observed, in particular with isotretinoin, and probably reflects a reduction in the thickness of the stratum corneum. *Staphylococcus aureus* colonization correlates with isotretinoin-induced reduction in sebum production and may lead to cutaneous infections. Diffuse hair loss due to telogen effluvium is a relatively common complaint, although objective alopecia tends to occur only at high dosage levels. Effects on the nail apparatus can include thinning, fragility, and shedding of the nail plate as well as paronychia-like changes with periungual granulation tissue that can resemble pyogenic granulomas.

Fig. 126.7 Retinoid dermatitis. Xerosis, peeling, and erythema of the face in a patient treated with oral isotretinoin.

Fig. 126.8 Cheilitis in an isotretinoin-treated patient.

Mucocutaneous side-effect profiles vary among the systemic retinoids. Isotretinoin causes more mucosal dryness, and acitretin has been associated with higher incidences of alopecia and palmoplantar peeling, whereas bexarotene induces milder mucocutaneous and ocular side effects than other oral retinoids. Delayed wound healing and abnormal scarring during isotretinoin therapy have been described, and it has traditionally been suggested that elective procedures be postponed until 6–12 months after discontinuing isotretinoin when possible. However, recent systematic reviews and consensus recommendations do not support delaying most surgical and cosmetic procedures in patients currently receiving or who have recently completed isotretinoin therapy, with the exception of fully ablative laser treatments and mechanical dermabrasion[64]. Medium-depth and deep chemical peels are also often delayed.

Common laboratory abnormalities

Dyslipidemia

Hypertriglyceridemia is the most frequently observed systemic effect of retinoid therapy. Isotretinoin and etretinate/acitretin elevate triglycerides in 25%–50% and cholesterol in 20%–30% of treated patients[65], whereas bexarotene elevates triglycerides and cholesterol in ~80% and ~50% of patients, respectively[23]. A concomitant increase in total and low-density lipoprotein (LDL) cholesterol is frequently observed. In cases of severe retinoid-induced hypertriglyceridemia, eruptive xanthomas and acute hemorrhagic pancreatitis may occur. A higher incidence of acute hemorrhagic pancreatitis has been encountered in patients taking bexarotene, as compared to first- or second-generation retinoids.

Baseline fasting serum lipid levels should be obtained before initiating bexarotene therapy and every 1–2 weeks during therapy until levels become stable (generally in 4–8 weeks). For other oral retinoids, monitoring of lipid levels (together with liver function tests) is typically performed monthly for the first 2 months and then at 3-month intervals if baseline lipid levels are normal, there are no increases in dosage, and risk factors (obesity, high alcohol intake, diabetes) are absent. Less frequent monitoring (e.g. at baseline and after 2 months of treatment if results are normal) has been recommended for low-risk adolescents and young adults receiving isotretinoin for acne or ichthyosis, with subsequent testing every 6–12 months for ichthyosis patients on long-term treatment[52,66]. Discontinuation of therapy is suggested if fasting triglycerides reach 800 mg/dl (8 g/L). Less severe increases may be treated by dose reduction, withdrawing therapy until normalization of serum lipids occurs, and changes in diet or lifestyle. In some instances, lipid-lowering agents may be indicated. Coadministration of bexarotene with a statin (e.g. atorvastatin) for hypercholesterolemia and/or fenofibrate for hypertriglyceridemia is recommended to treat retinoid-induced hyperlipidemia and to lower the risk of pancreatitis[16,67]. Some authors recommend starting all patients on fenofibrate 7 days before initiating bexarotene treatment[37].

The effects of retinoid-induced hyperlipidemia during long-term therapy on the development of atherosclerotic cardiovascular disease is unknown. Retinoids are thought to cause hyperlipidemia by interfering with lipid clearance. Bexarotene increases the expression of apolipoprotein C-III, which prevents the uptake of lipids from very-low-density lipoproteins (VLDL) into cells.

Liver effects

Transient elevations in serum transaminases occur in ~20% of patients treated with acitretin and much less frequently in those receiving isotretinoin or bexarotene therapy. Circulating levels of alkaline phosphatase, lactic dehydrogenase, and bilirubin may also occasionally become elevated during retinoid therapy. Liver function test abnormalities are typically mild, usually developing between 2 and 8 weeks after starting therapy and then returning to normal within another 2–4 weeks despite continued therapy. Severe or persistent hepatotoxic reactions occur in <1% of patients. Acitretin therapy elicited no biopsy-proven hepatotoxicity in a 2-year prospective study, thus suggesting that periodic liver biopsy is not necessary[68]. No studies have specifically evaluated the use of retinoids in patients with hepatic insufficiency. However, since retinoids are metabolized by hepatic cytochrome P450 isoenzymes

(e.g. CYP3A4) and undergo partial biliary elimination, significant hepatic insufficiency is likely to interfere with drug elimination. Transaminase elevations to greater than three times the upper limit of normal should prompt discontinuation of retinoid therapy. Other causes of hepatic dysfunction should be excluded.

Other systemic adverse effects

Ophthalmologic effects

The most common ocular retinoid effects are dryness and irritation. Xerophthalmia due to decreased Meibomian gland secretions may prohibit the use of contact lenses and can lead to blepharoconjunctivitis, keratitis, or corneal opacities (especially with isotretinoin). Alterations in visual function, mainly nyctalopia (reduced night vision), excessive glare sensitivity, and changes in color perception, have also been reported[69]. Competitive inhibition of ocular retinol dehydrogenase by retinoids, resulting in decreased rhodopsin formation, may be the cause of nyctalopia.

Bone effects

Bone pain can occur in retinoid-treated patients without objective evidence of any abnormalities and without sequelae. Several reports have also implicated therapy with oral retinoids, including etretinate and isotretinoin, in the formation of diffuse hyperostoses of the spine (diffuse idiopathic skeletal hyperostosis [DISH] syndrome-like changes) as well as calcification of tendons and ligaments, particularly in the ankles[70]. These changes are thought to be related to the dose and duration of retinoid treatment[52], with specific findings including anterior spinal ligament calcification, osteophyte ("spur") formation, extraspinal calcifications, and bony bridges, but not narrowing of the disk space. Of note, many of the bone changes observed are common in the general population (especially in adults) and not clinically significant. Prospective studies have shown that the likely potential effect of retinoids is to worsen pre-existing skeletal overgrowth rather than to induce *de novo* changes.

Osteoporosis has been observed with hypervitaminosis A and after long-term therapy with etretinate but not with acitretin or isotretinoin. Several investigations in patients receiving a standard isotretinoin course for acne (~1 mg/kg/day for 5–6 months), including an open-label trial in 217 adolescents and three controlled studies in adolescents (n = 21; n = 358) and young adults (n=36), showed no significant changes in bone mineral density[71,72]. Likewise, a study of 30 adults found no association between acitretin therapy (median duration, 3.6 years) for chronic dermatoses and risk of osteopenia or osteoporosis. Although there are rare reports of premature epiphyseal closure in children treated with oral retinoids (e.g. >1 mg/kg/day for ≥4–6 years)[52], this has not been observed in acne treatment studies. A baseline radiographic survey or bone density evaluation is not required prior to administering an oral retinoid, although monitoring high-risk patients who require prolonged high-dose therapy may be useful.

Muscle effects

Although muscular pain and cramps can occur in patients taking acitretin, these symptoms are more common with higher doses of isotretinoin therapy, especially in individuals involved in vigorous physical activity. Occasionally, elevated creatine kinase levels may be observed. Increased muscle tone as well as axial muscle rigidity and myopathy have been reported in patients receiving etretinate and acitretin therapy, respectively.

Central nervous system and psychiatric effects

Although individual signs of increased intracranial pressure, such as headache, nausea and vomiting, are occasionally observed in patients taking a systemic retinoid, the complete pseudotumor cerebri syndrome with papilledema and blurred vision is very rare[73]. Concomitant use of other drugs associated with intracranial hypertension (e.g. tetracyclines) is considered a risk factor for developing pseudotumor cerebri and should therefore be avoided[74]. Examination for papilledema should be performed immediately when a patient receiving retinoid therapy complains of a persistent headache, especially if it is accompanied by visual changes, nausea or vomiting, or when pseudotumor cerebri is otherwise suspected.

Although there have been anecdotal reports of depression, psychosis, and suicide attempts in acne patients taking isotretinoin, a causal link has not been established. Multiple prospective and population-based studies as well as case–control, prescription sequence symmetry, and meta-analyses have failed to find an increased risk of depression or suicidal behavior associated with isotretinoin therapy for acne[75–77]. In contrast, several studies and meta-analyses actually noted a significant *decrease* in depressive symptoms in individuals treated with isotretinoin compared to baseline or a control group receiving other acne therapies[75–77], while one small case-crossover study showed a positive correlation between recent exposure to isotretinoin and diagnosis of depression in patients with acne. Acne patients should be informed of possible associations between isotretinoin and psychiatric issues prior to initiating this treatment and monitored for depressive symptoms or suicidal ideation during therapy.

Hypothyroidism

Clinical and biochemical central hypothyroidism occurred in 40% of patients in CTCL trials with bexarotene and was rapidly and completely reversible with cessation of therapy[23,78]. Dose-dependent decreases in serum thyroid-stimulating hormone (TSH) levels were also noted in clinical trials of alitretinoin. This effect is probably mediated via suppressed secretion of the β-subunit of TSH by the thyrotrope cells of the anterior pituitary, which express RXR-γ. Free T4 levels should be monitored before and during bexarotene and alitretinoin therapy and normalized with thyroid hormone replacement as necessary[37].

Hematologic effects

A high incidence (~30%) of dose-related leukopenia was reported in studies of bexarotene for CTCL, occurring as early as 2–4 weeks and characterized by a decrease in neutrophils rather than lymphocytes[23]. Hematologic abnormalities are much less common with other retinoids, but monitoring the complete blood count in HIV-infected patients is warranted.

Gastrointestinal effects

Uncommon nonspecific gastrointestinal complaints have been reported in association with retinoid therapy. Although there have been case reports of isotretinoin administration preceding the onset of inflammatory bowel disease (IBD) and one study showed an association between previous isotretinoin use and the development of ulcerative colitis, a cause-and-effect relationship has not been established. Several large population-based studies found that patients with IBD were no more likely to have used isotretinoin prior to diagnosis than matched controls[79,80], and a meta-analysis concluded that isotretinoin use does not increase the risk of IBD overall or ulcerative colitis specifically[79]. Potential confounding effects of severe inflammatory acne itself and treatment with oral antibiotics may also contribute to an apparent association between isotretinoin and IBD.

Renal effects

Renal toxicity is not characteristic of retinoid therapy. Isotretinoin has been safely administered to patients with end-stage kidney disease who were undergoing hemodialysis. Renal function should be monitored in patients with a history of kidney disease.

Summary

Most adverse effects associated with retinoids are preventable or manageable through proper patient selection, diligent monitoring, and dose adjustments (or occasionally discontinuation of treatment) as indicated.

INTERACTIONS

Concurrent use of systemic retinoids with alcohol or other medications having similar side effects may increase the incidence of adverse events. The following should be avoided or used with caution:

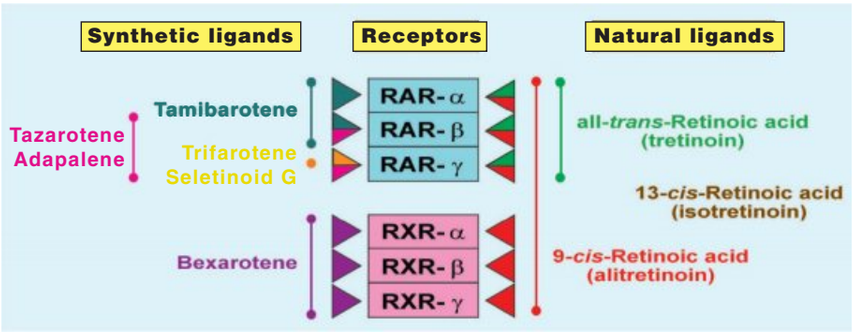
- tetracycline, doxycycline, minocycline (may increase intracranial pressure)
- alcohol (increased conversion of acitretin to etretinate and hepatotoxicity)
- methotrexate (synergistic liver toxicity with retinoids; however, combination may be used with caution in patients with PRP or severe psoriasis)
- vitamin A supplements (risk of hypervitaminosis A).

Retinoid drug levels and resultant potential for toxicity may increase with CYP3A4 inhibitors such as azoles and macrolides. In contrast, medications and herbal supplements including antituberculous drugs (e.g. rifampin), anticonvulsants (e.g. phenytoin, carbamazepine), and St. John's wort may decrease the drug levels of retinoids via CYP3A4 induction (see Table 131.8). Retinoids may also increase the drug levels of cyclosporine via competition for CYP3A4 metabolism[16]. Concomitant administration of bexarotene and gemfibrozil results in a substantial increase in plasma concentrations of bexarotene, at least partially because of cytochrome P450 CYP3A4 inhibition that is induced by gemfibrozil. Concomitant administration of fenofibrate (for hypertriglyceridemia) or atorvastatin (for hypercholesterolemia) does not affect bexarotene plasma levels and, therefore, can be utilized together with bexarotene (see Table 126.4).

In rare instances, patients with diabetes mellitus may have more difficult glucose control while taking a retinoid; however, the causal relationship remains uncertain. Acitretin has been shown to possibly reduce the efficacy of progestin-only contraceptives. Also, unprotected UVR exposure or photosensitizing medications should be avoided because of the potential for increased photosensitivity related to retinoid therapy. Since retinoids act through nuclear receptor dimers, cross-talk with other nuclear receptors may provide synergistic effects: for example, interactions between RXR and vitamin D receptor (VDR) positively influence the action of vitamin D_3, and cross-talk with PPAR and its ligands is under investigation.

USE IN PREGNANCY AND LACTATION

All systemic retinoids are teratogenic and are absolutely contraindicated during pregnancy and lactation (formerly FDA category X). As discussed above, pregnancy testing is necessary for female patients of childbearing potential before instituting oral retinoid therapy (two tests required in the US for isotretinoin) and then at regular intervals (e.g. monthly for isotretinoin) during its administration. Adequate contraception for at least 1 month before initiation and throughout the treatment course is also mandatory in this patient group. Acitretin requires contraception for 3 years (US) or 2 years (Europe) after cessation of therapy, whereas isotretinoin, bexarotene, and alitretinoin require contraception for just 1 month after cessation of therapy.



Although no evidence exists for teratogenicity of topical retinoids in humans, they are nevertheless not recommended for use during pregnancy. Since no dermatologic condition that is known to be responsive to topical retinoids is life-threatening to the mother or fetus, it is wiser to postpone treatment until after delivery, primarily for medicolegal reasons rather than scientific data in the opinion of the authors. As it is not known whether topical retinoids pass into the breast milk, topical retinoid use is generally not recommended during breastfeeding.

127 Antimicrobial Drugs

Ashley N. Millard-Garcia, Alexandra Cameli Carley, Erik J. Stratman, Jack L. Lesher Jr and R. Carol McConnell

Key features

- Bacterial, fungal, and viral infections of the skin and soft tissue are very common
- Selection of the appropriate treatment depends on the infecting microorganism, the site and extent of the infection, and patient characteristics (e.g. age, pregnancy/lactation, comorbid medical conditions)
- Physicians must be aware of the drug interactions and potential adverse effects of antimicrobial medications

ANTIBACTERIAL AGENTS

INTRODUCTION

With hundreds of antibiotics now available, physicians have abundant therapeutic options, which can potentially be confusing and overwhelming. Selection of the most appropriate antibiotic depends upon identification of the infecting microorganism and its sensitivity to antimicrobial agents. When possible and practical, a culture should be obtained prior to starting therapy.

In acutely ill patients, empiric therapy with broad-spectrum antibiotics may initially be necessary. Knowledge of local bacterial resistance patterns should guide antibiotic selection. Once the microbe is identified, preferably along with antibiotic sensitivities, medications can be adjusted accordingly. Indiscriminate use of broad-spectrum antibiotics leads to development of resistant bacteria. The site and extent of the infection; the side effect profiles and costs of possible medication choices; and patient characteristics, including age and medical comorbidities (e.g. impaired renal or hepatic function) as well as pregnancy and lactation status, also influence drug selection.

Antibacterial drugs are characterized as either bacteriostatic or bactericidal (Table 127.1). Bacteriostatic drugs inhibit growth and replication of bacteria and limit spread of infection, allowing the immune system to eliminate the pathogen. Bactericidal agents kill bacteria directly.

BACTERIOSTATIC VERSUS BACTERICIDAL DRUGS

Bacteriostatic	Bactericidal
Chloramphenicol	Aminoglycosides
Clindamycin	Bacitracin
Erythromycin	Carbapenems
Oxazolidinones	Monobactams
Sulfonamides	Nitroimidazoles
Tetracyclines	Penicillins
Trimethoprim	Polymyxin B
	Quinolones
	Vancomycin
	Lipoglycopeptides

Table 127.1 Bacteriostatic versus bactericidal drugs. Clindamycin may be either bacteriostatic or bactericidal depending on the susceptibility of the infecting organism and the concentration achieved at the site of infection. Factors such as the infecting organism and growth conditions can also affect whether other drugs are bacteriostatic or bactericidal.

TOPICAL ANTIBACTERIAL AGENTS

Introduction

Topical antibacterials are used to treat acne vulgaris, rosacea, and superficial bacterial infections and to prevent infection after surgery or injuries. Topical antibacterials are applied directly to the affected skin and thus deliver a high concentration of the medication locally with little chance of adverse systemic effects. However, their utility is limited to localized superficial conditions.

Topical Antibacterial Agents Used to Treat Acne Vulgaris and Rosacea

Table 127.2 lists topical antibiotics commonly used to treat inflammatory acne vulgaris and rosacea, with contributions from their anti-inflammatory as well as antibacterial effects.

Mechanisms of action

Azelaic acid is a dicarboxylic acid derivative with activity against *Cutibacterium acnes* (formerly *Propionibacterium acnes*) and *Staphylococcus epidermidis*. It is usually bacteriostatic but can be bactericidal in high concentrations. Its activity may be due to inhibition of microbial cellular protein synthesis. Azelaic acid also has anticomedonal effects by normalizing keratinization. It thins the stratum corneum, decreases the number and size of keratohyalin granules, and reduces the amount and distribution of filaggrin in the epidermis. Azelaic acid has antiproliferative effects against hyperactive and abnormal melanocytes, but it rarely causes hypo- or depigmentation of normally pigmented skin (see Table 127.2).

Benzoyl peroxide is bacteriostatic against *C. acnes*. Once absorbed by the skin, it is converted to benzoic acid. Its effects are believed to be due to oxidation of bacterial proteins by reactive oxygen species, which are released when the drug is decomposed by cysteine in the skin. Daily use of 10% benzoyl peroxide for 2 weeks decreases free fatty acids by 50% and *C. acnes* by 98%, which is comparable to results obtained after use of topical antibiotics for 4 weeks[1]. Benzoyl peroxide also has keratolytic and desquamative effects.

Clindamycin is a semisynthetic lincosamide antibiotic that inhibits protein synthesis by binding to the bacterial 50 S ribosomal subunit. It is active against Gram-positive cocci and anaerobes including staphylococci, streptococci, *C. acnes*, *Corynebacterium* spp., *Clostridium* spp., and *Gardnerella vaginalis*. Clindamycin may be either bacteriostatic or bactericidal, depending on the susceptibility of the infecting organism and the concentration achieved at the site of infection.

Erythromycin is a macrolide antibiotic that also inhibits protein synthesis by binding to the bacterial 50 S ribosomal subunit. It is active against Gram-positive cocci including group A β-hemolytic streptococci and *Staphylococcus aureus*, as well as some Gram-negative bacilli. Erythromycin has additional anti-inflammatory properties (see Macrolides below).

Tetracycline (topical formulation not available in the US; used to treat acne and superficial skin infections) and *minocycline* are tetracycline-class antibiotics that inhibit the bacterial 30 S ribosomal subunit and have anti-inflammatory as well as bacteriostatic effects (see Tetracyclines below). Minocycline's lipophilicity allows it to achieve high concentrations in the sebaceous follicle, and *C. acnes* has a low propensity for developing minocycline resistance[2].

Sodium sulfacetamide is a sulfonamide whose bacteriostatic effects involve disruption of folic acid synthesis (see Fig. 127.6). It is active against several Gram-positive and Gram-negative organisms. Some topical preparations combine sodium sulfacetamide with sulfur, which acts as a keratolytic as well as antimicrobial agent (see Ch. 129).

Metronidazole is a nitroimidazole with antioxidant and anti-inflammatory as well as antimicrobial effects against anaerobic bacteria. DNA strand breaking is its presumed mechanism of action.

TOPICAL ANTIBACTERIALS USED FOR ACNE VULGARIS AND ROSACEA					
Generic name	**Selected trade name(s)®**	**Formulations**	**Dosing frequency**	**Considered safe to use during pregnancy***	**Side effects**
Azelaic acid	Azelex, Cutacelan, Finacea, Finevin, Skinoderm, Skinoren	20% cream, 15% gel	BID		Pruritus, burning/stinging, dryness, peeling; rarely hypo-/depigmentation, hypertrichosis, allergic contact dermatitis, keratosis pilaris, exacerbation of recurrent herpes labialis
Benzoyl peroxide	Acne-Aid, Benoxyl, Benzac, Benzagel, BenzaShave, BenzEFoam, Brevoxyl, Clearasil, Dermoxyl, Desquam-X, Oxy, NeoBenz, PanOxyl, Persa-Gel, Triaz, Zapzyt	2.5%–10% lotion, cream, gel, foam, solution, stick, cleansing bar, cleansing lotion, cloths, pads, mask, shaving cream	Daily–TID; mask qwk	√*	Irritation, allergic contact dermatitis; occasionally blistering, crusting, severe erythema & edema; bleaches hair and colored fabrics
Clindamycin	Basocin, Cleocin T, Clinac, Clinda-Derm, Clindagel, Clindets, Cutaclin, Dalacin, Dalagis, Eurocin-A, Evoclin	1% gel, lotion, solution, foam, pledgets; 2% vaginal cream	BID	√	Gram-negative folliculitis, bacterial resistance; possible rare pseudomembranous colitis (risk from topical use is likely not clinically significant[56])
Erythromycin	Akne-Mycin, A/T/S, Emgel, Erycette, Eryderm, Erygel, Erymax, Ery-Sol, Erythra-Derm, ETS, Ilotycin, Sans-Acne, Staticin, Theramycin Z, T-Stat, Zineryt	1.5% or 2% solution; 2% pledgets, gel, ointment	BID	√	Eye irritation, skin tenderness, Gram-negative folliculitis, bacterial resistance; rarely generalized urticarial reactions
Minocycline	Amzeeq, Zilexi	1.5% or 4% foam	Daily		Erythema, dryness, pruritus, water-soluble yellow discoloration
Sodium sulfacetamide	Klaron, Mexar, Ovace, Seb-Prev, Sebizon *With 5% sulfur:* Avar Cleanser, Clarifoam, Clenia, Novacet, Plexion, Prascion, Rosac, Rosaderm, Rosanil, Rosula, Sulfacet-R, Sulfatol, SulZee, Sumaxin, Suphera, Topisulf, Zetacet	10% lotion, cream, suspension, foam, wash/cleanser, cleansing cloths	BID		Dryness, pruritus; may cross-react in patients allergic to related oral medications
Metronidazole	MetroGel, MetroCream, MetroLotion, Noritate	0.75% or 1% gel, cream, lotion	Daily–BID	√	Watery eyes, metallic taste in the mouth, nausea, numbness and paresthesias have been reported with topical use[19]; may cross-react in patients allergic to the oral form
Dapsone	Aczone	5% gel 7.5% gel	BID Daily		Dryness, peeling, erythema; in patients with G6PD deficiency, occasional drop in hemoglobin level and rarely methemoglobinemia; concurrent use with benzoyl peroxide may cause temporary local yellow–orange skin discoloration
Benzoyl peroxide/ erythromycin	Benzamycin	5%/3% gel	BID	√*	See above
Benzoyl peroxide/ clindamycin	Acanya, Benzaclin, Duac, Neuac, Z-Clinz	2.5%–10%/1% gel	BID	√*	See above
Benzoyl peroxide/ adapalene	Epiduo, Epiduo Forte	2.5/0.1%–0.3% gel	Daily		See above
Clindamycin phosphate/tretinoin	Veltin, Ziana	1.2/0.025% gel	Daily		See above

*Formerly FDA pregnancy category B, with the exception of products containing benzoyl peroxide, which were category C but have only ~2% systemic absorption.

Table 127.2 Topical antibacterials used for acne vulgaris and rosacea. Erythromycin has also been combined with zinc acetate (e.g. Zyneret® lotion or solution; not available in the US), as has benzoyl peroxide with zinc lactate (e.g. Triaz® products); zinc has possible antiandrogenic activity and may suppress sebum production. BID, twice daily; qwk, weekly; TID, three times daily.

Dapsone is a sulfone drug whose antimicrobial effects include inhibition of dihydropteroate synthase and prevention of bacterial folic acid synthesis. It also has anti-inflammatory effects that target neutrophils, inhibiting their chemotaxis and decreasing myeloperoxidase activity.

Indications

Azelaic acid, benzoyl peroxide, clindamycin, erythromycin, minocycline, sodium sulfacetamide, and dapsone are used topically for mild to moderate inflammatory acne vulgaris and rosacea. Studies have shown

that combining erythromycin or clindamycin with benzoyl peroxide is more effective for the treatment of acne than either of the former agents alone; clindamycin plus benzoyl peroxide is also more effective than benzoyl peroxide alone[3]. These synergistic combinations may slow the development of antibiotic resistance, which is a significant issue with erythromycin, clindamycin, and tetracycline.

Azelaic acid may also be useful for melasma and other forms of hyperpigmentation. Topical clindamycin and erythromycin can treat superficial bacterial infections of the skin, whereas topical clindamycin and metronidazole are both indicated for bacterial vaginosis.

Dosages

Topical antibacterial agents are usually used once or twice a day (see Table 127.2). A small amount of medication is applied in a thin layer onto clean, dry skin. Benzoyl peroxide cleansing bars and washes are used one to three times a day. Benzoyl peroxide shave cream is used like other shaving creams, and the mask is applied in a thin layer once a week, left on for 15 to 25 minutes, and then rinsed off.

Contraindications

The chief contraindication for these medications is a history of hypersensitivity to any component of the formulation. Azelaic acid, sodium sulfacetamide, erythromycin, and clindamycin preparations may contain propylene glycol, which can be a sensitizer. Topical clindamycin should be used with caution in patients with a history of inflammatory bowel disease or antibiotic-associated colitis.

Major side effects

Adverse reactions to topical antibacterial agents used to treat acne vulgaris and rosacea are usually mild and transient. Stinging is especially common with alcohol-containing solutions and pledgets. Table 127.2 lists side effects of individual drugs.

Interactions

Simultaneous application of more than one topical medication can increase or decrease the effect of one or both of the medications. Benzoyl peroxide may increase irritant effects of other topical acne medications, and it can decrease the activity of tretinoin when applied together. A temporary yellow–orange staining of the skin and hair occasionally occurs with concomitant use of topical dapsone and benzoyl peroxide.

Pregnancy and lactation

Formal studies on the use of most topical antibacterial agents during pregnancy and breastfeeding are lacking, but significant exposure to the fetus or nursing infant is not expected. In general, topical antibiotics are considered safe during pregnancy and lactation[4].

Topical Antibacterial Agents Used to Treat Superficial Infections

Table 127.3 lists antibacterial agents commonly used to prevent and treat superficial skin infections.

Mechanisms of action

The mechanisms of action of the topical antibacterial agents used to treat superficial infections are listed in Table 127.3.

Mupirocin (pseudomonic acid A) is derived from *Pseudomonas fluorescens*. It is clinically active against staphylococci; groups A, B, C, and G streptococci; and some Gram-negative aerobic bacteria. It is usually bacteriostatic but may be bactericidal at high concentrations.

Retapamulin is in the pleuromutilin class, derived from fermentation of a mushroom, *Clitopilus passeckerianus*. It has activity against *Streptococcus pyogenes* and *S. aureus*[5].

Ozenoxacin is a quinolone antibiotic active against Gram-positive organisms including *S. aureus* and *Str. pyogenes*[5].

Neomycin and *gentamicin* are aminoglycoside antibiotics. Neomycin is bactericidal against Gram-positive and Gram-negative bacteria including *S. aureus, Escherichia coli, Haemophilus influenzae, Proteus* spp., and *Serratia* spp. It is generally not effective against *Pseudomonas aeruginosa*. Gentamicin is effective against sensitive strains of group A β-hemolytic and α-hemolytic streptococci, *S. aureus* (coagulase-positive, coagulase-negative, and some penicillinase-producing strains), and Gram-negative bacteria including *P. aeruginosa, Aerobacter aerogenes, E. coli, Proteus vulgaris*, and *Klebsiella pneumoniae*.

Bacitracin is a cyclic polypeptide antibiotic that has a thiazolidine ring and peptide side chains. Bacitracin is active against Gram-positive organisms such as staphylococci, streptococci, corynebacteria, and clostridia.

Polymyxin B is a cyclic lipopeptide antibiotic that is rapidly bactericidal for various Gram-negative organisms, including *P. aeruginosa, E. coli, K. pneumoniae, Enterobacter aerogenes, H. influenzae, Proteus mirabilis*, and *Serratia marcescens*. It is not active against Gram-positive organisms.

TOPICAL ANTIBACTERIAL AGENTS USED FOR SUPERFICIAL SKIN INFECTIONS

Generic name	Trade name(s)®	Formulations (OTC/Rx)	Dosing frequency	Considered safe to use during pregnancy*	Class – mechanism of action
Mupirocin	Bactoderm, Bactroban, Centany, Eismycin	2% ointment or cream (Rx)	TID	√ (topical antibiotic of choice during pregnancy)	Monoxycarbolic acid – inhibits protein synthesis by reversibly binding to bacterial isoleucyl transfer RNA synthetase
Retapamulin	Altabax	1% ointment (Rx)	BID	√	Pleuromutilin – inhibits protein synthesis by interacting with the L3 protein on the bacterial 50S ribosomal subunit
Ozenoxacin	Xepi	1% cream (Rx)	BID		Quinolone – disrupts bacterial replication through inhibition of DNA gyrase and topoisomerase IV
Neomycin	Myciguent	0.5% ointment or cream (OTC)	Daily–TID		Aminoglycoside – inhibits protein synthesis by binding to the bacterial 30S ribosomal subunit; may also inhibit bacterial DNA polymerase
Gentamicin	Garamycin, Gentamar, G-Myticin	0.1% ointment or cream (Rx)	TID–4 times daily		
Bacitracin	Baciguent	400–500 units per gram ointment (OTC)	TID		Cyclic polypeptide – inhibits bacterial cell wall synthesis by forming a complex with C55-phenol pyrophosphate in the bacterial cell wall
Polymyxin B	Polysporin ointment = bacitracin + polymyxin B Neosporin ointment = bacitracin, polymyxin B + neomycin Neosporin cream = polymyxin B + neomycin only	5000–10 000 units per gram ointment (OTC)	Daily–TID		Cyclic lipopeptide – interacts with the phospholipids of bacterial cell membranes, increasing their cellular permeability

*Formerly FDA pregnancy category B.

Table 127.3 Topical antibacterial agents used for superficial skin infections. BID, twice daily; OTC, over-the-counter; Rx, prescription; TID, three times daily.

Indications

Mupirocin, retapamulin, ozenoxacin, gentamicin, neomycin, bacitracin, and combination products containing polymyxin B are utilized for the treatment and prevention of superficial bacterial skin infections. The intranasal preparation made with the calcium salt of mupirocin is indicated for the eradication of nasopharyngeal carriage of *S. aureus*. Studies implicating nasal staphylococci as a potential source for wound infections and bacteremia suggest that intranasal application of mupirocin may decrease the incidence of infections in susceptible individuals (e.g. those with recurrent staphylococcal infections)[6]. Decolonization of known *S. aureus* carriers with the use of mupirocin nasal ointment and chlorhexidine body wash for five days prior to Mohs micrographic surgery may reduce the risk of surgical site infection and be more effective than oral antibiotic prophylaxis on the day of surgery[7].

Mupirocin has been shown to be as effective as systemic antibiotics for localized impetigo due to *Str. pyogenes* or *S. aureus* in patients ≥2 months of age[8]. Retapamulin and ozenoxacin are also indicated for the topical treatment of impetigo due to *Str. pyogenes* or *S. aureus* in patients ≥9 and ≥2 months of age, respectively. Although retapamulin is FDA-approved for infections with methicillin-sensitive *S. aureus* (MSSA) only, rates of retapamulin resistance in methicillin-resistant *S. aureus* (MRSA) isolates are low[5].

Dosages

Table 127.3 outlines the formulations and dosing for the antibacterial agents used for the treatment of superficial skin infections. Intranasal mupirocin is applied into the nares two to four times a day for 5 to 14 days.

Contraindications

As with all topical medications, the main contraindication is a history of hypersensitivity to any component of the formulation.

Major side effects

Potential side effects of *mupirocin* include burning, stinging, pain, and pruritus, as well as erythema, edema, increased exudate, allergic contact dermatitis, headache, and nausea. Use of nasal mupirocin is occasionally associated with headaches, rhinitis, respiratory tract congestion, pharyngitis, dysgeusia, burning, stinging, and cough. Use of mupirocin on extensive areas of skin with decreased barrier function has been reported to cause renal toxicity from systemic absorption of polyethylene glycol. *Retapamulin* can cause application site irritation and pruritus.

Side effects of *neomycin* include allergic contact dermatitis in 5% to 15% of patients[9], in particular when neomycin is applied to cutaneous ulcerations and/or areas of chronic stasis dermatitis. The most common symptoms are pruritus, erythema, and edema. In the setting of impaired renal function, there is an increased risk of side effects related to systemic absorption; caution should also be exercised if the medication is used over extensive areas. Irreversible ototoxicity and renal failure have been reported with the use of topical neomycin on open wounds[10]. Neomycin may also cause mast cell degranulation and histamine release[1].

Possible side effects of *gentamicin* include erythema, pruritus, edema, and photosensitization. There is a risk of producing gentamicin-resistant strains of *Pseudomonas* when this agent is applied to heavily colonized skin (e.g. leg ulcers).

Adverse effects of *bacitracin* include irritant and allergic contact dermatitis. Chronic stasis dermatitis predisposes to the latter. Anaphylaxis has been reported in patients with a history of multiple previous exposures when bacitracin was applied to open wounds.

There are few side effects from *polymyxin B*. Contact sensitization has been reported. Of note, some cross-reactivity exists between bacitracin and polymyxin B because they are both derived from *Bacillus* species.

Interactions

There are no known significant drug interactions with the topical antibiotics used for superficial skin infections.

Pregnancy and lactation

In general, topical antibiotics are considered safe during pregnancy and lactation[4]. Neither topical nor nasal mupirocin has been specifically studied in pregnant women. However, mupirocin has not been shown to cause birth defects or other problems in animal studies and there is very little systemic absorption of topically applied mupirocin, making it the topical antibiotic of choice during pregnancy[11].

Fig. 127.1 Localized argyria. Gray discoloration due to application of silver sulfadiazine cream.

Other Topical Antibacterial Agents

Fusidic acid is a fusidane antibiotic isolated from the fungus *Fusidium coccineum*. It is not approved in the US but is used in Europe and Canada for mild to moderately severe cutaneous infections, external eye infections, and eradication of nasopharyngeal carriage of *S. aureus*. It is available as a 2% cream, ointment, or impregnated gauze applied three times daily. It has a steroid-like structure but no steroid effects[12]. Fusidic acid inhibits bacterial protein synthesis by interfering with elongation factor G. It is active against Gram-positive bacteria, especially *S. aureus*. This medication has a bacteriologic efficacy comparable to that of mupirocin or retapamulin for impetigo and may be more cost-effective[12,13]. When combined with topical corticosteroids, it is useful in treating atopic dermatitis with superimposed staphylococcal infection[12]; it is also effective for erythrasma[14]. Fusidic acid has few adverse effects, although allergic contact dermatitis has been reported.

Iodoquinol is a halogenated oxyquinoline with antibacterial and antifungal activity. Its mechanism of action is unknown. Commercially available combination products containing 1% iodoquinol plus 1%–2% hydrocortisone are applied three to four times a day for superficial bacterial and fungal skin infections. Topical iodoquinol (1%) preparations have a high iodine content, and data on their safety during pregnancy is lacking. A related medication, topical clioquinol (iodochlorhydroxyquin), is used primarily for the treatment of superficial fungal infections (see below).

Mafenide acetate cream, a sulfonamide, is applied once or twice daily for thermal burns. It has antibacterial and antifungal activity. The most common side effect is burning; urticaria or facial edema can also occur. Rarely, mafenide acetate may cause bone marrow suppression or lead to hemolytic anemia in patients with G6PD deficiency. It should be used with caution in patients with renal or pulmonary disease due to its potential to cause metabolic acidosis. Furthermore, mafenide acetate may cause intense pain upon application and can be associated with *Candida* superinfection.

Silver sulfadiazine is a 1% cream applied once to twice daily for thermal burns. It interacts with bacterial cell walls and membranes, resulting in broad antimicrobial effects. Silver sulfadiazine may interfere with the activity of topical proteolytic enzymes. It is contraindicated in patients with a history of sulfonamide hypersensitivity and should be used with caution in patients with G6PD deficiency (due to risk of hemolysis), renal or hepatic impairment, and porphyria. Localized argyria due to deposits of silver in the dermis can also occur (Fig. 127.1).

SYSTEMIC ANTIBACTERIAL AGENTS

Systemic antibacterial agents have the potential to cause a wide range of adverse effects and to have significant interactions with other systemic medications. For example, rifampin may reduce the efficacy

SITES OF ACTION OF DIFFERENT CLASSES OF SYSTEMIC ANTIBACTERIAL DRUGS	
Site of action	**Drug class(es)**
Cell wall	Penicillins Cephalosporins Carbapenems Monobactams Vancomycin Lipoglycopeptides β-lactamase inhibitors
Cell membrane	Daptomycin Oritavancin, telavancin
Inhibit nucleic acid synthesis	Sulfonamides Trimethoprim
DNA gyrase	Quinolones
DNA strand breakage	Nitroimidazoles (e.g. metronidazole)
Ribosomal subunit	Aminoglycosides – 30S Tetracyclines – 30S Glycylcycline (tigecycline) – 30S Chloramphenicol – 50S Clindamycin – 50S Macrolides – 50S Oxazolidinones – 50S Streptogramins (quinupristin/dalfopristin) – 50S

Table 127.4 Sites of action of different classes of systemic antibacterial drugs.

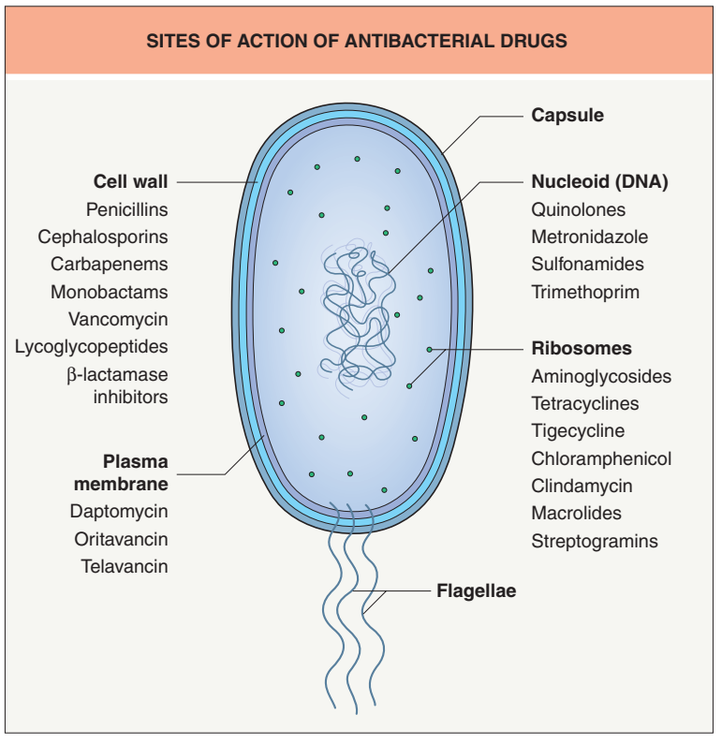

Fig. 127.2 Sites of action of antibacterial drugs. This figure illustrates a prototypical bacterial cell. Each class of antibacterial drug exerts its effect on a particular component of the cell.

of oral contraceptives. Bacteriostatic antibacterial agents can decrease the efficacy of bactericidal antibacterial agents, because the latter target actively dividing cells. In addition, use of systemic antibacterial agents can lead to the development of bacterial resistance. The mechanisms of action of the major classes of antibacterial drugs are listed in Table 127.4 and illustrated in Fig. 127.2. Systemic antibiotics may be used perioperatively by dermatologic surgeons to prevent surgical site infections in high-risk situations such as procedures involving the lower extremity or groin, wedge excisions on the lip or ear, skin flaps on the nose, and skin grafts. Antibiotic prophylaxis is also recommended in patients at high risk for infective endocarditis or hematogenous infection of a total joint replacement who have surgery involving the oral mucosa or infected skin (see Ch. 151)[15].

Penicillins

Mechanism of action

Penicillins are β-lactam antibiotics that exert bactericidal effects by binding and inactivating penicillin-binding proteins in bacterial cell walls. They inhibit bacterial cell wall synthesis by blocking transpeptidase cross-linking of peptidoglycan chains (Fig. 127.3).

The natural penicillins (penicillin G and penicillin V) are active against Gram-positive and Gram-negative cocci, most Gram-positive bacilli, and spirochetes. Penicillinase-resistant penicillins (methicillin, nafcillin, and dicloxacillin), referred to as anti-staphylococcal penicillins, have greater efficacy against *S. aureus*. Aminopenicillins (ampicillin, amoxicillin) have an extended spectrum to include *H. influenzae*, *E. coli*, *Salmonella* and *Shigella* spp., and some other Gram-negative bacteria, but not *Pseudomonas* spp. Antipseudomonal penicillins (e.g. piperacillin, azlocillin) cover *P. aeruginosa* and depending upon the particular drug, *B. fragilis* and *Klebsiella* spp. However, in general, this group of penicillins has been replaced by cefepime and when anaerobe coverage is desired, the carbapenem meropenem. Addition of the β-lactamase inhibitors clavulanic acid, sulbactam, tazobactam, avibactam, and durlobactam extends the spectrum of penicillins to include staphylococci and other β-lactamase-producing bacteria (Fig. 127.4).

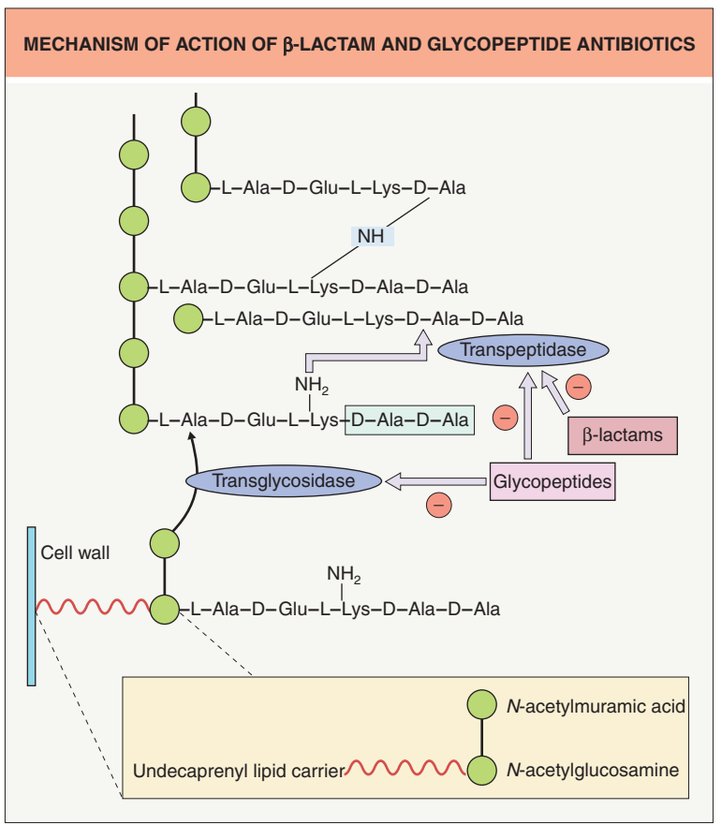

Fig. 127.3 Mechanism of action of β-lactam and glycopeptide antibiotics. Simplified schematic of mechanisms of action of β-lactam antibiotics (penicillins, cephalosporins) and glycopeptides (e.g. vancomycin, dalbavancin) in interfering with enzymatic steps in bacterial cell wall (peptidoglycan) synthesis.

Indications

Penicillins are used for syphilis and streptococcal skin infections, such as erysipelas, as well as other cutaneous infections such as erysipeloid. Amoxicillin with clavulanic acid is the drug of choice for cat, dog, and human bites. It is useful also for acute paronychia. The penicillinase-resistant penicillins, e.g. dicloxacillin, are used for suspected MSSA skin infections such as impetigo, folliculitis, and non-purulent cellulitis; however, sensitivity testing should be obtained when MRSA is a clinical concern (see Ch. 74). Amoxicillin may be used for Lyme disease when doxycycline is contraindicated.

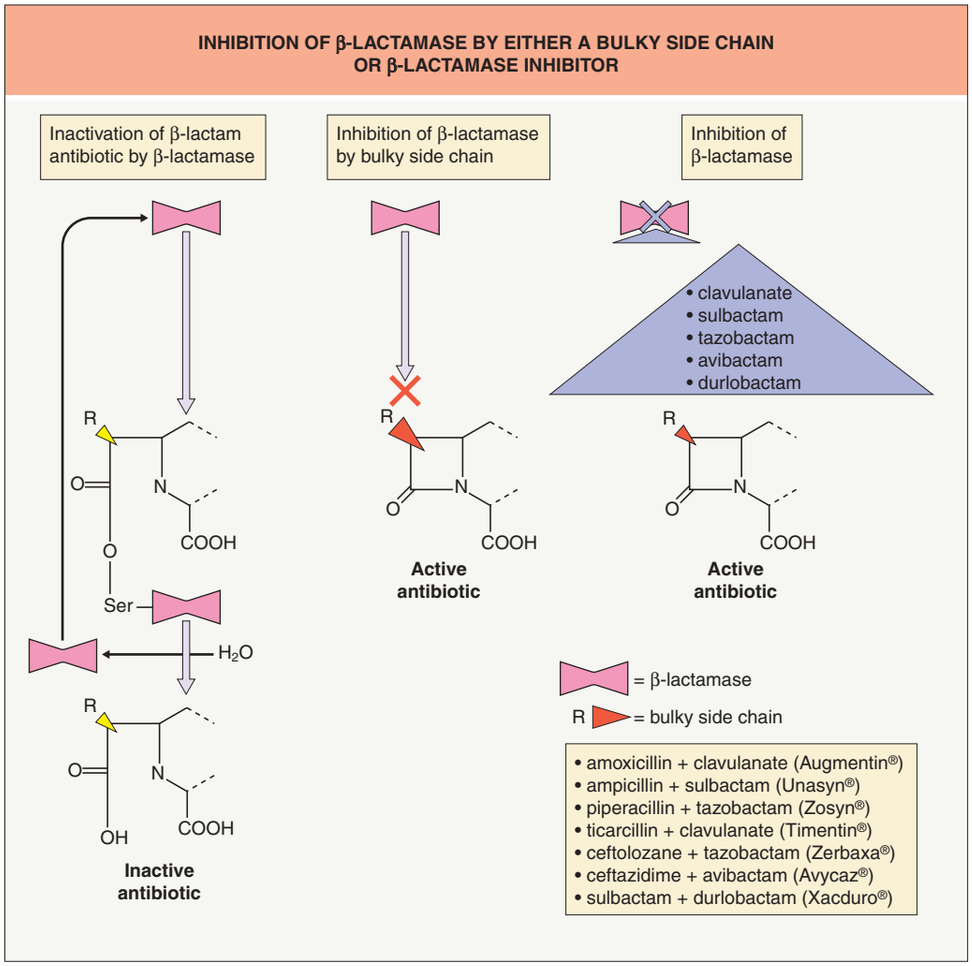

Fig. 127.4 Inhibition of β-lactamase by either a bulky side chain or β-lactamase inhibitor. Placement of a bulky side chain on the penicillin molecule (e.g. methicillin, nafcillin, dicloxacillin) can inhibit bacterial β-lactamase, as can the combination of a penicillin with a β-lactamase inhibitor (e.g. clavulanic acid, sulbactam, tazobactam). The latter group of drugs has no inherent antibacterial activity. Inhibition of β-lactamase allows the antibiotic to remain active and inhibit bacterial transpeptidase.

Dosages

The pediatric and adult dosages of commonly used penicillins are listed in Table 127.5. Amoxicillin and amoxicillin with clavulanic acid should be taken with food. Other penicillins should be taken on an empty stomach.

Contraindications

Penicillins are contraindicated in patients with known immediate-type (IgE-mediated) hypersensitivity to any penicillin, such as a history of penicillin-associated urticaria, angioedema, or anaphylaxis. However, only 10%–20% of patients who report a history of allergy to penicillins have an allergy identified upon skin testing[16]. Among patients allergic to penicillin, ~2%–15% are allergic to cephalosporins and <1% to carbapenems through cross-reactivity[17].

Skin testing for penicillin allergy utilizes: (1) the major allergen benzylpenicilloyl polylysine; (2) the minor allergens benzylpenicillin G, benzylpenicilloate, and penicilloyl propylamine; and (3) negative (saline) and positive (histamine) controls. Either epicutaneous (prick) or intradermal testing may be performed, usually by an allergist. Antihistamines should be avoided prior to testing. Patients who have had a life-threatening reaction to penicillin should be tested with 100-fold dilutions of the allergens before being tested with full-strength allergens in a monitored setting where treatment for anaphylaxis is available.

Patients who report a history of penicillin allergy but are skin-test-negative to all major and minor allergenic determinants can use penicillin in a monitored setting. Skin-test-positive patients may be desensitized orally or intravenously in a hospital setting over ~4 hours. Rarely, serious IgE-mediated allergic reactions can occur. Blood tests can also be used to detect specific IgE directed against penicillin, but this method is less sensitive and informative than skin tests.

Major side effects

Drugs in the penicillin group cause hypersensitivity reactions characterized by urticaria, flushing, and pruritus in 5%–15% of patients. In severe cases, anaphylaxis, shock, and even death may occur. In addition, penicillins can cause morbilliform and other exanthematous eruptions (Fig. 127.5A), which may be associated with fever and eosinophilia. Serum sickness-like reactions, Stevens–Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and pustular eruptions such as acute generalized exanthematous pustulosis (AGEP) develop less often. These drugs also occasionally lead to autoimmune phenomena, including hemolytic anemia or vasculitis. Of note, ampicillin and amoxicillin almost invariably cause a generalized morbilliform eruption in patients with infectious mononucleosis; this reaction is also more likely in patients with chronic lymphocytic leukemia and those taking concomitant allopurinol.

Penicillins can induce acute interstitial nephritis characterized by proteinuria, hematuria, renal casts, eosinophilia, eosinophiluria, fever, and declining renal function. Prolonged use of penicillins may lead to reversible neutropenia, anemia, agranulocytosis, and platelet dysfunction. Penicillins can cause diarrhea, pseudomembranous colitis, and hepatic dysfunction. Treatment with penicillins is associated with oral or vaginal overgrowth of *Candida* spp. in ~10% of patients.

ORAL DOSAGES OF COMMONLY USED PENICILLINS

Generic name	Pediatric oral dosage	Adult oral dosage
Penicillin V potassium	25–50 mg/kg/day divided q6–8 h	250–500 mg 4 times daily
Dicloxacillin	12.5–50 mg/kg/day divided q6 h	125–500 mg 4 times daily
Ampicillin	50–100 mg/kg/day divided q6 h	250–500 mg 4 times daily
Amoxicillin	25–50 mg/kg/day divided q8 h or q12 h	250–500 mg BID
Amoxicillin/clavulanate	20–40 mg/kg/day (of amoxicillin) divided q8 h or q12 h*	500–875 mg BID

*Do not double the dose of clavulanate if you double the amoxicillin dose, as this causes excessive clavulanate dosage and increased risk of gastrointestinal side effects like diarrhea.

Table 127.5 Oral dosages of commonly used penicillins. BID, twice daily; h, hours; q, every.

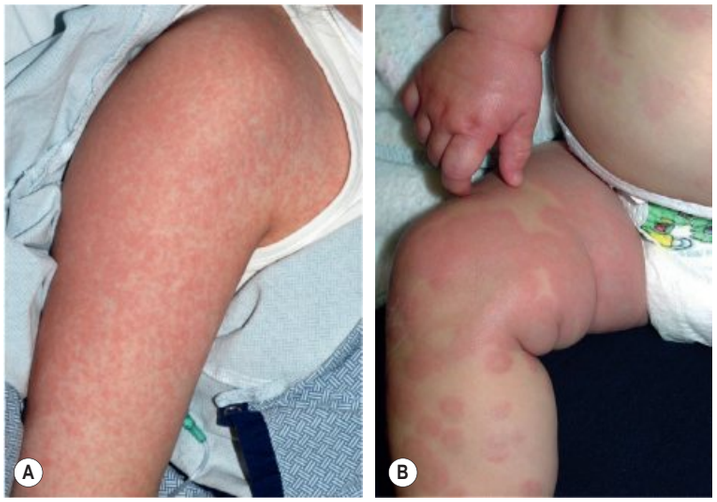

Fig. 127.5 Drug eruptions secondary to β-lactam antibiotics. A Morbilliform exanthem due to amoxicillin. **B** Serum sickness-like reaction presenting with coalescing annular erythematous plaques in an infant treated with cefaclor. Note the dusky centers of some lesions. *A, Courtesy Julie V. Schaffer, MD.*

Interactions

Because probenecid blocks the secretion of penicillins in the distal renal tubules, concomitant administration of these two drugs increases the serum levels and duration of action of the penicillins. When amoxicillin or ampicillin is used concomitantly with allopurinol, there is an increased risk of morbilliform drug eruption, and when tetracyclines are used together with penicillins, the bactericidal effect of penicillins is decreased.

Pregnancy and lactation

Penicillins are generally safe during pregnancy and in nursing mothers.

Cephalosporins

Mechanism of action

Like the penicillins, the cephalosporins are bactericidal β-lactam antibiotics that bind to penicillin-binding proteins and interfere with bacterial cell wall synthesis (Table 127.6). First-generation cephalosporins are very effective against Gram-positive organisms (staphylococci and streptococci) and less effective against Gram-negative organisms; however, they are active against *E. coli, Klebsiella*, and *Proteus* spp. Second-generation cephalosporins are equally effective against Gram-positive and Gram-negative bacteria. Their spectrum includes all of the organisms covered by first-generation cephalosporins plus *Enterobacter* spp., *Neisseria gonorrhea*, and *H. influenzae*. Third-generation cephalosporins are more effective against Gram-negative bacteria than Gram-positive bacteria. Fourth-generation cephalosporins have an extended spectrum against Gram-negative (including *Enterobacter* and *Klebsiella* spp.) and Gram-positive organisms, but have minimal resistance to β-lactamase. Fifth-generation cephalosporins (e.g. ceftaroline) have activity against *S. aureus* including MRSA, *Str. pyogenes*, *Str. agalactiae*, *Str. pneumoniae*, *H. influenzae*, *E. coli*, and *Klebsiella*. Cephamycins, β-lactam antibiotics very similar to cephalosporins, are resistant to β-lactamase and have a broad spectrum, including *E. coli, Klebsiella*, *Proteus*, *Serratia*, and *Bacteroides* spp.

Indications

Cephalosporins are useful in staphylococcal and streptococcal skin and soft tissue infections. A first-generation agent such as cephalexin or cefadroxil is the cephalosporin of choice in uncomplicated skin infections such as impetigo, staphylococcal folliculitis, erysipelas, cellulitis, and ecthyma. However, with the exception of fifth generation agents (e.g. ceftaroline), MRSA is resistant to cephalosporins.

Dosages

See Table 127.7 for dosages of the more commonly used cephalosporins.

DIFFERENT CLASSES OF CEPHALOSPORINS AND ROUTES OF ADMINISTRATION

Generic name	Trade name(s)®	Route(s) of administration
First generation		
Cefadroxil	Duracef, Ultracef	po
Cefazolin	Ancef, Kefzol, Zolicef	im, iv
Cephalexin	Keflex, Keftab, Biocef	po
Cephalothin*	Keflin, Seffin	im, iv
Cephapirin*	Cefadyl	im, iv
Cephradine*	Velosef, Anspor	po, im, iv
Second generation		
Cefaclor	Ceclor, Ceclor CD	po
Cefamandole*	Mandol	im, iv
Cefmetazole*	Zefazone	iv
Cefonicid*	Monocid	im, iv
Cefprozil	Cefzil	po
Cefuroxime sodium	Zinacef, Kefurox	im, iv
Cefuroxime axetil	Ceftin	po
Loracarbef (a carbacephem)*	Lorabid	po
Third generation		
Cefdinir	Omnicef	po
Cefditoren	Spectracef	po
Cefixime	Suprax	po
Cefoperazone*	Cefobid	im, iv
Cefotaxime	Claforan	im, iv
Cefpodoxime proxetil	Vantin	po
Ceftazidime	Ceptaz, Fortaz, Tazidime, Tazicef	im, iv
Ceftibuten	Cedax	po
Ceftizoxime	Cefizox	im, iv
Ceftriaxone	Rocephin	im, iv
Fourth generation		
Cefepime	Maxipime	im, iv
Fifth generation		
Ceftaroline	Teflaro	iv
Ceftolozane	Zerbaxa (with tazobactam)	iv
Ceftobiprole*	Zevtera, Mabelio	iv
Cephamycins†		
Cefoxitin	Mefoxin	im, iv
Cefotetan	Cefotan	im, iv
Siderophore cephalosporin‡		
Cefiderocol	Fetroja	iv

*Not currently available in the US.
†Sometimes grouped with second-generation cephalosporins.
‡Only active against aerobic Gram-negative bacilli.

Table 127.6 Different classes of cephalosporins and routes of administration. im, intramuscularly; iv, intravenously; po, orally.

Contraindications

Cephalosporins are contraindicated in patients with a history of an immediate-type (IgE-mediated) hypersensitivity to this class of drugs. Approximately 10%–15% of adults and 2% of children allergic to penicillins have cross-reactivity to cephalosporins[17].

DOSAGES OF COMMONLY PRESCRIBED CEPHALOSPORINS		
Generic name	**Pediatric dosage**	**Adult dosage**
Cephalexin	25–100 mg/kg/day divided q6 h or q12 h	250–500 mg 4 times daily
Cefadroxil	30 mg/kg/day divided q12 h	1–2 g daily
Cefaclor	40 mg/kg/day divided q8 h or q12 h	250–500 mg TID
Cefprozil	30 mg/kg/day divided q12 h	250–500 mg daily
Cefuroxime axetil	20–30 mg/kg/day divided q12 h	250–500 mg BID
Cefpodoxime proxetil	10 mg/kg/day divided q12 h	100–400 mg BID
Ceftibuten	9 mg/kg/day divided q24 h	400 mg daily
Cefixime	8 mg/kg/day divided q12 h or q24 h	200 mg BID or 400 mg daily
Ceftriaxone	50 mg/kg im × 1 (max 1 g)	1–4 g im daily; 250 mg im × 1 for uncomplicated gonorrhea
Cefdinir	14 mg/kg/day divided q12 h or q24 h	300 mg BID or 600 mg daily

Table 127.7 Dosages of commonly prescribed cephalosporins. Administration is oral unless otherwise noted. BID, twice daily; h, hours; im, intramuscularly; q, every; TID, three times daily.

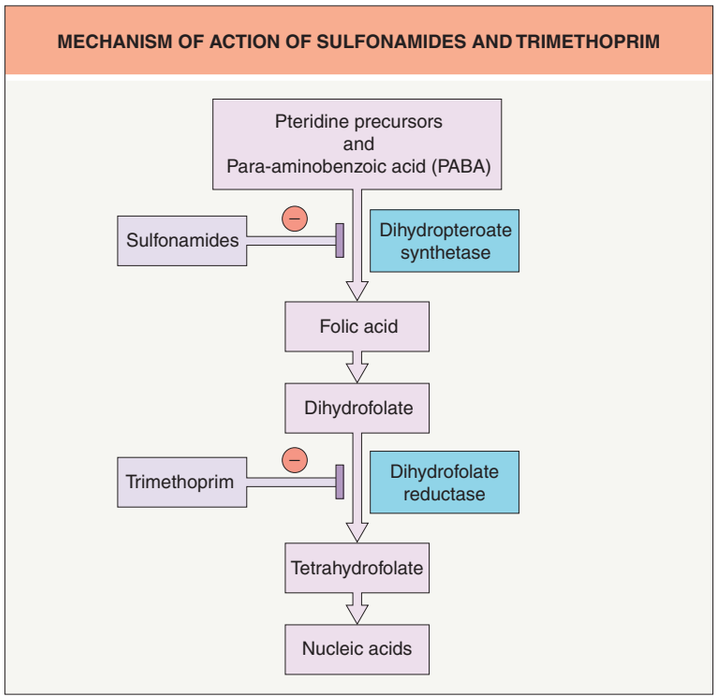

Fig. 127.6 Mechanism of action of sulfonamides and trimethoprim. Sulfonamides inhibit the conversion of pteridine precursors and PABA to folic acid by dihydropteroate synthetase. Trimethoprim inhibits the conversion of dihydrofolate to tetrahydrofolate by dihydrofolate reductase. The end result of both actions is inhibition of bacterial nucleic acid synthesis.

Major side effects

Cutaneous reactions are similar to those seen with the penicillins, including morbilliform eruptions, urticaria, anaphylaxis, and AGEP. Cefaclor is associated with a significantly higher rate of serum sickness-like reactions in children compared to other cephalosporins and other antibiotic classes (Fig. 127.5B)[18]. Cephalosporins may also lead to neutropenia, thrombocytopenia, and Coombs-positive hemolytic anemia, especially in the setting of renal insufficiency. They can cause diarrhea, nausea, and pseudomembranous colitis. Certain cephalosporins/cephamycins with a methylthiotetrazole side group (e.g. cefotetan, cefoperazone, cefamandole) can cause a disulfiram-like effect when alcohol is ingested concomitantly and have anti-vitamin K effects leading to an enhanced risk of bleeding.

Cephalosporins (particularly cefepime) can cause toxic-metabolic encephalopathy. It manifests as seizures, myoclonus, confusion and, less frequently, psychosis 1–10 days after medication initiation[19]. Risk factors include elevated plasma drug levels, renal insufficiency, and pre-existing CNS impairment[19].

Interactions

Administration of oral cephalosporins together with aminoglycosides can increase the likelihood of nephrotoxicity. Probenecid may decrease renal clearance of cephalosporins. Antacids, didanosine, and proton pump inhibitors may decrease absorption of some oral cephalosporins (e.g. cefuroxime).

Pregnancy and lactation

Cephalosporins have not shown adverse effects during pregnancy or lactation and are considered compatible with breastfeeding[4,20].

Sulfonamides and Co-trimoxazole

Mechanism of action

Sulfamethoxazole, *sulfasalazine*, and *sulfisoxazole* are sulfonamides that compete with para-aminobenzoic acid (PABA) to be the substrate for dihydropteroate synthetase (Fig. 127.6). Dihydropteroate synthetase catalyzes the reaction that combines pteridine precursors with PABA to make folic acid. Thus, sulfonamides prevent the synthesis of bacterial folic acid, an essential cofactor for bacterial nucleic acid synthesis. They have a bacteriostatic effect against Gram-positive bacteria (especially *S. aureus*), Gram-negative bacteria, *Chlamydia*, and *Nocardia* spp.

Co-trimoxazole is a synergistic combination of sulfamethoxazole and trimethoprim. It blocks two consecutive steps in the biosynthesis of bacterial nucleic acids (see Fig. 127.6). The sulfonamide inhibits dihydropteroate synthetase and trimethoprim blocks the action of dihydrofolate reductase, which normally converts dihydrofolate to tetrahydrofolate (the active form of folic acid). This combination may be bactericidal or bacteriostatic depending on the drug concentration and the susceptibility of the infecting organism. It is active against most Gram-positive and Gram-negative organisms.

Indications

Co-trimoxazole is used for furuncles or purulent cellulitis suspected to be due to MRSA, inflammatory acne vulgaris recalcitrant to other antibacterial agents, and granuloma inguinale. Other indications for co-trimoxazole include respiratory tract, prostate, urinary tract, and gastrointestinal infections. It is utilized to treat *Pneumocystis jirovecii* pneumonia and as *P. jirovecii* prophylaxis in patients who are immunosuppressed due to systemic medications or HIV infections. Systemic sulfonamides are also used for *Chlamydia* conjunctivitis and *Nocardia* infections. Sulfasalazine is commonly prescribed for ulcerative colitis and psoriatic arthritis.

Dosages

One double-strength capsule of co-trimoxazole contains 160 mg of trimethoprim and 800 mg of sulfamethoxazole (Septra DS®, Bactrim DS®), and in adults this is given twice a day; for *Pneumocystis* prophylaxis, it is taken thrice weekly. In children, the dose is 8–12 mg/kg/day of trimethoprim and 40–60 mg/kg/day of sulfamethoxazole, divided into two doses. Oral sulfadiazine and sulfisoxazole are typically dosed at 2–4 g/day in adults or 75–150 mg/kg/day in children, divided every 4–8 hours.

Contraindications

The sulfonamides and co-trimoxazole are contraindicated in patients with a history of hypersensitivity to this class of medications. Sulfonamides are contraindicated in the third trimester of pregnancy and in lactating patients (see below). They are also contraindicated in patients with porphyria. Sulfonamides can precipitate an acute attack of pseudoporphyria or true porphyria, possibly by increasing levels of porphyrins via hepatocellular damage, stimulating cytochrome P450 activity, or inhibiting other liver enzymes. Co-trimoxazole is contraindicated in patients with megaloblastic anemia, folate deficiency, or G6PD deficiency. It should be used cautiously in patients with impaired hepatic or renal function and in individuals with bone marrow suppression.

Major side effects

The sulfonamides and co-trimoxazole may cause fixed drug or morbilliform eruptions, urticaria, angioedema, photosensitivity, SJS, TEN, exfoliative erythroderma, and vasculitis. Additional uncommon cutaneous side effects include AGEP, Sweet syndrome, linear IgA bullous dermatosis, erythema nodosum, and radiation recall. In HIV-infected patients, these drugs are especially common causes of cutaneous eruptions. Non-cutaneous side effects include hemolytic anemia in the setting of G6PD deficiency, agranulocytosis, thrombocytopenia, eosinophilia, methemoglobinemia, nephrotoxicity, hepatotoxicity, neurotoxicity, and kernicterus in newborns. Co-trimoxazole may also cause nausea, vomiting, glossitis, and stomatitis, as well as dizziness and headaches. Trimethoprim (alone or in combination with sulfamethoxazole) can induce folate deficiency with megaloblastic anemia, leukopenia, and granulocytopenia. It can also cause thrombocytopenia. Administration of folinic acid, which does not impair antibacterial activity because it does not enter bacteria, can reverse the sequelae of folate deficiency.

Interactions

Sulfonamides decrease protein binding and renal clearance of methotrexate, and both agents (as well as the trimethoprim in co-trimoxazole) inhibit folic acid metabolism; these mechanisms can lead to potentially life-threatening methotrexate-induced myelosuppression and other toxicities such as mucositis. The sulfonamides and co-trimoxazole can potentiate the effects of oral hypoglycemics and the anticoagulant effect of warfarin. They should not be used in patients on methenamine for urinary tract infections. Monoamine oxidase (MAO) inhibitors and probenecid may increase sulfonamide adverse effects through altered hepatic metabolism and renal clearance, respectively.

Pregnancy and lactation

Co-trimoxazole should be avoided during pregnancy and lactation as well as for the first 2 months of life. The sulfonamides and co-trimoxazole may cause fetal harm due to their inhibition of folic acid during the first two trimesters; they also result in increased risk of kernicterus during the third trimester. Systemic sulfonamides are excreted in breast milk and may cause hepatic toxicity, anemia, and other adverse effects in nursing infants.

Macrolides

Mechanism of action

Macrolides are bacteriostatic and inhibit bacterial protein synthesis by binding to the 50S ribosomal subunit. Erythromycin is effective against Gram-positive and Gram-negative cocci, most Gram-positive bacilli, and spirochetes. Clarithromycin has an expanded spectrum that includes *H. influenzae* and *Moraxella catarrhalis*. Azithromycin also covers *H. influenzae*. Clarithromycin and azithromycin are both effective against atypical mycobacteria, *Treponema pallidum*, and *Borrelia burgdorferi*; however, they are not first-line agents for infections with the latter two organisms.

Macrolides also have anti-inflammatory effects, including inhibiting production of proinflammatory cytokines (e.g. interleukin [IL]-8, tumor necrosis factor [TNF]), reducing expression of matrix metalloproteinases, and decreasing leukocyte migration and adhesion.

Indications

Macrolides are commonly used for staphylococcal and streptococcal skin infections in patients allergic to penicillins. However, there are regions where a significant percentage of *S. aureus* isolates are erythromycin-resistant, and occasionally *Str. pyogenes* is resistant to erythromycin. Other dermatologic applications of erythromycin and azithromycin include inflammatory acne or rosacea, erythrasma, pitted keratolysis, bacillary angiomatosis, and cat scratch disease. These agents can also be used for the acute and chronic forms of pityriasis lichenoides. In addition, macrolides are indicated for several sexually transmitted diseases, including chancroid, lymphogranuloma venereum, chlamydia, and granuloma inguinale. Macrolides are employed for non-tuberculous mycobacterial infections and a variety of bacterial respiratory infections, including pharyngitis, mycoplasmal pneumonia, Legionnaires disease, diphtheria, and pertussis.

Dosages

Table 127.8 outlines the dosages for commonly prescribed macrolides. Erythromycin base should be taken on an empty stomach; other formulations should be taken with food.

Contraindications

Macrolides are contraindicated in patients with a history of hypersensitivity or hepatic impairment related to this drug class. These agents should be used with caution in those with QT prolongation, electrolyte abnormalities (e.g. hypokalemia, hypomagnesemia), hepatic dysfunction, or renal dysfunction.

Major side effects

The use of erythromycin may be limited by gastrointestinal side effects (e.g. nausea, vomiting, abdominal cramping), whereas azithromycin has improved gastrointestinal tolerance. Erythromycin estolate can cause intrahepatic cholestasis in adults, and this risk increases during pregnancy. Less common side effects include stomatitis, jaundice, transient deafness, and cardiac arrhythmias. Although hypersensitivity reactions to macrolides are uncommon, AGEP may occur. Urticaria, SJS, TEN, and vasculitis are unusual complications.

Interactions

Macrolides have numerous significant drug interactions. Due to CYP3A4 inhibition (see Ch. 131), macrolides (clarithromycin and erythromycin > azithromycin) increase the risk of *torsades de pointes* when used with grepafloxacin, sparfloxacin, terfenadine, astemizole, or cisapride; all of the latter drugs have been removed from the US

DOSAGES OF COMMONLY USED MACROLIDES

Generic name	Oral pediatric dosage	Oral adult dosage
Azithromycin	Bacterial infections: 10 mg/kg (max 500 mg) on day 1, then 5 mg/kg (max 250 mg) daily on days 2–5 Acne vulgaris, rosacea, or pityriasis lichenoides: 5–10 mg/kg thrice weekly	Bacterial infections: 500 mg on day 1, then 250 mg daily on days 2–5 (Zithromax® "Z-pack") Chancroid: 1 g once Acne vulgaris, rosacea, or pityriasis lichenoides: 250–500 mg thrice weekly
Clarithromycin	15 mg/kg daily divided q12 h Maximum 1 g/day Adjust for decreased renal function	250–500 mg BID Adjust for decreased renal function
Erythromycin base	30–50 mg/kg daily divided q6–8 h Maximum 2 g/day	250–500 mg 4 times daily or 333 mg TID or 500 mg BID
Erythromycin estolate	20–50 mg/kg daily divided q6–12 h Maximum 2 g/day	250–500 mg BID–4 times daily
Erythromycin ethyl succinate	20–50 mg/kg daily divided q8–12 h Maximum 2 g/day	400 mg 4 times daily
Erythromycin stearate	20–50 mg/kg daily divided q6 h	250–500 mg BID–4 times daily

Table 127.8 Dosages of commonly used macrolides. BID, twice daily; h, hours; q, every.

and most worldwide markets because of this cardiac risk. By the same mechanism, macrolides increase serum levels and potential toxicity of anticonvulsants, benzodiazepines, buspirone, corticosteroids, warfarin, HMG-CoA reductase inhibitors, colchicine, oral contraceptives, cyclosporine, tacrolimus, disopyramide, felodipine, and ergot alkaloids. Macrolides can increase serum levels of theophylline by inhibiting CYP1A2, leading to cardiac arrhythmias. Macrolides may also increase digoxin levels by altering gut flora, which metabolize digoxin.

Clarithromycin administered in conjunction with calcium channel blockers increases the risk of bradycardia and hypotension. Erythromycin used concomitantly with lovastatin has been reported to cause rhabdomyolysis. Macrolides may interfere with the effectiveness of chloramphenicol or clindamycin (see below), and antacids can decrease the absorption of azithromycin. Clarithromycin levels may be increased when this drug is administered with fluconazole, hexobarbital, alfentanil, disopyramide, or bromocriptine.

Pregnancy and lactation

Erythromycin (with the exception of erythromycin estolate) and azithromycin are generally considered safe during pregnancy, whereas clarithromycin is not recommended due to adverse fetal effects in animal studies. Erythromycin estolate is contraindicated in pregnancy due to the risk of maternal cholestatic hepatitis. This may represent a hypersensitivity reaction to the estolate component, and it can be accompanied by rash, fever, leukocytosis, and eosinophilia in addition to findings related to liver disease (e.g. nausea, vomiting, abdominal pain, jaundice, liver enzyme abnormalities). An increased risk of infantile hypertrophic pyloric stenosis has been described when: (1) mothers received oral macrolides during late pregnancy or while breastfeeding in the neonatal period; and (2) infants received macrolides during the first two weeks of life[4].

Tetracyclines

Mechanism of action

Tetracyclines (Table 127.9) inhibit bacterial protein synthesis by binding to the 30 S ribosomal subunit. They are mainly bacteriostatic but may be bactericidal at high concentrations. Tetracyclines are active against many bacteria, including MRSA, *Rickettsia*, *Chlamydia*, and *Mycoplasma* spp. However, they are not active against *Proteus* spp. or *P. aeruginosa*. Tetracyclines also have anti-inflammatory effects, such as inhibition of matrix metalloproteinase activity, leukocyte chemotaxis, and production of proinflammatory cytokines (e.g. TNF, IL-1β).

Indications

Tetracyclines are indicated for acne vulgaris, rosacea, and periorificial dermatitis. They are first-line treatments for rickettsial infections (e.g. Rocky Mountain spotted fever, rickettsialpox, typhus, Q fever, trench fever), Lyme disease, and ehrlichiosis. These agents are used in syphilis (in penicillin-allergic patients), granuloma inguinale, chlamydial infections (including lymphogranuloma venereum and psittacosis), actinomycosis, brucellosis, mycoplasmal pneumonia, and cholera. Tetracyclines are also useful for treating skin infections due to MRSA (e.g. furuncles, purulent cellulitis) as well as MSSA, *Vibrio vulnificus*, and *Mycobacterium marinum*. In addition, tetracyclines are employed for pityriasis lichenoides and in conjunction with nicotinamide for bullous pemphigoid.

Dosages

Doxycycline, minocycline, and sarecycline may be taken with or without food. To decrease the likelihood of esophagitis, the pills should not be "dry swallowed" and should be taken at least half an hour prior to bedtime. Table 127.9 lists the dosages of commonly prescribed tetracyclines.

DOSAGES AND ROUTES OF ADMINISTRATION OF THE TETRACYCLINES

Generic name	Trade name(s)®	Routes of administration	Adult dosage	Dose adjustment for renal impairment
Demeclocycline	Declomycin, Declostatin, Ledermycin	po	300 mg q12 h	Decrease dose and/or increase interval
Doxycycline hyclate	Vibramycin, Vibra-Tabs, Doxy-Caps, Acticlate, Atridox	po	50–100 mg daily–q12 h; 150 mg daily	None
	Periostat		20 mg q12 h (sub-antimicrobial)	
Doxycycline hyclate delayed release	Doryx, Doxteric	po	50–200 mg daily	None
Doxycycline monohydrate	Monodox, Adoxa, Doxyhexal	po	50–100 mg daily–q12 h	None
Doxycycline monohydrate immediate and delayed release	Oracea	po	40 mg daily	Dose adjustment may be considered (per package insert)
Minocycline	Minocin, Dynacin, Vectrin	po	50–100 mg daily–q12 h	Decrease dose and/or increase interval; for CrCl <80 ml/min, do not exceed 200 mg daily
Minocycline extended release	Solodyn	po	45–135 mg daily	Decrease dose and/or increase interval
Oxytetracycline	Terramycin	po, im	250–500 mg q6 h	Decrease dose and/or increase interval
Tetracycline	Panmycin, Sumycin	po,	250–1500 mg/day divided into 2–4 doses	Decrease dose and/or increase interval*
Sarecycline	Seysara	po	60–150 mg daily	No dose adjustment for renal impairment; not studied in end-stage renal disease
Omadacycline	Nuzyra	po, iv	Skin infections: 450 mg po daily on days 1 and 2, then 300 mg po daily; 200 mg iv on day 1, then either 100 mg iv or 300 mg po daily	No dose adjustment, including in end-stage renal disease

*Recommended interval adjustments for dose of 250–500 mg (originally given q6 to q12 h), based on CrCl: if 50–80 ml/min, administer q8 to q12 h; if 10–50 ml/min, administer q12 h to daily; if <10 ml/min, administer daily.

Table 127.9 Dosages and routes of administration of the tetracyclines. Sarecycline is approved for the treatment of moderate to severe, non-nodular, inflammatory acne vulgaris in patients ≥9 years of age but has not been evaluated for the treatment of infections. Omadacycline is indicated for the treatment of community-acquired bacterial pneumonia and bacterial skin infections in adults. CrCl, creatinine clearance; h, hours; im, intramuscularly; iv, intravenously; min, minute; po, orally; q, every.

Contraindications

Tetracyclines should not be administered for a duration >21 days in patients <8 years of age (to avoid tooth discoloration) or in pregnant women (see below). All tetracyclines except doxycycline and omadacycline should be dose-adjusted in patients with renal impairment (see Table 127.9). Sarecycline has not been studied in the setting of end-stage renal disease or severe hepatic impairment.

Major side effects

Common side effects of tetracyclines include gastrointestinal upset, vaginal candidiasis, and phototoxicity (especially doxycycline). Minocycline does not typically lead to overt phototoxicity but may cause diffuse "muddy brown" hyperpigmentation that is accentuated in sun-exposed areas, as well as bluish discoloration of scars (including those due to acne) and normal skin (in particular on the shins) (Fig. 127.7; see Table 67.5). Gray to blue–gray discoloration of the oral mucosa, sclerae, nails, and teeth (including occasional tooth discoloration in adults) can also occur, as can black pigmentation of the thyroid gland. Deposition of tetracyclines in the teeth and bones occurs in children, causing discoloration and hypoplasia of the teeth (deciduous and permanent) and occasionally temporarily stunting growth. Dizziness is another potential side effect of minocycline.

Tetracyclines (especially minocycline) can cause allergic reactions, including urticaria and a minocycline "hypersensitivity syndrome" (drug reaction with eosinophilia and systemic symptoms [DRESS]; see Ch. 21) that often includes pneumonitis as well as hepatitis; these reactions may occur more frequently in Black patients[21]. Tetracyclines have also been associated with serum sickness-like reactions, esophageal ulcerations, infectious enterocolitis, blood dyscrasias, idiopathic intracranial hypertension (risk of which may be increased when given together with a systemic retinoid), nephrotoxicity, nephrogenic diabetes insipidus, and hepatitis. Minocycline use has been linked to a variety of autoimmune conditions, including drug-induced lupus, polyarteritis nodosa, polyarthritis, antiphospholipid antibody syndrome, and autoimmune hepatitis. These autoimmune reactions often develop after a year or more of therapy, and affected individuals frequently have anti-neutrophil cytoplasmic antibodies (ANCA), usually with perinuclear staining and myeloperoxidase specificity, as well as anti-nuclear antibodies (ANA)[22].

Additional adverse effects of omadacycline include infusion site reactions, hypertension, insomnia, and increased mortality compared to moxifloxacin (2% vs 1%) in patients treated for community-acquired bacterial pneumonia.

Interactions

Food decreases the absorption of tetracycline and omadacycline by about 50%. Patients should not eat or drink (other than water) for 2 hours before or 1 hour after taking tetracycline, or for 4 hours before and 2 hours (4 hours

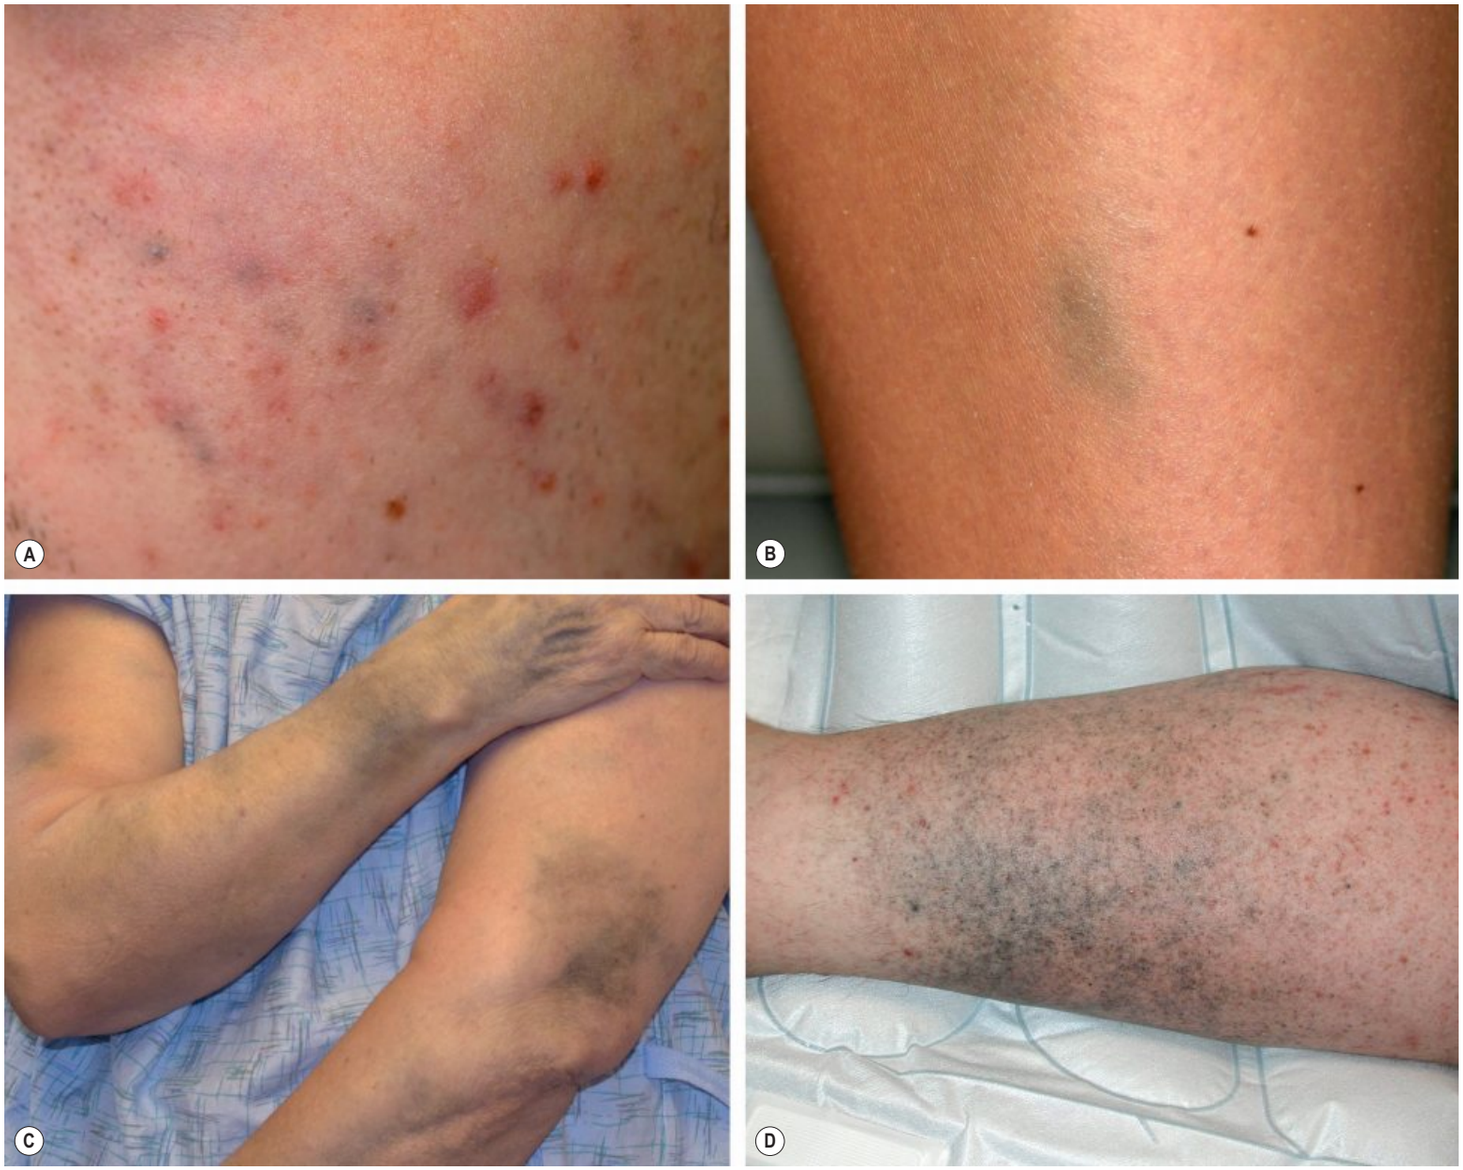

Fig. 127.7 Minocycline pigmentation. Blue–gray discoloration of acne scars (**A**) and in previously normal skin, including a subtle solitary patch on the shin (**B**) as well as more extensive macules and patches (**C, D**). Involvement of the shins and arms may be misdiagnosed as ecchymoses.

for dairy products, antacids, and multivitamins) after taking omadacycline. Minocycline, doxycycline, and sarecycline may be taken with food to avoid gastrointestinal upset. Absorption of tetracyclines is impaired by polyvalent cations such as calcium, aluminum, magnesium, iron, zinc, and bismuth. Thus, absorption of tetracyclines can be inhibited by antacids, some laxatives, medications containing magnesium (e.g. quinapril), dietary supplements, and dairy products (the latter primarily for tetracycline and omadacycline). Antacids, H2 blockers, and proton pump inhibitors can also decrease tetracycline absorption by increasing stomach pH. Tetracyclines increase the serum levels and potential toxicity of digoxin, lithium and warfarin, and they can reduce insulin requirements. Barbiturates, phenytoin, and carbamazepine decrease the half-life of doxycycline. As noted above, bacteriostatic tetracyclines may interfere with the effectiveness of bactericidal penicillins, and coadministration of tetracyclines and oral retinoids may increase the risk of idiopathic intracranial hypertension.

Pregnancy and lactation

Systemic tetracyclines should not be used during pregnancy or lactation. These drugs cross the placenta and are excreted in breast milk, potentially leading to staining of the deciduous teeth, enamel hypoplasia, and impaired skeletal growth in developing fetuses and nursing infants.

Clindamycin

Mechanism of action

Clindamycin is a lincosamide that suppresses bacterial protein synthesis by binding to the bacterial 50S ribosomal subunit. It is active against Gram-positive cocci, including *S. aureus*, *Streptococcus pneumoniae*, *Str. pyogenes*, *Str. viridans*, and anaerobic streptococci. It is not active against enterococci. Clindamycin is also active against anaerobes, including peptostreptococci, peptococci, *Bacteroides* spp., and fusobacteria.

Indications

Clindamycin may be used for anaerobic abscesses, chlamydial infections, and bacterial vaginosis. Clindamycin can be effective in skin infections caused by MRSA as well as MSSA or *Str. pyogenes*, including impetigo, cellulitis, folliculitis, furunculosis, and ecthyma. It may also be useful in necrotizing fasciitis and (considering its inhibition of protein production) toxin-mediated conditions such as staphylococcal scalded skin and toxic shock syndromes. Of note, staphylococci and β-hemolytic streptococci that are sensitive to clindamycin but resistant to erythromycin on initial susceptibility testing should be evaluated with the D (double-disk diffusion)-test for inducible clindamycin resistance. This occurs in bacteria that carry the *erm* gene which encodes erythromycin ribosomal methylase; when expression of this protein is induced (e.g. by erythromycin) or becomes constitutive (selected for during clindamycin therapy), it modifies the bacterial ribosome and results in resistance to both macrolides and lincosamides (see Ch. 74).

Dosages

Clindamycin is formulated for oral, intravenous, and intramuscular administration. It is typically dosed from 150–450 mg 3–4 times daily in adults, and 8–25 mg/kg/day divided into 3–4 doses in children.

Contraindications

Clindamycin is contraindicated in patients with hypersensitivity to the drug and in patients with colitis.

Major side effects

Clindamycin carries a relatively high risk of pseudomembranous colitis, with reported rates from 0.01% to 10%[23]. It occasionally increases serum levels of liver enzymes. Clindamycin may also cause hypersensitivity reactions (especially in HIV-positive patients), transient neutropenia, thrombocytopenia, eosinophilia, and possibly neuromuscular blockade. SJS and TEN are rare side effects.

Interactions

Clindamycin binds at or near the sites of binding of erythromycin and chloramphenicol. These drugs should not be used concomitantly. It may potentiate the neuromuscular effect of botulinum toxin or neuromuscular blockers.

Pregnancy and lactation

There are no known adverse effects of systemic clindamycin on the developing fetus[4]. In rat and mouse studies, oral and subcutaneous clindamycin have not been shown to cause birth defects. Although clindamycin is generally considered to be compatible with breastfeeding[4,20], it may modify the bowel flora of nursing infants and can potentially interfere with the interpretation of bacterial culture results obtained in a febrile nursing infant.

Quinolones

Mechanism of action

Quinolones are rapidly bactericidal by inhibiting two bacterial type II topoisomerases, DNA gyrase and topoisomerase IV. They are active against Gram-negative aerobes, staphylococci, and streptococci, but not against anaerobes.

Table 127.10 lists the drugs in this class.

Indications

Quinolones are indicated for sinusitis, acute exacerbations of chronic bronchitis, community acquired pneumonia, urinary tract infections, gastrointestinal infections, chlamydia, osteomyelitis, and some skin and soft tissue infections.

Second-generation quinolones (e.g. ciprofloxacin, ofloxacin, norfloxacin) have good coverage of Gram-negative rods and some Gram-positive coverage, and they are the most potent antipseudomonal quinolones. Third-generation quinolones (e.g. levofloxacin) are broad spectrum, with coverage of Gram-negative rods and greater Gram-positive cocci coverage, especially of *Streptococcus* spp. Fourth-generation quinolones (e.g. moxifloxacin, gemifloxacin) are very broad spectrum, with coverage of Gram-negative rods, Gram-positive cocci, anaerobes, and atypical bacteria. They have minimal antipseudomonal activity but cover *Streptococcus* spp. and *S. aureus*; however, quinolone resistance to the latter organism can develop rapidly. A newer quinolone, delafloxacin, has activity against MRSA and is approved for bacterial skin infections as well as community-acquired bacterial pneumonia.

Dosages

Ciprofloxacin and levofloxacin are dosed at 250 to 750 mg twice a day. Quinolone doses must be adjusted for renal impairment. Although quinolone use in pediatric patients is generally avoided unless there is no safe and effective alternative[24] (see below), ciprofloxacin 20–40 mg/kg/day in two divided doses has been administered to children.

QUINOLONES			
Generic name	**Trade name(s)®**	**Generation**	**Routes of administration**
Alatrofloxacin*	Trovan IV	4th	iv, im
Ciprofloxacin	Cipro	2nd	po, iv
Delafloxacin	Baxdela		po, iv
Enoxacin*	Penetrex	2nd	po
Gatifloxacin*	Tequin	4th	po, iv
Gemifloxacin	Factive	4th	po
Levofloxacin	Levaquin	3rd	po, iv
Lomefloxacin*	Maxaquin	2nd	po
Moxifloxacin	Avelox	4th	po
Norfloxacin*	Chibroxin, Noroxin	2nd	po
Ofloxacin	Floxin	2nd	po, iv
Sparfloxacin*	Zagam	3rd	po
Trovafloxacin*	Trovan	4th	po, iv

*Withdrawn from US market.

Table 127.10 Quinolones. im, intramuscularly; iv, intravenously; po, orally.

Contraindications

Quinolones are contraindicated in patients with QT prolongation or hypokalemia as well as in those with a history of hypersensitivity to this drug class. Quinolones are also avoided, if possible, during pregnancy and in patients under 18 years of age because of a potential risk of arthropathy and tendinopathy (see below).

Major side effects

In studies involving juvenile animals, quinolones have been shown to damage cartilage in weight-bearing joints. However, quinolones have been used to treat children with cystic fibrosis, and a systematic literature review found that joint changes (most often arthralgias or stiffness) were reversible and affected <1.5% (232/16 184) of pediatric patients treated with ciprofloxacin[24]. Quinolones may cause gastrointestinal upset, changes in taste, abnormal liver function tests, phototoxicity, nephrotoxicity, headache, dizziness, lightheadedness, drowsiness and, rarely, increased intracranial pressure and seizures. Rupture of tendons, in particular the Achilles tendon, is occasionally observed. Exacerbation of myasthenia gravis has also been described, and gatifloxacin has been associated with dysglycemia.

Interactions

Cations (e.g. calcium, aluminum, magnesium, iron, and zinc salts), antacids, and sucralfate prevent absorption of quinolones. Quinolones increase serum levels and potential toxicities of caffeine, theophylline, and aminophylline due to CYP1A2 inhibition. They may also increase serum levels of warfarin. Use of quinolones in combination with cyclosporine may increase serum creatinine levels in renal transplant patients. Quinolones can also increase circulating levels of procainamide by decreasing its renal clearance.

Quinolones should be used with caution in patients who are taking antiarrhythmics, erythromycin, antipsychotics, tricyclic antidepressants, or other drugs that can cause QT prolongation or lower the seizure threshold. Quinolones may also increase seizure risk if administered with NSAIDs. Use of gatifloxacin, or to a lesser degree other quinolones, in combination with sulfonylureas increases the risk of hypoglycemia, especially in elderly patients.

Pregnancy and lactation

Quinolones should be avoided during pregnancy or nursing because of the arthropathy identified in animal studies.

Metronidazole

Mechanism of action

Metronidazole is an nitroimidazole. Its mechanism of action is thought to be due to DNA strand breaking.

Indications

In addition to its antiprotozoal actions, metronidazole has activity against anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* spp.), anaerobic Gram-negative bacilli (including *Bacteroides* and *Fusobacterium* spp.), and anaerobic Gram-positive bacilli (including *Clostridium* spp.). It is indicated for trichomoniasis, amebiasis, and anaerobic bacterial infections. Metronidazole has been utilized for skin and soft tissue infections; oral and dental infections; intra-abdominal, pelvic and brain abscesses; anaerobic pulmonary infections; and osteomyelitis. It is used in combination with a broad-spectrum β-lactamase inhibitor–penicillin combination to treat Fournier gangrene. Metronidazole is also used to treat giardiasis, New World mucocutaneous leishmaniasis, and bacterial vaginosis. Another nitroimidazole, *secnidazole*, was recently approved for the treatment of bacterial vaginosis and trichomoniasis via a single oral dose (2 g) in patients ≥12 years of age.

Dosages

Metronidazole is available for oral and intravenous administration. For bacterial infections, it is given as 500 mg orally every 6 to 8 hours for 7 to 14 days. For bacterial vaginosis or trichomoniasis, a single 2 g dose is given or 500 mg may be taken twice a day for 7 days. The pediatric dose is 30 mg/kg/day in divided doses every 6 hours.

Contraindications

Metronidazole is contraindicated in patients with prior hypersensitivity to the drug. It should be used with caution in patients with impaired liver function.

Major side effects

Metronidazole can cause a morbilliform or pityriasis rosea-like eruption, pruritus, fever, gastrointestinal disturbances, a metallic taste, and xerostomia. Other potential adverse effects include thrombophlebitis, transient leukopenia, dark urine, and neurologic symptoms (e.g. headache, confusion, syncope, seizures, sensory neuropathy).

Interactions

Metronidazole increases circulating levels of cyclosporine, tacrolimus, and phenytoin; it may increase the anticoagulant effect of warfarin. Metronidazole can cause a disulfiram-like reaction when combined with ethanol or protease inhibitors, and administration of metronidazole with disulfiram may precipitate psychosis. Metronidazole may increase the risk of neuropathy due to reverse transcriptase inhibitors.

Pregnancy and lactation

Although metronidazole crosses the placenta, multiple cross-sectional and cohort studies in pregnant women have shown no teratogenicity or mutagenic effects on the developing human fetus. The CDC therefore no longer recommends that metronidazole be avoided during the first trimester of pregnancy. Metronidazole is secreted in breast milk, but reported series have not shown adverse effects in exposed nursing infants. Its use is thought to be compatible with breastfeeding[4,20], although some clinicians recommend deferring nursing for 24 hours following treatment with a single 2 g dose.

Other Antibacterial Agents Used in Gram-Positive Skin Infections

In addition to vancomycin, *linezolid* and *tedizolid* (oxazolidinones), *quinupristin/dalfopristin* (streptogramins), and *tigecycline* (a glycylcycline) can be used to treat serious streptococcal and staphylococcal skin infections, including MRSA (Table 127.11). These three latter antibiotic classes inhibit bacterial protein synthesis (see Table 127.4). *Vancomycin*, a cyclic glycopeptide, and related lipoglycopeptides (e.g. *dalbavancin*, *oritavancin*, *telavancin*) bind to peptidoglycan and thereby inhibit bacterial cell wall synthesis (see Fig. 127.3); in addition, oritavancin and telavancin disrupt bacterial membrane integrity. *Daptomycin*, a cyclic lipopeptide used for complicated skin infections, also kills bacteria by its effects on cell membranes, resulting in depolarization that inhibits protein and nucleic acid synthesis. Table 127.11 outlines the indications, dosages, and side effects of these antibacterial agents.

Dapsone

The oral form of dapsone, a sulfone drug that is used in combination therapy for leprosy and for the treatment of neutrophilic dermatoses, is discussed in Chapters 31 and 130.

ANTIFUNGAL AND ANTIVIRAL AGENTS

ANTIFUNGAL AGENTS

Localized superficial dermatophytoses usually respond to topical antifungal agents (Table 127.12), which rarely have serious side effects. Several of these products are available without a prescription. Fungal infections of the hair and nails as well as systemic mycoses generally require systemic antifungal medications. In addition, fungal skin infections in patients who are immunocompromised, have extensive areas of involvement, or fail to respond to topical therapy may need systemic treatment.

Mechanisms of Action

The mechanisms of action of antifungal agents are outlined in Table 127.13 and illustrated in Figures 127.8 and 127.9. Most azoles

OTHER ANTIBACTERIAL AGENTS USED IN GRAM-POSITIVE SKIN INFECTIONS					
Generic name	**Trade name(s)®**	**Formulations**	**Indications and dosing**	**Data on use during pregnancy***	**Major side effects**
Oxazolidinones					
Linezolid	Zyvox	600 mg tablet 100 mg/5 ml oral suspension iv	Skin infections (e.g. with MRSA): 10 mg/kg up to 400–600 mg po or (if complicated) iv q12 h† × 7–14 days Adjust dose for renal impairment	Potential fetal risk based on animal studies	Headache, insomnia, diarrhea (occasionally due to *Clostridium difficile*), nausea/vomiting, bone marrow suppression (thrombocytopenia > anemia or leukopenia; especially if treated >14 days), neuropathy (peripheral or optic; primarily if treated >28 days), pancreatitis, elevated transaminase levels, lactic acidosis (rare), serotonin syndrome (when taken concurrently with other MAOIs, SSRIs or tricyclics), hypertension (when taken with α-agonist drugs)
Tedizolid	Sivextro	200 mg tablet iv	Acute Gram-positive skin infections in adults: 200 mg po or iv q24 h × 6 days	Potential fetal risk based on animal studies	Headache, nausea/vomiting, diarrhea (occasionally due to *Clostridium difficile*), dizziness, bone marrow suppression (anemia or thrombocytopenia > neutropenia), neuropathy (peripheral or optic); drug interactions potentially leading to serotonin syndrome or hypertension (see linezolid above)
Glycopeptides‡					
Vancomycin	Vancocin	iv¶	Serious infections due to MRSA or other Gram-positive bacteria: 500 mg iv q6 h or 1 g q12 h in adults; 10 mg/kg iv q6 h in children Adjust dose for renal impairment	Animal studies have not shown fetal risk	Nephrotoxicity (increased risk if given together with aminoglycosides or other nephrotoxic drugs), infusion site reactions, hypotension and vancomycin flushing syndrome, ototoxicity, neutropenia, nausea/vomiting, diarrhea (occasionally due to *C. difficile*); occasionally other drug eruptions, including linear IgA bullous dermatosis
Lipoglycopeptides					
Telavancin	Vibativ	iv	Complicated skin infections due to MRSA or other Gram-positive bacteria: 10 mg/kg iv q24 h × 7–14 days Adjust dose for renal impairment	Potential fetal risk based on animal studies	Nephrotoxicity, infusion site reactions, flushing syndrome, QT prolongation, headache, insomnia, foamy urine, dysgeusia, nausea/vomiting, diarrhea (occasionally due to *C. difficile*)
Oritavancin	Orbactiv	iv	Acute Gram-positive skin infections in adults: 1200 mg iv as *single dose*	Animal studies have not shown fetal risk	Headache, nausea/vomiting, diarrhea (occasionally due to *C. difficile*), pruritus, infusion site reactions, flushing syndrome, dizziness, tachycardia, elevated hepatic transaminases; abscesses and osteomyelitis, perhaps due to incomplete bacterial clearance; falsely elevates aPTT for 120 hours (iv unfractionated heparin is contraindicated during this period) and PT/INR for 12 hours; may increase warfarin levels
Dalbavancin	Dalvance	iv	Acute Gram-positive skin infections in adults: 1500 mg iv as single dose, or 1000 mg iv on day 1 + 500 mg iv on day 8 Adjust dose for renal impairment	Animal studies have not shown fetal risk	Headache, nausea/vomiting, diarrhea (occasionally due to *C. difficile*), pruritus, flushing syndrome, elevated hepatic transaminases
Lipopeptides					
Daptomycin	Cubicin	iv	Complicated Gram-positive skin infections: 4 mg/kg iv q24 h × 7–14 days Adjust dose for renal or hepatic impairment	Animal studies have not shown fetal risk	Constipation, diarrhea, nausea/vomiting, headache, insomnia, morbilliform eruptions, infusion site reactions, elevated transaminase and creatine kinase levels, myopathy (at higher doses), nephrotoxicity, eosinophilic pneumonia (rare)
Others					
Quinupristin/dalfopristin	Synercid	iv	Serious skin infections due to *S. aureus* or *Str. pyogenes*: 7.5 mg/kg iv q12 h	Animal studies have not shown fetal risk	Hyperbilirubinemia, infusion site reactions, arthralgias/myalgias, headache, nausea/vomiting, diarrhea (occasionally due to *C. difficile*)
Tigecycline	Tygacil	iv	Complicated skin infections: 50 mg iv q12 h × 5–14 days Adjust dose for hepatic impairment	Fetal risk (inhibition of bone growth, tooth discoloration) with use in 2nd and 3rd trimesters based on animal studies	Nausea/vomiting, diarrhea (occasionally due to *C. difficile*), abdominal pain, headache, infusion site reactions, tooth discoloration (if age <8 years), anaphylaxis/hypersensitivity§, photosensitivity, pancreatitis, hepatic dysfunction, pseudotumor cerebri; black box warning for increased all-cause mortality; use only if no alternatives are available

*These medications should only be used during pregnancy if the potential maternal benefits outweigh the fetal risks; there are no adequate human studies on the use of these agents during pregnancy.
†Every 8 hours for children with complicated infections or who are <5 years of age.
‡Additional glycopeptide antibiotics not available in the US include teicoplanin.
¶Oral capsules and solution with minimal systemic absorption are also available to treat *C. difficile*-associated diarrhea and staphylococcal enterocolitis.
§Cross-reacts with tetracyclines.

Table 127.11 Other antibacterial agents used in Gram-positive skin infections. aPTT, activated partial thromboplastin time; INR, international normalized ratio; MAOI, monoamine oxidase inhibitor; MRSA, methicillin-resistant *Staphylococcus aureus*; PT, prothrombin time; SSRI, selective serotonin reuptake inhibitor. h, hours; iv, intravenous(ly); po, orally; q, every.

TOPICAL ANTIFUNGAL AGENTS				
Generic name	**Trade name(s)®**	**Formulation(s)**	**Considered safe to use during pregnancy***	**OTC/Rx**
Imidazoles				
Butoconazole	Femstat-3, Gynazole-1, Mycelex-3	2% vaginal cream		OTC
Clotrimazole	Canesten, Clotrimaderm, Cruex, Desenex AF, FemCare, Gyne-Lotrimin, Lotrimin AF, Mycelex, Myclo, Myclo-Gyne, Neo-Zol	1% lotion, solution, cream, aerosol solution, lozenges, troches, powder	√	OTC, Rx
Econazole	Spectazole, Ecostatin	1% cream, lotion, spray		Rx
Efinaconazole	Jublia	10% topical solution		Rx
Ketoconazole	Nizoral, Nizoral AD shampoo, Extina, Xolegel	2% cream, gel, foam; 1% and 2% shampoo		OTC, Rx
Luliconazole	Luzu	1% cream		Rx
Miconazole	Femizol-M, Micatin, Micozole, Monistat, Monistat-Derm, Triple Paste AF, Vusion, Zeasorb AF	2% cream, lotion, powder, aerosol powder, aerosol solution; 0.25% ointment (with zinc oxide)		OTC, Rx
Oxiconazole	Myfungar, Oceral, Oceral GB, Okinazole, Oxistat, Oxizole	1% cream, lotion	√	Rx
Sertaconazole	Ertaczo	2% cream		Rx
Sulconazole	Exelderm, Sulcosyn	1% cream, solution		Rx
Terconazole	Fungistat 3 or 5, Terazol 3 or 7, Tercospor	0.4% and 0.8% vaginal cream, 80 mg vaginal suppositories		Rx
Tioconazole	GyneCure, Trosyd AF, Trosyd J, Vagistat 1	20% nail lacquer, 6.5% vaginal cream, ointment		OTC
Allylamines				
Naftifine	Naftin	1% cream and gel, 2% gel	√	Rx
Terbinafine	Lamisil, Lamifen	1% cream, solution, aerosol solution	√	OTC
Benzylamine				
Butenafine	Mentax, Lotrimin Ultra	1% cream		OTC, Rx
Polyenes				
Nystatin	Acronistina, Barstatin, Bio-Statin, Candio, Canstat, Kandistatin, Korostatin, Lystin, Micostatin, Moronal, Mycostatin, Mycostatine, Mykinac, Mytrex, Nadostine, Nilstat, Nyaderm, Nystacid, Nystan, Nystex, Nystop, O-V Statin, Pedi-Dri	100 000 USP units/g cream, ointment, powder, oral suspension, lozenges (pastilles), vaginal tablets	√ (for pastilles)	Rx
Amphotericin B†	Fungizone	3% cream, ointment, lotion	√	Rx
Others				
Ciclopirox olamine	Batrafen, Batrafen Nail Lacquer, Brumixol, Ciclochem, Fungowas, Loprox, Miclast, Micoxolamina, Mycoster, Nail Batrafen, Penlac, Primax	0.77% and 1% cream, gel, lotion, solution, 8% nail lacquer	√	Rx
Tavaborole	Kerydin	5% solution		Rx
Tolnaftate	Aftate, Equate, Genaspore, NP-27, Pitrex, Tinactin, Ting	1% cream, gel, powder, solution, aerosol liquid, aerosol powder		OTC
Undecylenic acid	Caldesene, Cruex, Decylenes, Gordochom	20% cream, 25% ointment, solution, 15% powder, aerosol foam, aerosol powder		OTC
Clioquinol†	Vioform HC, Lococorten-Vioform	3% clioquinol with 1% hydrocortisone or 0.02% flumethasone in a cream or ointment		–
Iodoquinol (iodochlorhydroxyquin)‡	Alcortin, Vytone	1% iodoquinol with 2% hydrocortisone gel		Rx

*Formerly FDA pregnancy category B. However, topical administration of all the listed agents typically results in minimal systemic absorption.
†Not currently available in the US.
‡A synthetic hydroxyquinoline with both antifungal and antibacterial effects.

Table 127.12 Topical antifungal agents. Topical agents with antifungal activity not listed in this table include Whitfield's ointment (benzoic acid and salicylic acid), selenium sulfide, sodium thiosulfate, salicylic acid plus sulfur, zinc pyrithione, haloprogin, mafenide, amorolfine, propylene glycol and benzoyl peroxide. OTC, over the counter; Rx, prescription.

are fungistatic, although some are fungicidal at high concentrations. Allylamines, benzylamines, and ciclopirox olamine have both fungistatic and fungicidal effects. The polyene antifungal agents – nystatin and amphotericin B – are fungistatic at low concentrations and fungicidal at high concentrations. Amphotericin B is available in three lipid formulations (liposomal, lipid complex, and cholesteryl complex [colloidal dispersion]) that are less nephrotoxic but more expensive than the conventional form of this agent.

MECHANISM OF ACTION OF ANTIFUNGAL DRUGS	
Drug class(es)	**Mechanism of action**
Allylamines Benzylamines Tolnaftate (a thiocarbamate)	Interferes with cell membrane synthesis via inhibition of squalene epoxidase, which is required for lanosterol formation; the resultant accumulation of intracellular squalene is fungicidal
Ciclopirox olamine (a hydroxypyridone)	Chelates polyvalent cations (e.g. Fe^{3+}) that have important functions in fungal cytochromes, catalases, and peroxidases; it thereby inhibits respiration, blocks transport of amino acids and alters cell membrane permeability
Echinocandins Ibrexafungerp (a triterpenoid)	Interfere with cell wall synthesis/permeability via inhibition of β-(1,3)-D-glucan synthesis
Flucytosine	Cytosine analogue that interferes with DNA synthesis
Griseofulvin	Disrupts mitotic spindle by interacting with microtubules, thereby inhibiting mitosis in dermatophytes
Imidazoles Triazoles	Interfere with cell membrane synthesis via inhibition of the fungal cytochrome P450-dependent 14-α-demethylase, which normally converts lanosterol to 14-demethyl lanosterol; this leads to accumulation of toxic 14-α-methyl sterols and prevents synthesis of ergosterol, which is required for structural integrity of the fungal cell membrane; these drugs may also impair fungal triglyceride/phospholipid synthesis and inhibit fungal oxidative/peroxidase enzymes (resulting in accumulation of toxic levels of hydrogen peroxide)
Polyenes	Bind irreversibly to cell membrane sterols (e.g. ergosterol) and increase membrane permeability
Selenium sulfide	Antimitotic properties; reduces cellular adhesion in the stratum corneum, facilitating shedding of fungi
Tavaborole (an oxaborole)	Blocks fungal protein synthesis via inhibition of the fungal leucyl-transfer ribonucleic acid (tRNA) synthetase

Table 127.13 Mechanism of action of antifungal drugs. In addition to antifungal effects, these agents have anti-inflammatory properties (see text).

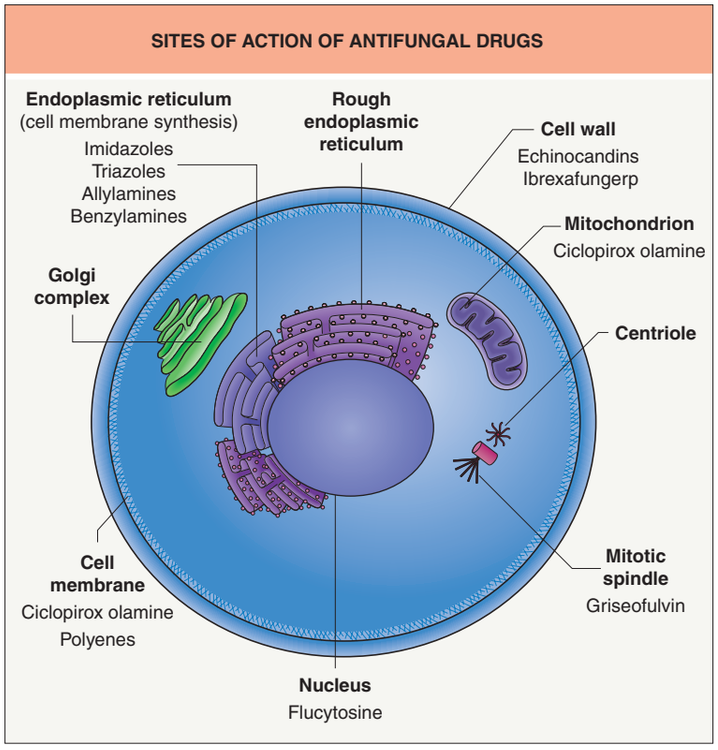

Fig. 127.8 Sites of action of antifungal drugs. Of note, ciclopirox olamine has more than one site of action. In addition, tavaborole inhibits a fungal aminoacyl-tRNA synthetase.

The aforementioned classes of antifungal agents all have anti-inflammatory effects. For example, naftifine inhibits chemotaxis and the production of reactive oxygen intermediates by neutrophils. Azoles inhibit neutrophil chemotaxis, calmodulin activity, synthesis of leukotrienes and prostaglandins, and histamine release from mast cells. Ketoconazole has anti-inflammatory activity comparable to that of hydrocortisone[25]. Ciclopirox olamine is also anti-inflammatory due to its inhibition of prostaglandin and leukotriene synthesis.

Griseofulvin is fungistatic against *Trichophyton*, *Microsporum*, and *Epidermophyton* spp. It is not active against yeast (including *Malassezia* and *Cryptococcus* spp.), dimorphic fungi, or the fungi that cause chromomycosis.

Indications

Topical antifungal agents

Topical azoles are indicated for tinea corporis, tinea pedis, tinea cruris, tinea (pityriasis) versicolor, and mucocutaneous candidiasis. In addition, *efinaconazole* 10% solution has been approved for the topical treatment of onychomycosis due to *Trichophyton rubrum* and *T. mentagrophytes*, with a combined clinical and mycologic cure rate of 15%–20% after daily application for 48 weeks. Of the topical azoles, oxiconazole and sulconazole have relatively weak activity against *Candida* spp. Butoconazole, clotrimazole, econazole, miconazole, terconazole, and tioconazole are available in vaginal preparations to treat *Candida* vaginitis. *Ketoconazole* is additionally indicated for seborrheic dermatitis. Topical antifungal therapy for limited tinea versicolor may have equivalent or better efficacy than oral therapy, with fewer side effects[26].

Topical allylamines and *benzylamines* are indicated for tinea pedis, tinea cruris, and tinea corporis. *In vitro*, butenafine and terbinafine have been shown to be 10 to 100 times and 2 to 30 times more effective than azole antifungals against common dermatophytes, respectively[27,28]. Clinical trials have shown that terbinafine, butenafine, and naftifine were superior to azole antifungals for tinea pedis, with significantly higher mycologic cure rates a month after stopping treatment and lower clinical relapse rates[27,29]. Butenafine 1% cream applied daily for 2 weeks for tinea cruris resulted in a 62% combined clinical and mycologic cure rate 4 weeks after the end of treatment[30]. *Topical terbinafine* and *butenafine* are also indicated for *Candida* infections, although they have relatively weak anti-*Candida* action compared to the topical azoles. In some geographic regions (e.g. India), isolates of *Trichophyton* with increasing resistance to terbinafine have been observed due to mutations in the gene that encodes squalene epoxidase[31].

Of the two topical polyenes, only *nystatin* is commonly used. It is indicated for mucocutaneous *Candida* infections. Polyenes are not effective against dermatophytes[32]. Nystatin is not well absorbed when taken orally. However, this fact may be used to an advantage in treating anogenital candidiasis and candidal diaper dermatitis.

Ciclopirox olamine is active against dermatophytes, *Malassezia* spp., *Candida*, actinomycetes, molds, and Gram-positive and Gram-negative bacteria. It is indicated for tinea corporis, tinea pedis, tinea cruris, onychomycosis, tinea versicolor, mucocutaneous candidiasis, and seborrheic dermatitis. *In vitro*, it is less potent against dermatophytes than the allylamine and benzylamine antifungals, but more potent than azole antifungals. However, it is more effective than the azoles, allylamines, or benzylamines against *Candida*.

Tavaborole 5% solution is an oxaborole approved to treat toenail onychomycosis caused by *T. rubrum* and *T. mentagrophytes*. The combined clinical and mycologic cure rate is 6%–10% following daily application for 48 weeks.

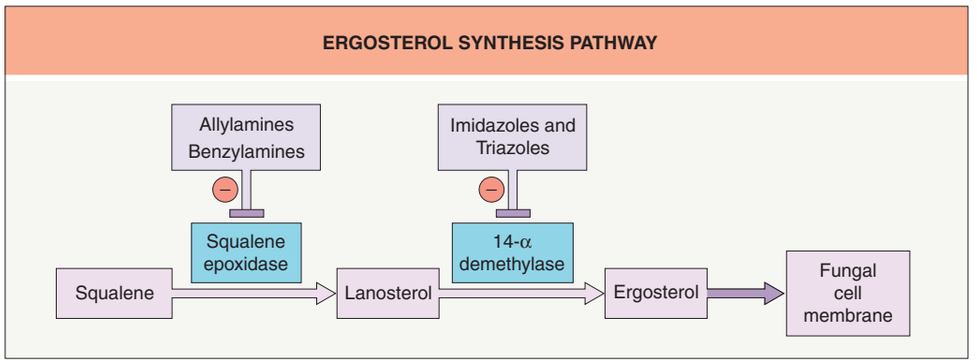

Fig. 127.9 Ergosterol synthesis pathway. Squalene is converted to lanosterol by squalene epoxidase. This enzyme is inhibited by the allylamine and benzylamine antifungals. 14-α demethylase converts lanosterol to ergosterol. Imidazole and triazole antifungals inhibit this conversion.

INDICATIONS FOR SYSTEMIC ANTIFUNGAL AGENTS

Generic name	Antifungal spectra	Indications
Terbinafine	*Epidermophyton floccosum*, *Trichophyton mentagrophytes*, *T. rubrum*, *T. tonsurans*	Onychomycosis Superficial fungal infections: widespread, severe, or resistant to topical antifungals*
Itraconazole	Dermatophytes, yeasts (*Candida*, *Pityrosporum* spp.), dimorphic fungi, some molds	Blastomycosis, histoplasmosis, and aspergillosis (oral and intravenous); onychomycosis (oral); oropharyngeal and esophageal candidiasis (solution) Superficial fungal infections: widespread, severe, or resistant to topical antifungals*
Fluconazole	*Candida* spp., *T. tonsurans*, *T. rubrum*, *Microsporum canis*	Oropharyngeal, esophageal, vaginal, and systemic candidiasis Cryptococcal meningitis Superficial fungal infections resistant to topical antifungals*
Voriconazole	*Aspergillus*, *Candida*, *Fusarium*, *Scedosporium* spp.	Invasive aspergillosis (superior to amphotericin B), disseminated or esophageal candidiasis, serious infections caused by *Fusarium* and *Scedosporium apiospermum*
Posaconazole	*Candida*, *Aspergillus*, *Cryptococcus*, *Fusarium*, *Zygomycetes* spp.	Prevention of invasive aspergillosis and *Candida* infections in immunosuppressed hosts Treatment of oropharyngeal candidiasis, especially if resistant to other azoles
Isavuconazonium sulfate (isavuconazole)	*Candida, Aspergillus, and Cryptococcus* spp.; Zygomycetes; dimorphic fungi	Invasive aspergillosis and mucormycosis
Oteseconazole	*Candida* spp.	Recurrent vulvovaginal candidiasis
Griseofulvin	*Trichophyton*, *Microsporum*, *Epidermophyton* spp. (no activity against *Candida* or *Malassezia* spp.)	Tinea capitis and onychomycosis Superficial fungal infections: widespread, severe or resistant to topical antifungals
Amphotericin B	*Candida* spp., *Cryptococcus neoformans*, dimorphic fungi (*Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*), *Aspergillus* spp.	Severe fungal infections including disseminated systemic candidiasis, cryptococcal meningitis, blastomycosis, disseminated histoplasmosis, extracutaneous sporotrichosis, coccidioidomycosis, paracoccidioidomycosis, mucormycosis, and aspergillosis
Flucytosine	*Candida*, *Cryptococcus*, *Aspergillus* spp., agents of chromomycosis	Second-line or combination therapy for severe fungal infections including candidiasis, cryptococcosis, aspergillosis, and chromomycosis
Caspofungin acetate†	*Aspergillus fumigatus*, *A. flavus*, *A. terrus*, *Candida* spp.	Invasive aspergillosis in patients refractory to or intolerant of other antifungals, candidemia, esophageal candidiasis
Micafungin†	*Candida*, *Aspergillus* spp.	Prophylaxis for *Candida* infections in hematopoietic stem cell transplant patients, esophageal candidiasis
Anidulafungin†	*Candida*, *Aspergillus* spp.	Candidemia, esophageal candidiasis, intra-abdominal *Candida* infections and peritonitis
Ibrexafungerp	*Candida*, *Aspergillus* spp.	Vulvovaginal candidiasis
Ketoconazole	Most dermatophytes, *Candida* spp., dimorphic fungi	Systemic fungal infections in patients who have failed or are intolerant to other therapies: histoplasmosis, coccidioidomycosis, blastomycosis

*Resistant superficial fungal infections treated by systemic terbinafine and azole antifungals include tinea corporis, tinea cruris and tinea pedis. The azoles are also used for tinea versicolor.
†Members of the echinocandin class of antifungal drugs.

Table 127.14 Indications for systemic antifungal agents. Fosravuconazole is approved in Japan for the treatment of onychomycosis. The use of flucytosine is declining, but it is still given in certain situations.

Tolnaftate, *undecylenic acid*, and *clioquinol* are indicated for dermatophyte infections, but they are less efficacious than the aforementioned topical agents; tolnaftate is also effective for *Malassezia* infections.

Systemic antifungal agents

Indications for systemic antifungal agents are outlined in Table 127.14. *Griseofulvin* is classically the drug of choice for treating dermatophyte infections resistant to topical therapy in children. Mycologic cure rates are usually 80% to 95%. *Terbinafine*, *itraconazole*, and *fluconazole* are also effective in treating superficial dermatophyte infections of the skin, hair, and nails in adults and children. Terbinafine therapy for onychomycosis results in a mycologic cure rate of ~70% for the toenails and 80% for fingernails, but there are significant recurrence rates, especially for toenails. Itraconazole, used continuously or in a pulse regimen, produces

similar mycologic cure rates. Terbinafine has been shown to have a higher combined clinical and mycologic cure rate than itraconazole (38% vs 23%, $p=0.004$) after 12 weeks of continuous oral therapy for toenail onychomycosis[33]. Fluconazole is generally the drug of choice for systemic candidiasis. However, fungemia due to azole-resistant *Candida* can occur. Because fluconazole is relatively hydrophilic compared to other systemic azole antifungal drugs, it is distributed to the cerebrospinal fluid and can be used to treat fungal meningitis. *Oteseconazole* is FDA approved for the treatment of recurrent vulvovaginal candidiasis in women who do not have reproductive potential. *Ibrexafungerp* is also approved for the treatment and prevention of recurrences of vulvovaginal candidiasis in women and post-menarchal girls.

DOSING OF TERBINAFINE	
Oral tablets	
Adults	250 mg daily
Children over 2 years old and under 20 kg	62.5 mg daily
Children over 2 years old and 20–40 kg	125 mg daily
Children over 2 years old and over 40 kg	250 mg daily

Table 127.15 Dosing of terbinafine. Terbinafine comes in 250 mg tablets. 125 mg or 187.5 mg packets of granules were previously available; dosage was weight-based and the granules were taken after sprinkling on a non-acidic, non-fruity, soft food.

Dosages

Topical antifungal agents

Topical antifungal agents are generally applied twice a day until resolution of clinical signs and symptoms, usually for 1 to 4 weeks. Occlusion is not required. Shampoos are typically used every 3 to 4 days and are left in place for 5 minutes before rinsing. *Nystatin* oral suspension is held in the mouth for as long as possible before swallowing or expectorating, repeated four times daily. There is essentially no systemic absorption. Nystatin pastilles are allowed to dissolve slowly in the mouth four to five times a day for up to 14 days. *Ciclopirox olamine* nail lacquer is applied daily for 1 week and then removed with alcohol; this cycle is repeated for 48 weeks. *Efinaconazole* and *tavaborole* solutions are also applied daily for 48 weeks but do not require periodic removal. Each of these drugs can have some efficacy when applied over cosmetic nail polish, with an increase to twice daily use recommended for ciclopirox olamine.

Systemic antifungal agents

A typical treatment course of oral *terbinafine* is 12 weeks for toenail onychomycosis, 6 weeks for fingernail onychomycosis, and 2 weeks for superficial tinea infections resistant to topical antifungal agents. For tinea capitis, terbinafine is given continuously for 3–6 weeks. Dosages for adults and children are shown in Table 127.15.

Due to potential toxicity, oral *ketoconazole* is no longer routinely utilized for fungal infections of the skin or nails, including candidiasis and dermatophyte infections. Its use should be restricted to treatment of endemic mycoses (e.g. blastomycosis, coccidioidomycosis) in patients who have failed or are intolerant of other therapies.

Itraconazole oral solution should be taken on an empty stomach, whereas the capsules should be taken with a full meal to enhance absorption. Pediatric dosing is 3 to 5 mg/kg daily. Doses over 200 mg should be divided into two doses per day. For tinea capitis in children, itraconazole may be given continuously for 2 to 4 weeks or as 1- to 3-week-long pulses with 3 weeks without drug in between each pulse. Adult oral dosages for various indications are outlined in Table 127.16. Treatment of oropharyngeal and esophageal candidiasis is for at least 3 weeks and should be continued for at least 2 weeks after symptoms resolve. Itraconazole solution is swished in the mouth, 10 mg at a time, for several seconds and then swallowed.

Table 127.17 outlines the oral dosing of *fluconazole*. Unlike itraconazole, fluconazole is not dependent on a low gastric pH for absorption.

Voriconazole is used to treat serious fungal infections in patients ≥2 years of age. The recommended dose for adults is 4 mg/kg intravenously every 12 hours (following two loading doses of 6 mg/kg 12 hours apart) or 200 mg orally every 12 hours. For children ages ≤11 years or those 12–14 years weighing <50 kg, the usual dose is 8 mg/kg intravenously every 12 hours (following two loading doses of 9 mg/kg 12 hours apart) or 8 mg/kg (maximum 350 mg) orally every 12 hours. Dose adjustments should be made in patients with hepatic dysfunction, and oral administration is preferred in patients with renal impairment to avoid accumulation of the intravenous vehicle. In immunocompromised patients, such as recipients of hematopoietic stem cell transplants, the prophylactic regimen is typically the same oral dose used for treatment twice daily.

Posaconazole is available as 100 mg delayed-release (DR) tablets and a 40 mg/ml suspension, both taken with food and approved for patients ≥13 years of age. Intravenous administration is also approved for adults. For prophylaxis of invasive fungal infections in immunocompromised patients, the oral dosage is 200 mg three times daily of the suspension, or 300 mg twice daily on the first day and then 300 mg daily of the DR tablets. For oropharyngeal candidiasis, the oral suspension is given as 100 mg twice daily on the first day and then 100 mg daily for 13 days. In cases refractory to fluconazole or itraconazole, the dose is increased to 400 mg orally twice daily, and the duration of treatment varies according to the response[34]. Because of fewer cutaneous side effects (see Table 127.19), posaconazole is often preferred over voriconazole, but its greater cost can limit access.

ADULT DOSING OF ORAL ITRACONAZOLE	
Indication	**Adult dosage**
Tinea versicolor	200 mg po daily for 5–7 days
Tinea corporis, tinea cruris	100 mg po daily for 2 weeks – *or* – 200 mg po daily for 1 week
Tinea pedis	100 mg po daily for 2 weeks – *or* – 200 mg po daily for 1 week
Blastomycosis, histoplasmosis	200 mg po daily May increase by 100 mg increments to a maximum of 400 mg po daily for at least 3 months
Cutaneous sporotrichosis	200 mg po daily for 3–6 months or until 2–4 weeks after all lesions have resolved
Aspergillosis	200–400 mg po daily for at least 3 months May give loading dose of 200 mg TID for first 3 days in life-threatening conditions
Onychomycosis of toenails	200 mg po daily for 12 weeks – *or* – 200 mg po BID for 1 week, then 3 weeks without treatment, repeated twice more for a total of three pulses of therapy
Onychomycosis of fingernails	200 mg po daily for 6 weeks – *or* – 200 mg po BID for 1 week, then 3 weeks without treatment, then 200 mg po BID for 1 week (2 pulses)
Oropharyngeal candidiasis	Swish and swallow 200 mg daily for 1–2 weeks
Oropharyngeal candidiasis refractory to fluconazole	Swish and swallow 100 mg BID
Esophageal candidiasis	Swish and swallow 100–200 mg daily

Table 127.16 Adult dosing of oral itraconazole. Itraconazole is available in 100 mg capsules and a 10 mg/ml cherry-caramel-flavored solution. The safety of itraconazole in children has not been specifically studied. Children 3 to 16 years old have been treated for systemic fungal infections with itraconazole capsules or solution, typically at a dose of 5 mg/kg/day, without any problems. Animal studies have shown teratogenicity at high doses, causing skeletal defects in rats. Of note, itraconazole oral solution contains the excipient hydroxypropyl-β-cyclodextrin, which produced pancreatic adenocarcinomas in rats (but not mice) when given for extended periods. BID, twice daily; po, orally; TID, three times daily.

Isavuconazonium sulfate (prodrug of isavuconazole) is approved for treatment of invasive aspergillosis and mucormycosis in adults. It is available in 74.5 and 186 mg capsules as well as in a solution for intravenous administration, both given as a loading dose of 372 mg (equivalent to 200 mg of isavuconazole) every 8 hours for 6 doses, followed by 372 mg once daily starting 12–24 hours after the last loading dose.

Oteseconazole is available in 150 mg capsules and can be administered alone or in conjunction with initial fluconazole therapy for recurrent vulvovaginal candidiasis. In the oteseconazole-only regimen, 600 mg is

DOSING OF ORAL FLUCONAZOLE		
Indication	**Pediatric dosage**	**Adult dosage**
Tinea versicolor		400 mg once *or* 300 mg once, with possible second dose in 1 week, depending on clinical response
Tinea corporis, tinea cruris	6 mg/kg qwk for 2–4 weeks	50–100 mg daily *or* 150 mg qwk for 2–4 weeks
Tinea pedis	6 mg/kg qwk for 2–6 weeks	150–450 mg qwk for 2–6 weeks
Tinea capitis	6 mg/kg/day for 3–6 weeks	6 mg/kg/day for 3–6 weeks
Onychomycosis	6 mg/kg qwk for 3–4 months (fingernails) or 5–7 months (toenails), or until nails are clear	150–450 mg qwk for 6 months (fingernails) or 9 months (toenails), or until nails are clear
Oropharyngeal candidiasis	6 mg/kg on day 1 then 3 mg/kg q24–72 h for 14 days*	200 mg on day 1 then 100 mg daily for at least 2 weeks
Vaginal candidiasis		150 mg once
Esophageal candidiasis	6 mg/kg on day 1 then 3–12 mg/kg q24–72 h for 21 days*	200 mg on day 1 then 100 mg daily for at least 3 weeks Treat for at least 2 weeks after symptoms resolve
Systemic candidiasis	6–12 mg/kg q24–72 h for 28 days*	800 mg on day 1 then up to 400 mg daily
Prophylaxis of candidiasis in bone marrow transplantation	10–12 mg/kg q24 h (maximum 600 mg/day)	400 mg daily
Cryptococcal meningitis (following induction therapy, typically with a lipid formulation of amphotericin B + flucytosine for ≥2 weeks)	Consolidation: 10–12 mg/kg daily for 8 weeks Maintenance: 6 mg/kg daily for 6–12 months	Consolidation: 400 mg daily for 8 weeks Maintenance: 200 mg daily for 6–12 months
Prevention of relapse of cryptococcal meningitis in HIV patients		200 mg daily
*If the patient is less than 14 days old, dosing is every 24–72 h. If the patient is over 14 days old, dosing is every 24 h.		

Table 127.17 Dosing of oral fluconazole. Fluconazole is available as 50 mg, 100 mg, 150 mg, and 200 mg tablets and as an orange-flavored suspension in 10 mg/ml and 40 mg/ml strengths. Since oral fluconazole is highly bioavailable, intravenous therapy is only required for patients who are unable to take oral medications, expected to have poor gastrointestinal absorption, or severely ill. h, hours; q, every; qwk, weekly.

taken on day 1, then 450 mg on day 2, and then 150 mg weekly for 11 weeks beginning on day 14. Alternatively, fluconazole 150 mg can be given on days 1, 4, and 7, followed by oteseconazole 150 mg daily for 7 days and then weekly for 11 weeks beginning on day 28.

Ibrexafungerp is also available in 150 mg capsules. A 300 mg dose is administered twice, approximately 12 hours apart; this can be done once for treatment of vulvovaginal candidiasis and/or monthly for six months for prevention of recurrences.

Dosages for *griseofulvin* are shown in Table 127.18. In the US, increasing doses have been required for the treatment of tinea capitis due to *Trichophyton tonsurans*. The long duration of therapy required with griseofulvin is a disadvantage and contributes to non-compliance. Absorption of griseofulvin is improved when it is administered with fatty foods. Drug particle size reduction through micronization and ultra-micronization has also significantly enhanced oral absorption.

Dosing of intravenous *amphotericin B* varies depending upon the formulation of the medication (e.g. 0.75–1 mg/kg/day of conventional amphotericin B versus 3–5 mg/kg/day of lipid formulations). In adults, flucytosine is given at a dose of 150 mg/kg orally daily, divided into four doses. Taking the medicine over 15 minutes decreases associated nausea. Doses of both drugs should be adjusted in patients with renal insufficiency.

Caspofungin acetate is given by slow intravenous infusion over 1 hour. For treatment of *Aspergillus* infections, 70 mg is administered on day 1 and 50–70 mg daily thereafter. Caspofungin must not be mixed with solutions containing dextrose, and patients with moderate hepatic insufficiency should receive 35 mg daily after the 70 mg loading dose. This drug has not been adequately studied in children.

Micafungin is also only available in an intravenous form. For esophageal candidiasis, it is administered as 150 mg intravenously daily. In hematopoietic stem cell transplant patients, as prophylaxis for *Candida* infections, it may be given at a dose of 50 mg intravenously daily. *Anidulafungin* is available in an intravenous form for *Candida* infections as well. In candidemia, the dose is 100 mg intravenously daily after a loading dose of 200 mg; treatment should continue until 2 weeks after the most recent positive blood culture. For esophageal candidiasis, the dose is 50 mg daily after an initial loading dose of 100 mg.

ORAL DOSING OF GRISEOFULVIN			
Generic name	**Adult**		**Pediatric (over 2 years of age)**
	Tinea corporis, cruris	**Tinea pedis, manuum, unguium, capitis**	
Griseofulvin microsize* (125 mg/5 ml suspension; 250 and 500 mg tablets)	500–1000 mg daily	750–1500 mg daily	15–20 mg/kg daily (usual maximum 1 g); use higher range of 20–25 mg/kg daily for tinea capitis
Griseofulvin ultramicrosize* (125 and 250 mg tablets)	375–500 mg daily	500–750 mg daily	10–15 mg/kg/day (maximum usually 750 mg/day)
Duration of treatment			
2–4 weeks for tinea corporis 6–12 weeks for tinea capitis 4–6 weeks for tinea pedis 4 months or until nails are clear for fingernail onychomycosis† 6 months or until nails are clear for toenail onychomycosis†			
*To increase absorption, griseofulvin should be taken with a fatty meal. †No longer commonly used for this indication; may require a longer duration of treatment.			

Table 127.18 Oral dosing of griseofulvin.

Contraindications

Topical and systemic antifungals are contraindicated in patients with hypersensitivity to the agent or any of the formulation components. Because of the potential for severe hepatotoxicity and QT prolongation, use of *ketoconazole* should be restricted to systemic fungal infections in patients who have failed or are intolerant to other therapies. Systemic antifungals are contraindicated in patients who are taking other drugs

that may cause potentially serious interactions (see below). *Itraconazole* is contraindicated in patients with left-sided heart disease, and its use for onychomycosis should be avoided in pregnant or lactating patients. Ketoconazole and itraconazole may not be absorbed in patients with achlorhydria. *Fluconazole* absorption, however, is not dependent on a low gastric pH. *Griseofulvin* is contraindicated in patients with acute intermittent porphyria, variegate porphyria, porphyria cutanea tarda, or liver failure; it should not be given to pregnant women (see below). Both *oteseconazole* and *ibrexafungerp* are contraindicated during pregnancy; the latter drug is also contraindicated in all women of reproductive potential and during lactation (see below). All systemic antifungal agents should be used with caution in patients with liver or kidney disease. Flucytosine should be used with caution in patients with bone marrow suppression.

Fig. 127.10 Accelerated photoaging due to chronic voriconazole therapy. Note the solar lentigines in this young man with chronic granulomatous disease. *Courtesy Edward Cowen, MD.*

Major Side Effects

The most common side effect of topical antifungal drugs is local skin irritation, which may be more severe with occlusion. Clinical manifestations include burning, stinging, pruritus, erythema, edema, peeling, blistering, and allergic contact dermatitis. *Clioquinol* can cause discoloration of clothes, skin, hair, and nails.

Oral *terbinafine* may cause a morbilliform eruption and, less commonly, urticaria, pruritus, alopecia, or dermatitis. Additional cutaneous reactions include SJS, TEN, AGEP, flares of pustular or other forms of psoriasis, and subacute cutaneous lupus erythematosus. Non-cutaneous side effects of terbinafine include gastrointestinal disturbances, elevated liver enzymes, headaches, taste and visual disturbances, transient decreases in absolute lymphocyte count, and, rarely, neutropenia in immunosuppressed patients. This drug should be used with caution in patients with liver or kidney disease. It is recommended that liver enzyme tests be performed at baseline, although the utility of monitoring asymptomatic patients during therapy has been questioned[35]. The side effects of the *systemic azole antifungals* are listed in Table 127.19. Side effects of *ibrexafungerp* include diarrhea, nausea/vomiting, abdominal pain, headache, and dizziness.

Griseofulvin infrequently causes adverse effects, most commonly headache and gastrointestinal disturbances. Less often, it leads to cutaneous side effects such as fixed drug eruptions, photosensitivity, petechiae, pruritus, exfoliative dermatitis, urticaria/angioedema, and serum sickness-like reactions. It can also precipitate or exacerbate lupus erythematosus or porphyria. Griseofulvin has occasionally been associated with enuresis, proteinuria, increased urinary frequency, arthralgias, fever, neurologic side effects (confusion, blurred vision, vertigo, depression, nightmares, insomnia, ataxia, paresthesias), syncope, epistaxis, estrogen-like effects, sore throat, hepatotoxicity, and leukopenia.

SIDE EFFECTS OF SYSTEMIC AZOLE ANTIFUNGAL AGENTS	
Generic name	**Side effects**
Itraconazole	• Morbilliform eruption, pruritus, urticaria, alopecia, Stevens–Johnson syndrome (rarely); parenteral administration may result in infusion site reactions • Anorexia, nausea, vomiting, abdominal pain, hepatic dysfunction • Fatigue, headaches, dizziness • Fever, edema, hypokalemia, neutropenia (rarely) • Rarely causes congestive heart failure, pulmonary edema, anaphylaxis, peripheral neuropathy
Fluconazole	• Morbilliform eruption, exfoliative dermatitis (rarely) • Nausea, vomiting, abdominal pain, diarrhea, hepatotoxicity • Headache
Posaconazole	• QT prolongation • Hepatitis • Diarrhea, nausea, vomiting, fever, headache, hypokalemia, neutropenia • Avoid if moderate or severe renal impairment
Voriconazole	• Phototoxicity; this can lead to pseudoporphyria and (with chronic use) accelerated photoaging (Fig. 127.10), aggressive or multifocal cutaneous squamous cell carcinomas (especially in the setting of immunosuppression), and melanoma • Visual disturbances (e.g. blurred vision, altered color perception, photophobia), headache, hallucinations • Nausea, vomiting, diarrhea, abdominal pain, hepatotoxicity • Fever, peripheral edema • QT prolongation
Isavuconazonium sulfate (isavuconazole)	• Nausea, vomiting, diarrhea, hepatic dysfunction • Headache • Hypokalemia • Dyspnea, cough • Peripheral edema
Oteseconazole	• Headache • Nausea
Ketoconazole (FDA has advised against prescribing unless failure of other therapies for systemic fungal infections)	• FDA black box warnings: serious hepatotoxicity, QT prolongation and drug interactions leading to QT prolongation • Nausea, vomiting, abdominal pain • Anaphylaxis, urticaria, pruritus • Adrenocortical insufficiency (at doses ≥400 mg daily), decreased testosterone production

Table 127.19 Side effects of systemic azole antifungal agents.

Amphotericin B commonly causes fever, chills, nausea, and vomiting. Less often, it causes anorexia, diarrhea, orthostatic hypotension, hypertension, tachycardia, dyspnea, headache and skin eruptions, including exanthems, exfoliative dermatitis, fixed drug eruptions, flushing, urticaria, and infusion site reactions. Amphotericin B can also produce hypokalemia, thrombocytopenia, and renal toxicity characterized by increased BUN and creatinine; unusual side effects include seizures, arrhythmias, agranulocytosis, liver failure, and anaphylaxis.

Flucytosine can cause neurologic side effects (headaches, fatigue, vertigo, ataxia, paresthesias, confusion, hallucinations), gastrointestinal disturbances (nausea, vomiting, abdominal pain, diarrhea), hypokalemia, and hypoglycemia. Serious potential side effects include cardiac and respiratory arrest, renal failure, cytopenias, gastrointestinal bleeding, and colitis.

Caspofungin acetate may cause headaches, nausea, vomiting, fever, phlebitis, flushing, facial swelling, urticaria, other rashes, pruritus, infusion reactions, and anaphylaxis. Laboratory abnormalities that have been observed include increased alkaline phosphatase, hypokalemia, eosinophilia, proteinuria, and hematuria. *Micafungin* may uncommonly cause anaphylaxis, liver or kidney dysfunction, thrombophlebitis, and hemolytic anemia. It can also result in headaches, nausea, rigors, leukopenia, rashes, and injection site reactions. *Anidulafungin* may cause liver toxicity, diarrhea, hypokalemia, and infusion reactions.

Interactions

Systemic *terbinafine* inhibits the cytochrome P450 isoform CYP2D6. As such, it may increase serum levels and toxic effects of other drugs metabolized by this pathway, including β-blockers, tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), MAO inhibitors, and type B and class IC antiarrhythmics. Terbinafine increases cyclosporine clearance by 15% and decreases caffeine clearance by 19%. It also decreases the efficacy of codeine. Terbinafine used with thioridazine may cause prolonged QT intervals and arrhythmias. Whereas cimetidine increases terbinafine levels, rifampin decreases terbinafine levels by doubling its rate of clearance.

Azole antifungal drugs exert their therapeutic effect by inhibiting cytochrome P450 enzymes (see Table 127.13 and Ch. 131). Cytochrome P450 enzymes play a major role in transforming lipophilic drugs to more easily excreted metabolites. Inhibition of this enzyme family is the cause of many of the azole antifungals' drug–drug interactions. These interactions, which have resulted in black box warnings by the US FDA, are listed in Table 127.20.

Ibrexafungerp is a substrate of CYP3A. As a result, CYP3A inhibitors (e.g. azole antifungals) increase exposure and CYP3A inducers (e.g. rifampin, phenytoin) reduce exposure to ibrexafungerp.

Griseofulvin may decrease the levels and efficacy of warfarin and salicylates. Barbiturates may decrease griseofulvin efficacy by decreasing its absorption. Griseofulvin potentiates the effect of alcohol or may induce a disulfiram-like reaction. It also increases estrogen-metabolizing liver enzymes, which may make oral contraceptives less effective or cause menstrual irregularities.

Systemic corticosteroids, loop diuretics, and thiazide diuretics increase the risk of developing hypokalemia due to *amphotericin B*. Antipsychotics used concomitantly with amphotericin B may cause QT prolongation and cardiac arrhythmias. Nephrotoxic drugs such as

SELECTED DRUG INTERACTIONS OF SYSTEMIC AZOLE ANTIFUNGAL AGENTS

Interacting drug	Result	Azoles involved
Astemizole, terfenadine, cisapride (banned or restricted)	Arrhythmia, torsade de pointes	K, It, F, V, P, Is
Warfarin	Increased warfarin levels	K, It, F, V, P
Cyclosporine, tacrolimus, sirolimus	Increased levels of interacting drug, nephrotoxicity, neurotoxicity, hypertension	K, It, V, P, Is > F
Mycophenolate mofetil (MMF)	Increased MMF levels	Is
Rifampin, rifamycin, rifabutin	Decreased plasma levels of azole antifungals (K also decreases absorption of rifamycin)	K, It, F, V, P, Is
Phenytoin	Phenytoin causes decreased levels of Is, It, K, and P; F and P cause increased levels of phenytoin	K, It, F, V, P, Is
Sildenafil (Viagra®), tadalafil (Cialis®)	Increased levels of interacting drug	K, It, F, V, P, Is
Oral hypoglycemics	Hypoglycemia	K, It, F, V, P, Is, O
Oral contraceptives	Increased levels of estrogens & progestins; effects on contraception debated	K, It, F, V, Is, O
Antacids, H2 antihistamines, proton pump inhibitors, anticholinergics, didanosine	Decreased gastrointestinal absorption of azole antifungals Administration of omeprazole with V or Is causes increased levels of both drugs	K, Is, It, V, Is
Benzodiazepines	Excessive sedation	K, It, F, V, P, Is
Indinavir	Increased indinavir levels	K, P
Corticosteroids	Increased corticosteroid levels	K, P
Digoxin	Increased digoxin levels	It, F, V, P, Is
HMG-CoA reductase inhibitors/"statins" (e.g. atorvastatin, simvastatin)	Increased statin levels; rhabdomyolysis, myopathy	It, V, P, Is, O
Dihydropyridine calcium channel blockers	Edema	It, V, P, Is
Phenobarbital, carbamazepine, isoniazid, nevirapine	Decreased levels of azole antifungals; increased carbamazepine and nevirapine levels with P	It, V, P, Is
Pimozide, buspirone, quinidine, vincristine	Increased levels of interacting drug	It, V, P, Is
Thiazide diuretics (e.g. HCTZ)	Increased levels of F	F
Theophylline, nucleoside analogues	Increased levels of interacting drug	F, V, P
Ritonavir, lopinavir	Increased levels of interacting drug	It, K, P, Is
Ergotamine, dihydroergotamine	Increased levels of interacting drug	K, It, F, V, P, Is

Table 127.20 Selected drug interactions of systemic azole antifungal agents. Oteseconazole is an inhibitor of the breast cancer resistance protein (BCRP) and can lead to increased levels of BCRP substrates, which include mitoxantrone, methotrexate, topotecan, irinotecan, tyrosine kinase inhibitors (e.g. imatinib, gefitinib), statins, prazosin, glyburide, nitrofurantoin, dipyridamole, statins, and cimetidine. K, ketoconazole; It, itraconazole; F, fluconazole; V, voriconazole, P, posaconazole; Is, isavuconazonium sulfate (isavuconazole); O, oteseconazole.

cisplatin, flucytosine, gentamicin, and vancomycin can compound the nephrotoxicity of amphotericin B. Amphotericin may increase digoxin levels. Cisplatin used in conjunction with *flucytosine* increases the risk for nephrotoxicity and bone marrow suppression.

Caspofungin acetate does not affect the cytochrome P450 system. It does decrease tacrolimus levels, and cyclosporine increases caspofungin levels. Phenytoin, rifampin, dexamethasone, carbamazepine, and several antiretroviral drugs (efavirenz, nelfinavir, nevirapine) can decrease caspofungin levels.

Pregnancy and Lactation

Topical antifungal agents

Topical imidazoles, nystatin, ciclopirox olamine, tolnaftate, and undecylenic acid have not been shown to cause adverse fetal effects when used during pregnancy. Although a small amount of ciclopirox olamine is absorbed through the skin, animal studies involving mice, rats, rabbits, and monkeys showed no harm to the fetus at doses 10 times higher than the topical human dose. In general, topical antifungals are thought to be compatible with breastfeeding[4,20]. Topical oxiconazole is excreted in breast milk, but it is not known whether other topical imidazoles, nystatin, and ciclopirox olamine pass into breast milk.

Systemic antifungal agents

Systemic antifungal drugs should not be used to treat onychomycosis if the patient is pregnant or contemplating pregnancy. During pregnancy, they should be reserved for serious fungal infections and used only if the benefit outweighs the risk. Although animal studies of oral *terbinafine* have shown no adverse effects during pregnancy, there are no adequate studies in pregnant women. Orally administered terbinafine is secreted in breast milk and is not recommended for use in nursing mothers.

There are no adequate human studies of the effects of azole antifungals during pregnancy or nursing. The risk of fetal abnormalities is increased with exposure to *fluconazole*, *ketoconazole*, *itraconazole*, and *voriconazole* in the first trimester[4]. Of note, a single 150 mg dose of fluconazole has not been associated with fetal malformations, but it may increase the risk of miscarriage. *Itraconazole* is excreted in human milk and should be avoided in lactating patients. *Fluconazole* is excreted in breast milk, but the level of exposure is substantially lower than doses given safely to neonates[4,20]. Due to ocular abnormalities in exposed animal fetuses, *oteseconazole* is contraindicated in women of reproductive potential as well as during pregnancy and lactation.

Ibrexafungerp is also contraindicated during pregnancy due to fetal malformations in animal studies, and women of reproductive potential are advised to use effective contraception during treatment and for four days after the last dose. There are no human or animal data on the presence of ibrexafungerp in milk or its effects during nursing.

Griseofulvin has been associated with fetal abnormalities in rats and dogs. Rare cases of conjoined twins have been reported in women taking griseofulvin in the first trimester of pregnancy. Patients should avoid pregnancy during treatment with griseofulvin and for at least 1 month after its discontinuation[36].

ANTIVIRAL AGENTS

This section reviews antiviral agents used for infections with herpes simplex virus (HSV), varicella–zoster virus (VZV), and cytomegalovirus (CMV). Table 127.21 lists the topical antiherpetic antiviral medications. Antiretroviral medications are addressed in Chapter 78.

Mechanisms of Action

Fig. 127.11 illustrates the mechanism of action of antiherpetic drugs utilized for HSV and VZV infections.

Valacyclovir is the prodrug of acyclovir. It is almost completely converted to acyclovir by valacyclovir hydrolase while passing through the gastrointestinal tract and liver. It has an oral bioavailability approximately three times greater than that of acyclovir (55% vs 15%–30%) and more convenient dosing.

Penciclovir is an acyclic guanosine analogue with a mechanism of action similar to acyclovir. It reaches higher intracellular concentrations and has a longer intracellular half-life than acyclovir (2.3–3 hours vs 1.3–1.5 hours). However, it is less potent because it does not cause chain termination of viral DNA, and it has a poor oral bioavailability. For these reasons, this medication is only available in topical form. *Famciclovir* is the prodrug of penciclovir. The bioavailability of famciclovir is about 77%. Like valacyclovir, it is converted to its active form in the gastrointestinal tract and liver. *In vitro* studies show that penciclovir is at least as effective as acyclovir against HSV-1 and HSV-2[37].

Docosanol, also known as behenyl alcohol, is a saturated 22-carbon aliphatic alcohol that exhibits antiviral activity against several lipid-enveloped viruses, including HSV. After the virus has attached to the host cell, n-docosanol prevents the fusion of the HSV envelope with the plasma membrane of uninfected cells.

Indications

Topical antiviral agents

Topical acyclovir 5% ointment is indicated for the initial episode of genital herpes. It decreases the duration of viral shedding from 7 days to 4 days[38]. In some studies, it has also been shown to be effective in recurrent genital herpes[39]. Acyclovir 5% cream and an acyclovir 5% plus hydrocortisone 1% combination cream are indicated for recurrent orolabial herpes in immunocompetent individuals ages ≥12 years and ≥6 years, respectively; mean healing times are shortened by ~0.5 days

TOPICAL ANTIHERPETIC ANTIVIRAL AGENTS

Generic name	Selected trade name(s)®	Formulations (OTC/Rx)	Considered safe to use during pregnancy*	Dosage	Side effects
Acyclovir	Acic, Aciclosina, Acivir, Aclovir, Acyclo-V, Acyvir, Cicloferon, Cicloviral, Clinovir, Cusiviral, Cyclivex, Cyclovir, Deherp, Entir, Herpex, Lovir, Oppvir, Poviral, Supraviran, Vicorax, Virex, Virless, Zevin, Zoter, Zovir, Zovirax With 1% hydrocortisone: Xerese Buccal tablet: Sitavig	5% ointment, cream; 50 g mucoadhesive buccal tablet (Rx)	√	q3 h, 6 times/day for 7 days In Canada: 4–6 times/day for up to 10 days With hydrocortisone: 5 times/day for 5 days Buccal tablet: single application	Burning, stinging, discomfort; less often, pruritus, erythema, edema, or mucosal irritation (when applied to genital lesions)
Penciclovir	Denavir, Vectavir	1% cream (Rx)	√	q2 h while awake (≥6 times/day) for 4 days	Burning, stinging, discomfort; less often, erythema or decreased sensation (particularly to touch); occasionally, headache and dysgeusia
Docosanol	Abreva	10% cream (OTC)	√	5 times/day until resolved	Burning, pruritus, xerosis, erythema, edema, acne

*Former FDA pregnancy category B.

Table 127.21 Topical antiherpetic antiviral agents. OTC, over the counter; Rx, prescription.

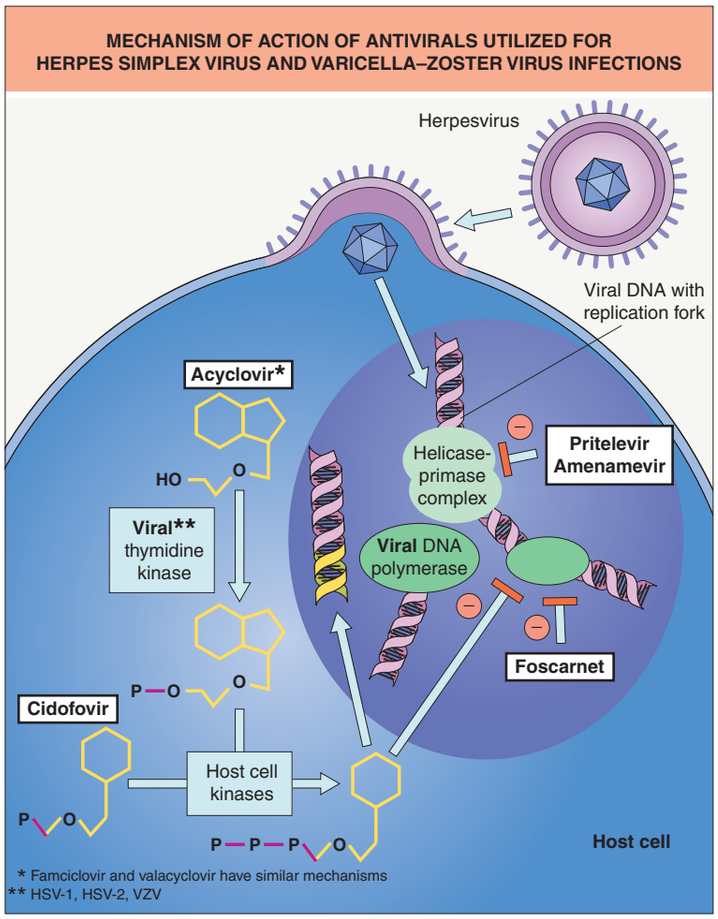

Fig. 127.11 Mechanism of action of antivirals utilized for herpes simplex virus (HSV) and varicella–zoster virus (VZV) infections. Acyclovir is a synthetic purine nucleoside analogue (similar in chemical structure to deoxyguanosine) that has a high affinity for HSV-1, HSV-2, and VZV thymidine kinase, which phosphorylates and activates the drug. Human cellular guanylate kinase then phosphorylates acyclovir twice, to transform it into acyclovir triphosphate, which blocks viral DNA synthesis by competitively inhibiting and inactivating viral DNA polymerase and by becoming irreversibly incorporated into the viral DNA chain, causing DNA chain termination. Valacyclovir, penciclovir, and famciclovir have similar mechanisms of action. Cidofovir is an acyclic nucleoside phosphate analogue of deoxycytosine monophosphate that does not require viral thymidine kinase to become activated, but otherwise also has a similar mechanism. Foscarnet, an inorganic pyrophosphate analogue, selectively inhibits viral DNA polymerase by blocking its pyrophosphate binding sites. Helicase-primase inhibitors (pritelivir, amenamevir) block DNA unwinding at the replication fork and synthesis of primers during viral replication. Pritelivir is being investigated as a treatment for acyclovir-resistant mucocutaneous HSV infections in immunocompromised hosts, and amenamevir is approved in Japan for the treatment of herpes zoster.

for acyclovir alone and 1.5 days for the combination. Although acyclovir ointment is also indicated for limited, non-life-threatening mucocutaneous herpes simplex infections in immunocompromised individuals, these patients often require systemic therapy.

Penciclovir is active against HSV-1, HSV-2, VZV, and EBV. Penciclovir 1% cream is indicated for treatment of recurrent orolabial herpes simplex infections in immunocompetent patients ≥12 years of age. Compared to placebo, topical penciclovir shortens healing time by ~0.5 days and decreases pain and viral shedding in herpes labialis[40]. *Docosanol* is available in the US as a non-prescription topical treatment for recurrent orolabial herpes in patients ≥12 years of age, shortening healing time by almost 1 day.

Systemic antiviral agents

Oral acyclovir and valacyclovir are indicated for initial and recurrent episodes of genital herpes, herpes simplex suppression, varicella (acyclovir for both children and adults, valacyclovir for children), and herpes zoster; valacyclovir and a single-dose acyclovir mucoadhesive buccal tablet are also indicated for recurrent orolabial herpes.

COMPARATIVE SUSCEPTIBILITY OF HERPESVIRUSES TO ANTIVIRAL DRUGS

Antiviral drug	Viral susceptibility				Main target organisms
	HSV-1	HSV-2	VZV	CMV	
Acyclovir, valacyclovir	+++	+++	++	–	HSV-1, HSV-2, VZV
Cidofovir	+	+	++	+++	CMV, resistant HSV
Famciclovir	+++	+++	++	–	HSV-1, HSV-2, VZV
Foscarnet	++	++	+	++	CMV, resistant HSV, VZV
Ganciclovir, valganciclovir	+	+	+	+++	CMV
Letermovir	–	–	–	+++	CMV
Maribavir	–	–	–	+++	CMV

Table 127.22 Comparative susceptibility of herpesviruses to antiviral drugs. CMV, cytomegalovirus; HSV, herpes simplex virus; VZV, varicella–zoster virus.

Intravenous acyclovir is used for HSV and VZV infections in immunocompromised patients, neonatal HSV infection, and other severe or disseminated HSV and VZV infections. Off-label uses of acyclovir and valacyclovir include prevention of recurrent herpes-associated erythema multiforme and treatment of eczema herpeticum, primary herpes gingivostomatitis, and herpetic whitlow. *Famciclovir* is indicated for herpes zoster, recurrent genital and orolabial herpes, and herpes suppression in immunocompetent adults as well as recurrent herpes simplex infections in HIV-infected adults.

Acyclovir, valacyclovir, and famciclovir are considered equivalent in safety and efficacy (time to healing, duration of pain, and viral shedding) for initial episodes of genital herpes[41]. Famciclovir and valacyclovir have the advantage of greater oral bioavailability and more convenient dosing. Valacyclovir is at least as effective as acyclovir in decreasing the duration of pain in herpes zoster[42]. Table 127.22 lists the relative susceptibilities of herpesviruses to the antiviral drugs.

Dosages

Antiviral therapy (topical or systemic) should be started as soon as possible after the onset of signs and symptoms. A glove or applicator should be used to apply topical antivirals to prevent autoinoculation of the finger. Table 127.21 details the dosing regimens of the *topical* antiviral drugs. Table 127.23 lists the available formulations of *systemic* antiviral medications. Table 80.4 outlines the dosages of the systemic antiherpetic medications for their various indications. Intravenous, rather than oral, treatment may be required in severely immunosuppressed patients, patients who cannot take medications orally, and those who cannot be relied upon to take the medication correctly[43].

The majority of people who are seropositive for HSV-2 are asymptomatic[44], and it is thought that asymptomatic viral shedding leads to most transmission of genital herpes. The physician must decide whether to treat on an episodic basis or in a continuous suppressive fashion. Factors that influence this decision include the number of outbreaks per year, the severity of outbreaks, a lack of prodromal symptoms, and an HSV-seronegative sexual partner[43]. Suppression with acyclovir 400 mg twice daily can decrease recurrences by 80%–90% and asymptomatic shedding by 95%[45]. A year-long, double-blind, placebo-controlled study demonstrated that 1 g of valacyclovir taken daily reduced recurrence rates by 78%[46]. In addition, a multicenter, randomized, placebo-controlled study showed that daily valacyclovir significantly lowered the risk of transmission of genital herpes in heterosexual, immunocompetent, monogamous, HSV-2 discordant couples[47].

Acyclovir, valacyclovir, and famciclovir are all effective against herpes labialis when used intermittently or suppressively, and they are all effective in treating herpes zoster. Treatment of varicella in healthy children is controversial, but it does not alter antibody production at 28 days or at 1 year[48]. Oral therapy is recommended for healthy adolescents and adults as well as children with chronic skin or lung disease or on long-term salicylates; intravenous administration is indicated for immunocompromised individuals, including those receiving chronic systemic corticosteroid therapy.

FORMULATIONS OF SYSTEMIC ANTIVIRAL DRUGS	
Antiviral drug	**Available formulations**
Acyclovir	200 mg capsules; 400 mg and 800 mg tablets; iv solution; 200 mg/5 ml banana-flavored suspension
Valacyclovir	500 mg and 1000 mg tablets*
Famciclovir	125 mg, 250 mg, and 500 mg tablets
Ganciclovir	250 mg and 500 mg capsules; iv solution
Valganciclovir	450 mg tablets; 50 mg/ml oral solution
Letermovir	240 mg, 480 mg tablets; iv solution
Maribavir	200 mg tablets
*Pharmacies can compound valacyclovir tablets into an oral suspension (25 or 50 mg/ml).	

Table 127.23 Formulations of systemic antiviral drugs. iv, intravenous.

Contraindications

As with other medications, antiviral agents are contraindicated in patients with hypersensitivity to the drug or any components of the formulation. Systemic antivirals need to be dose-adjusted for patients with impaired renal function (see Table 80.5); renal function should be monitored in patients taking nephrotoxic medications. Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome have been reported in immunocompromised patients receiving valacyclovir.

Major Side Effects

Table 127.21 lists the side effects of *topical* antiviral agents, which have limited systemic absorption, and Table 127.24 lists the side effects of *systemic* antiherpetic medications.

Interactions

No clinically important drug interactions with *topical* antivirals have been identified. Table 127.25 lists the interactions of the *systemic* antiviral agents with other medications.

Pregnancy and Lactation

Topical antiviral agents

There are no adequate studies of topical antiviral agents in pregnant or lactating women. Small amounts of topical acyclovir are absorbed through the skin and mucous membranes. Topical docosanol has not been shown to cause birth defects or other problems in animal studies using rats or rabbits. Although it is not known if topically applied antivirals pass into breast milk, to date, no problems in nursing infants due to these agents have been reported.

Systemic antiviral agents

Systemic acyclovir, valacyclovir, and famciclovir have not been shown to be teratogenic in animal studies and historically were FDA pregnancy category B. Acyclovir is traditionally the drug of choice for genital herpes in pregnant women because of its long history of safe use. Varicella in pregnant women should be treated with acyclovir due to the high risk of maternal mortality from varicella pneumonia as well as fetal death or premature delivery[49]. It is not known, however, whether acyclovir prevents congenital varicella syndrome. Acyclovir is excreted in breast milk; acyclovir and valacyclovir are considered to be compatible with breastfeeding, and they are preferred over famciclovir during lactation[20].

Other Antiviral Agents

Herpes infection resistant to commonly used drugs is a problem in immunocompromised patients. Foscarnet and cidofovir are two alternative treatments in this situation (see Table 127.22 and Fig. 127.11).

Foscarnet is an intravenous antiviral used for cytomegalovirus (CMV) retinitis or CMV skin infections in patients with HIV as well as for acyclovir-resistant herpes simplex infections. Foscarnet is an inorganic pyrophosphate analogue that selectively inhibits viral DNA polymerase by blocking its pyrophosphate binding sites, preventing cleavage of pyrophosphate from deoxyadenosine triphosphate. Foscarnet does not require phosphorylation to be activated, and thus it circumvents the commonest mode of viral resistance involving viral thymidine kinase (see Fig. 127.11). Foscarnet is active against all herpesviruses. Side effects of the intravenous form include nephrotoxicity, anemia, erosive penile lesions, thrombophlebitis, seizures, gastrointestinal disturbances, and changes in serum calcium, magnesium, and phosphate levels.

Cidofovir is an acyclic nucleoside phosphate analogue of deoxycytosine monophosphate. It inhibits viral DNA polymerase and causes DNA chain termination. It differs from acyclovir and penciclovir in that

SIDE EFFECTS OF SYSTEMIC ANTIVIRAL AGENTS COMMONLY USED IN DERMATOLOGY	
Acyclovir and valacyclovir	• Cutaneous: morbilliform eruption, Stevens–Johnson syndrome, injection site reaction, urticaria, angioedema • Gastrointestinal: nausea, vomiting, diarrhea, abdominal pain • Hematologic: aplastic anemia, leukopenia, thrombocytopenia • Neurologic: headaches, vertigo, lethargy, confusion, hallucinations, depression, seizures, encephalopathy, coma (CNS disturbances more likely in elderly patients) • Cardiovascular: hypertension, tachycardia, anaphylaxis • Other: malaise, arthralgia, myalgia, dyspnea, dysmenorrhea • Reversible crystalluria-induced nephropathy with intravenous acyclovir (typically in patients with pre-existing renal dysfunction or dehydration) • Thrombotic thrombocytopenic purpura or hemolytic uremic syndrome in immunocompromised patients with valacyclovir
Famciclovir	• Pruritus, paresthesias, headache, fatigue, nausea, vomiting, diarrhea, and flatulence

Table 127.24 Side effects of systemic antiviral agents commonly used in dermatology.

DRUG INTERACTIONS OF SYSTEMIC ANTIVIRAL AGENTS COMMONLY USED IN DERMATOLOGY	
Interacting drug	**Result**
Amphotericin	Increases serum acyclovir level
Cimetidine	Decreases rate of conversion of valacyclovir to acyclovir Increases serum levels of acyclovir and valacyclovir
Digoxin	Famciclovir increases digoxin levels
Glyburide with metformin (Glucovance®)	Acyclovir or valacyclovir may cause lactic acidosis in patients with decreased renal function
Interferon	May worsen potential neurotoxicity of acyclovir
Intrathecal methotrexate	May worsen potential neurotoxicity of acyclovir
Nephrotoxic drugs (i.e. cisplatin)	Acyclovir increases risk of nephrotoxicity
Probenecid	Decreases rate of conversion of valacyclovir to acyclovir Increases serum levels of acyclovir and valacyclovir
Theophylline	Acyclovir causes decreased metabolism and increased serum levels of theophylline Theophylline increases serum levels of acyclovir and valacyclovir
Zidovudine	Increases serum levels of acyclovir and valacyclovir

Table 127.25 Drug interactions of systemic antiviral agents commonly used in dermatology.

it does not require viral thymidine kinase to become activated. It is also used for CMV retinitis in patients with HIV. Cidofovir is currently available in intravenous form only, and side effects include nephrotoxicity, iritis, neutropenia, metabolic acidosis, and gastrointestinal disturbances. However, a compounded topical form has been used with some success for herpes simplex resistant to acyclovir, molluscum contagiosum, condyloma acuminata, verruca vulgaris, and viral-associated trichodysplasia spinulosa[50]. *In vitro*, cidofovir is active against DNA viruses including mpox, variola, and vaccinia.

Ganciclovir (oral and intravenous) and its prodrug *valganciclovir* (oral) are deoxynucleotide analogue CMV DNA polymerase inhibitors that are approved for the treatment of CMV retinitis in patients with HIV and prevention of CMV disease in transplant recipients. Side effects include diarrhea, nausea/vomiting, cytopenias, and impaired renal function.

Maribavir, an inhibitor of the CMV UL97 protein kinase, is an oral medication that is approved for patients ≥12 years of age with post-transplant CMV infections that fail to respond to other medications. Side effects include taste disturbance, nausea/vomiting, diarrhea, and fatigue.

Letermovir is an inhibitor of the CMV DNA terminase complex, which is necessary for the packaging and processing of CMV viral DNA. Available in oral and IV formulations, it is currently approved for prophylaxis against CMV disease in adult CMV-seropositive allogeneic hematopoietic stem cell transplant recipients[51]. Uncommon side effects include nausea/vomiting, abdominal pain, diarrhea, peripheral edema, cough, headache, fatigue, cardiac adverse events (tachycardia, atrial fibrillation), and rarely hypersensitivity reactions.

Drugs such as pritelivir and amenamevir that target the HSV helicase–primase complex (composed of three proteins that unravel DNA) have been shown to be effective *in vitro* as well as in animal models (see Fig. 127.11)[52]. In randomized controlled trials (RCTs), adults with a history of genital herpes due to HSV-2 who received pritelivir had significantly fewer days with genital lesions and decreased HSV shedding compared to those who received placebo[53,54]. Pritelivir received FDA Breakthrough Therapy designation in 2020 and is being investigated for acyclovir-resistant mucocutaneous HSV infections in immunocompromised hosts. Amenamevir is approved in Japan for the treatment of herpes zoster, and in a Japanese RCT, 7-day courses of amenamevir and valacyclovir had similar efficacy and safety for the treatment of herpes zoster in immunocompetent patients[55].

INTERFERONS

Interferons (IFNs) are a family of secretory glycoproteins produced by most eukaryotic cells in response to a variety of viral and non-viral stimuli. IFNs display antiviral activity and have immunoregulatory and antiproliferative effects. IFN does not inactivate viruses directly but rather renders cells resistant to viruses.

There are three antigenically distinct IFNs, originally described as leukocyte (α), fibroblast (β), and immune (γ)[1] (Table 128.1). IFN-α and IFN-β are type I interferons, whereas IFN-γ represents a type II interferon. Of note, a targeted immune modulator that inhibits the type I interferon receptor is approved as treatment for systemic lupus erythematosus. IFNs must be injected intralesionally or administered parenterally due to the large size of the protein. IFN-α-2a and IFN-α-2b are the agents most frequently used for cutaneous diseases. The dermatologic uses, side effects, and interactions of IFNs are outlined in Table 128.2.

INTERFERONS				
Generic name	**Trade name®**	**Route**	**Half-life**	**Peak effect**
Interferon-α-2a	Roferon-A	sc	5.1 h	3.8–7.3 h
Interferon-α-2a	Pegasys*	sc	160 h	72–96 h
Interferon-α-2b	Intron A Rebetrol when combined with ribavirin	iv, il, im, sc	2–3 h	30 min (iv) 3–12 h (im, sc)
Interferon-α-2b	PegIntron* Besremi*	sc sc	40 h 160 h	15–44 h 48–120 h
Interferon-α-N3	Alferon N	il	2–3 h	3–12 h
Interferon-β-1a	Avonex	im	10 h	3–15 h
	Rebif Plegridy*	sc sc, im	69 h 78 h	16 h 6–12 h
Interferon-β-1b	Betaseron Extavia	sc sc	4.3 h 4.3 h	1–8 h 6–12 h
Interferon-γ-1b	Actimmune	sc	5.9 h	4.7 h

*Pegylated forms in which polyethylene glycol (PEG) side chains were added to increase the half-life.

Table 128.1 Interferons. Dermatologic FDA-approved indications include condyloma acuminata (IFN-α-2b), melanoma (IFN-α-2b), and AIDS-associated Kaposi sarcoma (IFN-α-2a and IFN-α-2b). h, hours; il, intralesional; im, intramuscular; iv, intravenous; sc, subcutaneous.

GRANULOCYTE–MACROPHAGE AND GRANULOCYTE COLONY-STIMULATING FACTORS (GM-CSF AND G-CSF)

The indications and side effects of granulocyte–macrophage and granulocyte colony-stimulating factors (GM-CSF and G-CSF) are outlined in Table 128.3.

TARGETED IMMUNE MODULATORS

Key features

- Dermatologic indications for tumor necrosis factor (TNF) inhibitors such as etanercept, adalimumab, and infliximab include psoriasis and hidradenitis suppurativa
- Several agents that block interleukin (IL)-12 and/or IL-23 signaling, which is important for the Th17 immune response, are approved for the treatment of psoriasis. Ustekinumab binds to the p40 subunit shared by these cytokines, whereas guselkumab, risankizumab, and tildrakizumab bind to the p19 subunit of IL-23
- The IL-17 inhibitors secukinumab, ixekizumab, and brodalumab are approved for the treatment of psoriasis
- The IL-36 receptor antagonist spesolimab is approved for the treatment of generalized pustular psoriasis
- Agents that block IL-4 and/or IL-13 signaling are approved for the treatment of atopic dermatitis. Dupilumab binds to the IL-4 receptor α subunit shared by these cytokines, whereas tralokinumab and lebrikizumab bind to IL-13
- The IL-1 antagonists anakinra, canakinumab, and rilonacept are used to treat several autoinflammatory diseases, including cryopyrin-associated periodic syndromes and deficiency of the IL-1 receptor antagonist (DIRA)
- Rituximab blocks CD20 on B cells and is approved for the treatment of B cell lymphoma, pemphigus vulgaris, granulomatosis with polyangiitis, and microscopic polyangiitis
- Omalizumab binds to the IgE receptor on mast cells and is approved for the treatment of chronic spontaneous urticaria
- Oral Janus kinase (JAK) inhibitors are approved for the treatment of atopic dermatitis (upadacitinib and abrocitinib), alopecia areata (baricitinib and ritlecitinib), and graft-versus-host disease (ruxolitinib)

Introduction

Advances in molecular technology have enabled the development of drugs that target specific proteins involved in disease pathogenesis. This has resulted in effective therapies for a variety of immune-mediated skin disorders, including psoriasis, atopic dermatitis, hidradenitis suppurativa, pemphigus vulgaris, urticaria, alopecia areata, and cutaneous B cell lymphoma as well as the cutaneous manifestations of

DERMATOLOGIC USES, SIDE EFFECTS, AND INTERACTIONS OF INTERFERONS
FDA-approved indications
Condyloma acuminata (α) AIDS-associated Kaposi sarcoma (α) Melanoma (adjuvant) (α) Chronic granulomatous disease (γ)
Selected off-label dermatologic uses
Neoplasms
Basal cell carcinoma (α) Actinic keratoses (α) Squamous cell carcinoma (α) Giant condyloma of Buschke–Lowenstein (α) Cutaneous T cell lymphoma (α, β, γ) Granulomatous slack skin (α, γ) Infantile hemangioma (α) Tufted angioma (α)
Infections
Verrucae vulgaris (α, β, γ) Epidermodysplasia verruciformis (α) Herpes zoster (α) Herpes simplex (α) Necrolytic acral erythema (with hepatitis C) (α) Leishmaniasis (γ) Leprosy (γ) *Mycobacterium avium* complex infections (γ)
Inflammatory/other
Atopic dermatitis (γ) Keloids (α, γ) Behçet disease (α) Systemic sclerosis (γ) Scleromyxedema (α)
Side effects
• ***Systemic:*** flu-like symptoms (fever, chills, headache, myalgias, arthralgias), hypotension, tachycardia, arrhythmias, rhabdomyolysis, gastrointestinal symptoms (nausea, vomiting, diarrhea), hepatitis, bone marrow suppression (high-dose therapy), thyroiditis (hepatitis C patients) • ***Cutaneous:*** necrosis at injection site (IFN-β-1b for multiple sclerosis; Fig. 128.1), psoriasis (Fig. 128.2), vitiligo, alopecia areata
Interactions
• Decreased clearance of aminophylline; increased risk of renal failure when used with interleukin-2; additive effects with other myelosuppressive or neurotoxic medications
Pregnancy
• Animal studies have shown an increased risk of abortion at high doses; no adequate studies in pregnant women

Table 128.2 Dermatologic uses, side effects, and interactions of interferons. *Adapted from Wolverton SE. Comprehensive Dermatologic Drug Therapy, 3rd edition. Philadelphia: WB Saunders, 2012.*

GRANULOCYTE–MACROPHAGE AND GRANULOCYTE COLONY-STIMULATING FACTORS (GM-CSF & G-CSF)
Properties
These glycoproteins regulate the survival, proliferation, differentiation, and functional activation of hematopoietic cells
Uses
• Treatment of neutropenia in settings of myelosuppressive chemotherapy and hematopoietic stem cell transplantation • Other forms of neutropenia (e.g. associated with AIDS, WHIM syndrome, or dyskeratosis congenita) • Mobilization of peripheral blood progenitor cells • In dermatology, both have been studied as promoters of wound healing, and GM-CSF has been investigated as a component of melanoma vaccine therapy
Side effects
GM-CSF
• ***Systemic:*** fever, myalgias, bone pain; occasionally flares of autoimmune disease • ***Cutaneous:*** morbilliform eruption (within 24–48 hours of administration; mixed infiltrate with granulocytes/macrophages); pustular or urticarial injection site reactions (Fig. 128.3); Sweet syndrome, small vessel vasculitis, urticarial plaques with tense bullae, epidermolysis bullosa acquisita
G-CSF
• ***Systemic:*** bone pain (transient, mild "dull ache"; 20% of recipients); occasionally, elevated serum uric acid, LDH, or alkaline phosphatase • ***Cutaneous:*** Sweet syndrome (within 1–2 weeks of administration); injection site reactions, pyoderma gangrenosum, small vessel vasculitis, folliculitis; histologically, the infiltrate is composed of neutrophils, eosinophils and large histiocytes with cytologic atypia and many mitotic figures
Interactions
Additive effects with other drugs that cause neutrophilia, e.g. corticosteroids, lithium
Pregnancy and lactation
Animal reproduction studies have shown adverse fetal effects, but no adequate studies in pregnant women; unknown if excreted in breast milk

Table 128.3 Granulocyte–macrophage and granulocyte colony stimulating factors (GM-CSF & G-CSF). LDH, lactate dehydrogenase; WHIM, warts, hypogammaglobulinemia, infections, and myelokathexis.

systemic conditions such as Crohn disease, sarcoidosis, and vasculitis. These drugs, which are referred to as "biologic" agents, work via mechanisms that include altering T cell activation and differentiation into Th1, Th2, or Th17 cells; blocking cytokines, their receptors, or their intracellular signaling mechanisms; and eliminating pathogenic B cells.

The nomenclature utilized for targeted immune modulators is summarized in Table 128.4. In general, antibodies and fusion proteins represent large molecules that require parenteral administration.

Tumor Necrosis Factor Inhibitors

The FDA has approved multiple tumor necrosis factor (TNF; previously known as TNF-α) inhibitors: etanercept (Enbrel®), etanercept-szzs (Erelzi™), etanercept-ykro (Eticovo™), infliximab (Remicade®), infliximab-abda (Renflexis®), infliximab-axxq (Avsola™), infliximab-dyyb (Inflectra®), infliximab-qbtx (Ixifi™), adalimumab (Humira®), adalimumab-aacf (Idacio®), adalimumab-aaty (Yuflyma®),

NOMENCLATURE FOR MONOCLONAL ANTIBODIES AND FUSION PROTEINS						
Prefix	**Sub-stem A: *target* system [previous nomenclature system]**		**Sub-stem B: *source* system**		**Suffix**	
Variable "Peg-" can be used if pegylated (or can add pegol as a second word)	-anibi-	Angiogenesis	-a-	Rat	-mab	Immunoglobulin variable domain
	-b(a)- [-ba(c)-]	Bacterial	-e-	Hamster		
	-f(u)- [-fung-]	Fungal	-i-	Primate	-cept	Receptor (takes the place of a variable domain)
	-k(i)- [-ki(n)-]	Interleukin	-o-	Mouse		
	-l(i)- [-li(m)-]	Immunomodulating	-u-	Human	-nib	Tyrosine kinase inhibitor
	-n(e)- [-ne(u)(r)-]	Nervous system	-xi-	Chimeric†		
	-tox(a)-	Toxin*	-zu-	Humanized‡		
	-t(u)-	Tumor				
	-v(i)-	Viral				

*If conjugated to (rather than directed at) a toxin, the suffix -tox can be used in a second word.
†Contains contiguous *foreign*-derived amino acids comprising the *entire variable* region (both heavy and light chains), linked to a constant region of human origin.
‡Has segments of foreign-derived amino acids *interspersed* with human-derived amino acids in the *variable* region, linked to a constant region of human origin.

Table 128.4 Nomenclature for monoclonal antibodies and fusion proteins. For example, ada-lim-u-mab, inf-li-xi-mab and certo-li-zu-mab pegol are immunomodulating immunoglobulins that are human, chimeric, and humanized, respectively.

adalimumab-adaz (Hyrimoz®), adalimumab-adbm (Cyltezo®), adalimumab-afzb (Abrilada®), adalimumab-aqvh (Yusimry™), adalimumab-atto (Amjevita®), adalimumab-bwwd (Hadlima®), adalimumab-fkjp (Hulio™), golimumab (Simponi®), and certolizumab pegol (Cimzia®). A review of their mechanisms of action, major side effects, contraindications, and use in pregnancy is followed by a discussion of issues that relate specifically to individual drugs.

Mechanism of action

Infliximab, adalimumab, golimumab, and certolizumab pegol are monoclonal antibodies, while etanercept is a dimeric fusion protein composed of the extracellular portions of two p75 TNF receptors linked to the Fc portion of IgG1 (Fig. 128.4). Although all four monoclonal antibodies target human TNF, infliximab is chimeric (human–mouse) IgG1, adalimumab and golimumab are human recombinant IgG1, and certolizumab pegol is a humanized pegylated Fab fragment (see Table 128.4).

All of the TNF inhibitors bind to soluble TNF and block its ability to activate TNF receptors (Fig. 128.4). By interacting with membrane-bound TNF, the IgG1 monoclonal antibodies can also activate complement-dependent cytotoxicity and induce cellular apoptosis[2]. This capacity to destroy TNF-producing cells may explain the greater efficacy of these monoclonal antibodies compared to etanercept in the treatment of granulomatous conditions as well as the potentially higher risk of infections associated with their use. In addition to the anti-inflammatory effects of TNF inhibitors (see Fig. 8.1B), blocking TNF signaling may have an impact on the neuroendocrine system[3].

Contraindications

Each TNF inhibitor is contraindicated in patients with known hypersensitivity to that particular medication, and infliximab is contraindicated in those with an allergy to murine proteins. These agents should be avoided in patients with significant active infection, malignancy, congestive heart failure (especially if unstable), multiple sclerosis, or other demyelinating diseases[4,5] (see Table 8.19).

Major side effects (Table 128.5)

Infections

Disseminated and/or opportunistic infections such as histoplasmosis, coccidioidomycosis, listeriosis, and *Pneumocystis jirovecii* pneumonia may occur in patients treated with TNF inhibitors[6]. An increased risk of symptomatic mycobacterial infections (Fig. 128.5), including

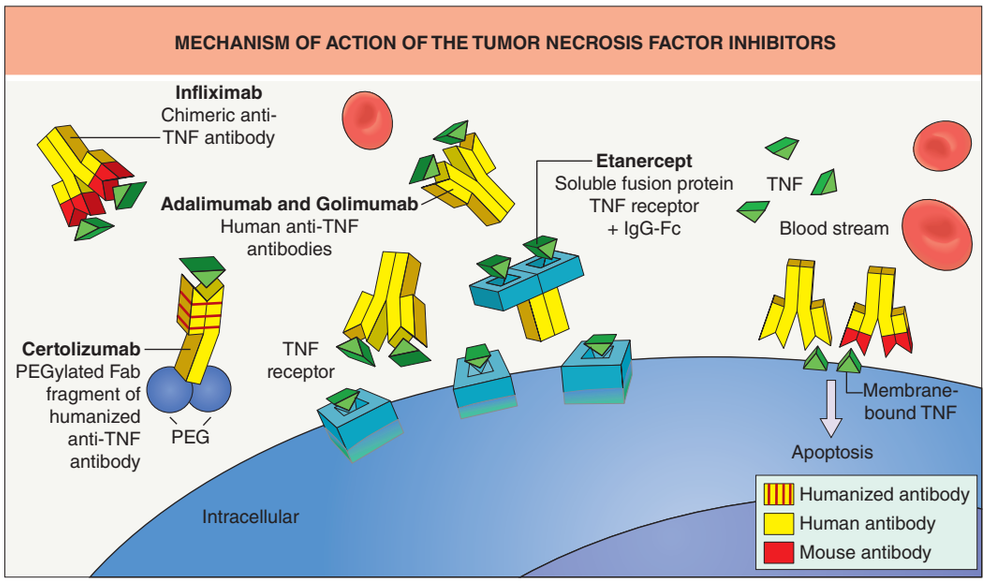

Fig. 128.4 Mechanism of action of the tumor necrosis factor (TNF) inhibitors.

FDA WARNINGS AND PRECAUTIONS FOR TARGETED IMMUNE MODULATORS WITH DERMATOLOGIC INDICATIONS
TNF inhibitors: adalimumab, certolizumab, etanercept, golimumab, infliximab

• Increased risk of serious infections, including tuberculosis, bacterial sepsis, systemic fungal infections (e.g. histoplasmosis), and infections due to opportunistic pathogens
• Risk of hepatitis B virus reactivation
• Malignancies (especially lymphomas) have been reported in patients receiving these agents, including children and adolescents
  • For *infliximab*, lymphomas are seen more often than in the general population and fatal hepatosplenic T cell lymphomas have developed in patients with inflammatory bowel disease who were also receiving azathioprine or 6-mercaptopurine
  • An increased risk of non-melanoma skin cancer and melanoma has been observed in patients with rheumatoid arthritis treated with TNF inhibitors
• Congestive heart failure (exacerbation or new onset) has been observed
• Demyelinating disease (exacerbation or new onset) has been observed
• Anaphylaxis or severe allergic reactions can occur, including serum sickness-like reactions to *infliximab*
• Other potential adverse events include autoimmune hepatitis, cytopenias, and a lupus-like syndrome; see Table 128.7 for additional cutaneous side effects

Ustekinumab

• Serious infections have been observed; may increase the risk of infection and reactivation of latent infections
  • Patients genetically deficient in IL-12/IL-23 have an increased risk of severe infections with mycobacteria and *Salmonella*
  • BCG vaccination should not be given in the year prior to initiation or the year following completion of ustekinumab therapy
• Could potentially increase the risk of malignancies
• Hypersensitivity reactions (e.g. angioedema, anaphylaxis) and pneumonitis have been reported
• Reversible posterior leukoencephalopathy syndrome has been reported

IL-23 inhibitors: guselkumab, risankizumab, tildrakizumab
• May increase the risk of infections including tuberculosis • Hypersensitivity reactions have been reported
IL-17 inhibitors: ixekizumab, secukinumab, brodalumab
• Serious infections have been observed; may increase the risk of infection and reactivation of latent infections   • Patients genetically deficient in IL-17 are prone to chronic mucocutaneous candidiasis • New onset and exacerbation of inflammatory bowel disease have occurred • Hypersensitivity reactions (e.g. angioedema, anaphylaxis) can develop • For *brodalumab*: suicidal ideation and behavior, including complete suicides, have occurred
IL-4/13 receptor and IL-13 inhibitors: dupilumab, tralokinumab
• Hypersensitivity reactions can occur • Conjunctivitis and keratitis may develop • May potentially affect the immune response to helminth infections
IL-1 inhibitors: anakinra, canakinumab, rilonacept
• Increased risk of serious infections • Coadministration with TNF inhibitors is not recommended • Hypersensitivity reactions (e.g. angioedema, anaphylaxis) can develop
Spesolimab
• May increase the risk of infections • Hypersensitivity and infusion-related reactions may develop, including drug reaction with eosinophilia and systemic symptoms

Table 128.5 US Food and Drug Administration (FDA) warnings and precautions for targeted immune modulators with dermatologic indications.

FDA WARNINGS AND PRECAUTIONS FOR TARGETED IMMUNE MODULATORS WITH DERMATOLOGIC INDICATIONS
Rituximab
• Severe infusion reactions can occur   • 80% of fatal reactions occur with the first infusion • Tumor lysis syndrome can develop in lymphoma patients, especially those with a high tumor burden, and lead to acute renal failure • Progressive multifocal leukoencephalopathy has been reported • Serious infections (bacterial, fungal, or viral) up to 1 year after completing therapy and reactivation of viral infections may occur, especially hepatitis B virus reactivation with fulminant hepatitis • Cardiac arrhythmias and angina can occur and may be life-threatening • Bowel obstruction and perforation have been described • Stevens–Johnson syndrome/toxic epidermal necrolysis and onset of paraneoplastic pemphigus have been described • Late-onset neutropenia (≥4 weeks after infusion) develops in a subset of patients • Decreased antibody responses to immunization, including COVID mRNA vaccines, has been noted • B cell lymphopenia can occur in infants exposed to rituximab *in utero*
Omalizumab
• Administer only in a healthcare setting prepared to manage anaphylaxis, which can be life-threatening, and observe patients for an appropriate period after administration • Patients can develop serum sickness-like reactions with fever, arthralgias, and an urticarial eruption • Malignancies have been observed in clinical studies of asthma patients, although a meta-analysis did not find an increased risk of malignancy • Do not abruptly discontinue corticosteroids upon initiation of omalizumab therapy
JAK inhibitors: abrocitinib, baricitinib, deucravacitinib, ritlecitinib, ruxolitinib, tofacitinib, upadacitinib
• Increased risk of bacterial, mycobacterial, invasive fungal and viral infections, including tuberculosis, herpes zoster, hepatitis B, and infections due to opportunistic pathogens • Laboratory monitoring is recommended due to potential changes in lymphocytes, neutrophils, hemoglobin, platelets (especially with abrocitinib, ritlecitinib, and ruxolitinib), liver enzymes, and lipids • Increased risk of major adverse cardiac events (MACE) and all-cause mortality in rheumatoid arthritis patients ≥50 years of age with at least one cardiovascular risk factor treated with *tofacitinib* compared with those treated with TNF inhibitors • Higher rate of malignancies (in particular lymphomas and lung cancers) in rheumatoid arthritis patients treated with *tofacitinib* compared with those treated with TNF inhibitors • Thrombosis (e.g. deep venous thrombosis, pulmonary embolism, arterial thrombosis) has occurred • Gastrointestinal perforations have been reported in patients treated with *baricitinib, tofacitinib, and upadacitinib* • Progressive multifocal leukoencephalopathy has been reported in a patient treated with *ruxolitinib* • Hypersensitivity reactions (e.g. angioedema, anaphylaxis) can develop • May cause fetal harm based on animal studies

Table 128.5 US Food and Drug Administration (FDA) warnings and precautions for targeted immune modulators with dermatologic indications. Live vaccines (see Table 128.8) should not be given to patients receiving these medications. BCG, bacillus Calmette–Guérin; IL, interleukin; JAK, Janus kinase; LE, lupus erythematosus; TNF, tumor necrosis factor.

Fig. 128.5 Atypical mycobacterial infection complicating adalimumab therapy. This patient was being treated for Crohn disease.

reactivation of latent tuberculosis, has also been observed in patients treated with these agents. However, most of the studies evaluating the risk of infection associated with the use of TNF inhibitors have been in patients with rheumatoid arthritis or inflammatory bowel disease, who often concomitantly receive additional immunosuppressive agents such as prednisone and methotrexate. The actual risk of infections is likely lower in patients receiving a TNF inhibitor as monotherapy. For example, a meta-analysis of 20 randomized controlled trials (RCTs; total n=6810) of TNF inhibitor therapy for psoriasis or psoriatic arthritis over rather limited periods of 12–30 weeks found no association between the use of these agents and the risk of infection (overall or serious) when adjusted for different follow-up times in treatment and control groups[7].

Recommended monitoring for dermatologic patients receiving TNF inhibitors is outlined in Table 128.6. A purified protein derivative (PPD) skin test, IFN-γ release assay (e.g. QuantiFERON® TB Gold Plus, T-SPOT®.TB), and/or chest X-ray (e.g. if immunosuppression or history of tuberculosis) is required at baseline and is typically, especially if risk factors, repeated annually during therapy. Patients with untreated or inadequately treated latent tuberculosis should receive antituberculous therapy prior to treatment with a TNF inhibitor. Reactivation of hepatitis B virus has also been observed in patients who are chronic hepatitis B carriers (i.e. hepatitis B surface antigen positive) while receiving a TNF inhibitor, so patients should be evaluated for hepatitis B virus infection prior to therapy. TNF inhibitors do not generally appear to have an adverse effect on viral load or hepatitis activity in psoriasis patients with chronic hepatitis C virus infection[8].

Risk of malignancy

The potential of TNF inhibitors to increase the risk of malignancy is controversial and may be dependent upon the disease being treated. TNF inhibitor therapy in patients with rheumatoid arthritis has been associated with an approximately threefold increase in the risk of lymphoma and malignancy in general[9,10]; however, this patient group is known to have a heightened susceptibility to lymphoma and often receives additional immunosuppressive agents. Most studies have not demonstrated an increase in the risk of other internal malignancies in patients treated with TNF inhibitors[11]. Keratinocyte carcinomas and melanoma may be more frequent in patients with rheumatoid arthritis who are treated with TNF inhibitors than those who do not receive

RECOMMENDED EVALUATION FOR PATIENTS RECEIVING TARGETED IMMUNE MODULATORS FOR DERMATOLOGIC DISORDERS	
Baseline history and physical examination	

• Complete medical history, including prior/current medications, vaccinations*, and allergies
• Complete physical examination
• Pay particular attention to history, risk, symptoms, and signs of:
  • Tuberculosis and other chronic as well as acute infections
  • Malignancy
  • For *TNF inhibitors*: congestive heart failure, demyelinating diseases (e.g. multiple sclerosis)
  • For *brodalumab*: depression, suicidal ideation/behavior
  • For *IL-17 inhibitors*: Crohn disease and ulcerative colitis
  • For *rituximab*: arrhythmias
  • For *JAK inhibitors*: risk factors for thrombosis and intestinal perforation (e.g. diverticulitis)
• Pregnancy status	

Laboratory testing	
Prior to treatment	***During treatment***

• PPD†/interferon-γ release assay‡ and/or (e.g. if immunosuppression or history of tuberculosis) chest X-ray
• CBC and CMP
• Hepatitis B and C virus serologic profiles
• Consider HIV testing
• For *JAK inhibitors*: also lipid profile
	• Annual PPD†/interferon-γ release assay‡ and/or chest X-ray
	• CBC and CMP as noted below or clinically indicated
	  • For *anakinra*: CBC monthly for 3 months and then every three months
	  • For *JAK inhibitors*: CBC, CMP, and lipid profile within 1–2 months and then every 3 months

*Recommended vaccines should be administered prior to initiation of therapy, with live vaccines (see Table 128.8) given at least 2–4 weeks prior to starting the medication; the bacillus Calmette–Guérin (BCG) vaccine should not be given in the year prior to beginning or the year after completing ustekinumab therapy. †≥5 mm of induration should be considered as positive. ‡e.g. QuantiFERON® TB Gold Plus or T-SPOT®.TB.	

Table 128.6 Recommended evaluation for patients receiving targeted immune modulators for dermatologic disorders. Table 8.19 provides guidance for the selection of systemic therapies in psoriasis patients with comorbidities. CBC, complete blood count with differential; CMP, comprehensive metabolic panel (includes liver function tests); IL, interleukin; JAK, Janus kinase; PPD, purified protein derivative skin test; TNF, tumor necrosis factor.

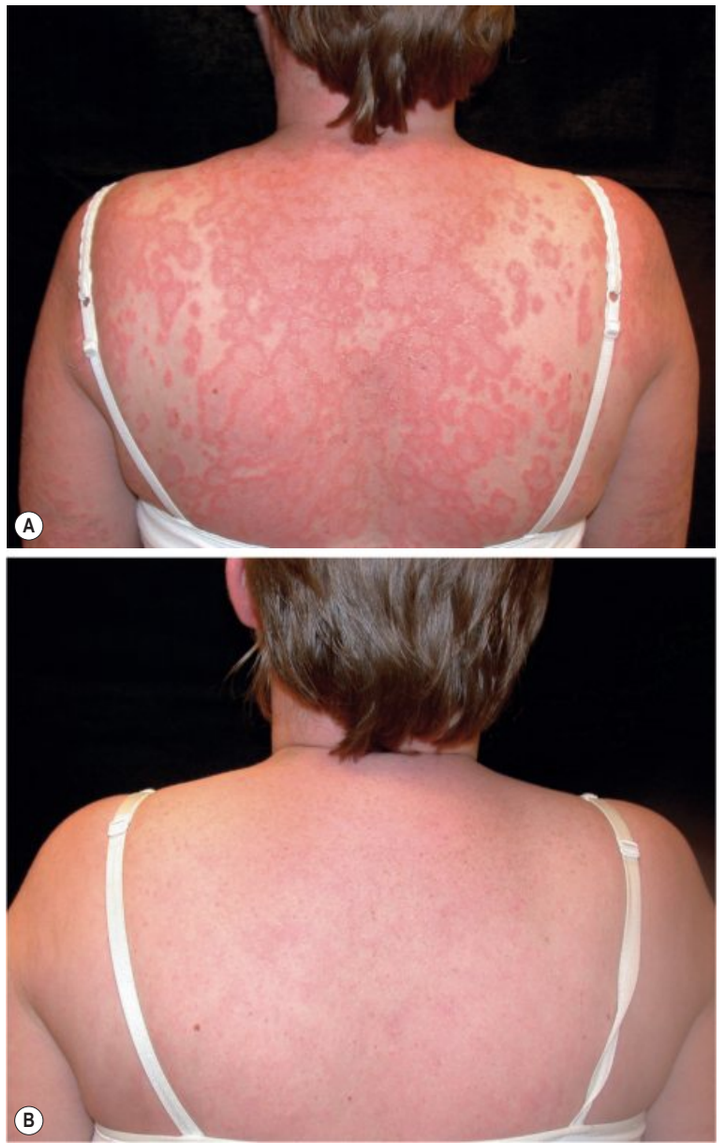

Fig. 128.6 Excellent clinical response to etanercept. Subacute cutaneous lupus erythematosus, before (**A**) and after (**B**) administration of etanercept.

these agents[12]. A meta-analysis of 20 RCTs (total n=6810) of TNF inhibitor therapy for psoriasis or psoriatic arthritis over rather limited periods of 12–30 weeks found no significant association with development of malignancy[13].

Adolescents and young adults with inflammatory bowel disease who receive infliximab and concomitant azathioprine or 6-mercaptopurine appear to have an increased risk of a rare, aggressive hepatosplenic T cell lymphoma. In an analysis of 48 malignancies in children and adolescents treated with TNF inhibitors that were reported to the FDA[14], it was noted that half were lymphomas, almost two-thirds were in patients taking infliximab, and 88% of the patients were concomitantly receiving another immunosuppressive agent. Although the incidence of malignancy was higher than the background rate in the general pediatric population, the potential role of other medications as well as the underlying disorders, primarily inflammatory bowel disease and juvenile idiopathic arthritis (JIA), precluded establishing a causal relationship with TNF inhibitor therapy.

Autoimmunity

Treatment with TNF inhibitors is associated with an increased likelihood of developing anti-nuclear and anti-dsDNA antibodies. Signs and symptoms of cutaneous and systemic lupus erythematosus (SLE) occasionally arise in patients receiving TNF inhibitors, but in general resolve upon cessation of treatment[15–17]. Conversely, several small case series have reported marked improvement of subacute cutaneous lupus erythematosus by etanercept[18,19] (Fig. 128.6). It is not necessary to evaluate patients for autoantibodies before or during therapy with TNF inhibitors. However, the development of anti-nuclear antibodies may be linked to loss of TNF inhibitor efficacy[20].

Demyelinating diseases

Although etanercept was originally utilized as a therapy for multiple sclerosis, new onset or exacerbation of multiple sclerosis or other demyelinating diseases represents a potential complication of TNF inhibitor treatment[4]. In some patients, symptoms of multiple sclerosis have abated despite continued therapy. It seems reasonable to avoid using TNF inhibitors in patients with a history of multiple sclerosis or other demyelinating diseases.

Congestive heart failure

There have been reports of congestive heart failure worsening or developing in patients receiving TNF inhibitors. As a result, it is recommended that therapy with TNF inhibitors be avoided in patients with unstable cardiac disease.

Cutaneous reactions

A variety of adverse skin reactions to TNF inhibitors have been described (Table 128.7). A new onset of psoriasis or a psoriasiform eruption occurs in ~5%–10% of patients with no previous history of psoriasis, often manifesting in adults as palmoplantar pustulosis (Fig. 128.7); in children, lesions tend to involve the scalp and ears[21–23]. Patients can also develop eczematous eruptions, which presumably reflect a shift towards Th1-mediated inflammation. Cutaneous small vessel vasculitis and reactive granulomatous dermatitis (RGD) have also been reported in patients undergoing TNF inhibitor therapy[24], but a subset of

CUTANEOUS SIDE EFFECTS OF TARGETED IMMUNE MODULATORS
Injectable agents
• Injection site reactions, e.g. erythema/edema, occasionally small vessel vasculitis; "recall" reactions at previous sites
Tumor necrosis factor inhibitors
• New-onset psoriasis, especially palmoplantar pustulosis • Interstitial granulomatous dermatitis and other granulomatous eruptions • Cutaneous small vessel vasculitis • Eczematous eruptions • Lichenoid dermatitis • Lupus-like syndrome-associated malar rash or discoid lesions • Other types of cutaneous lupus, e.g. SCLE, chilblain lupus
Interleukin-12/23, -23, and -17 inhibitors
• New-onset psoriasis, including palmoplantar pustulosis • Eczematous eruptions • Lichenoid dermatitis (primarily IL-17 inhibitors) • Granulomatous eruptions • Neutrophilic dermatoses (e.g. pyoderma gangrenosum) • Cutaneous small vessel vasculitis • Cutaneous lupus erythematosus (e.g. SCLE, discoid) • Vitiligo, alopecia areata, autoimmune bullous dermatoses • Hypertrichosis (IL-17 inhibitors)
Dupilumab
• Facial ± neck erythema or dermatitis • Psoriasis and psoriasiform eruptions • Lichen planus and lichenoid eruptions • Eosinophilic granulomatosis with polyangiitis • Alopecia areata, vitiligo • Unmasking of cutaneous T-cell lymphoma
JAK inhibitors
• Acne, papulopustular eruptions • Granulomatous dermatitis • Cutaneous small vessel vasculitis • SCLE • Lymphomatoid papulosis • Extensive cutaneous HPV infection, disseminated molluscum contagiosum • Keratinocyte and Merkel cell carcinomas

Table 128.7 Cutaneous side effects of targeted immune modulators. Allergic reactions manifesting with urticaria and angioedema can also occur with most agents. HPV, human papillomavirus; SCLE, subacute cutaneous lupus erythematosus; SJS, Stevens–Johnson syndrome.

these patients have rheumatoid arthritis, which itself can be associated with vasculitis and RGD (see Ch. 93)[25]. Additional cutaneous reactions that have been described in patients receiving TNF inhibitors include lichenoid dermatitis and other granulomatous conditions[26].

Vaccination

Live vaccines are contraindicated in patients receiving TNF inhibitors (Table 128.8). The effectiveness of vaccines in patients receiving these agents is unknown, but an immune response to influenza and pneumococcal vaccines has been documented[27]. It is recommended that patients (especially children) be brought up to date with all immunizations prior to initiating treatment with TNF inhibitors.

Use in pregnancy

In animal studies, TNF inhibitors have not shown evidence of harm to the fetus, but adequate studies in pregnant women have not been conducted[28]. Because IgG antibodies cross the placenta, their administration during late pregnancy could potentially increase risk of infection in the infant. Of note, pegylated certolizumab represents an exception as it has minimal placental transfer. Although TNF inhibitors are present in human milk, systemic exposure in a breastfed infant is expected to be low due to minimal oral absorption.

Etanercept

Etanercept (Enbrel®) and its biosimilars are fusion proteins consisting of the extracellular domain of the TNF receptor fused with the Fc portion of human IgG1[29].

Fig. 128.7 Psoriasiform reactions to tumor necrosis factor inhibitors. A Palmoplantar pustulosis that developed as a complication of infliximab. **B** Eruption of plaque psoriasis in a patient receiving infliximab therapy. The patient had received infliximab for GVHD of the gastrointestinal tract.

VACCINES THAT CONTAIN LIVE ATTENUATED VIRUSES OR BACTERIA
Adenovirus Bacillus Calmette–Guérin (BCG) Cholera, *oral form in the US* Herpes zoster, *live attenuated form (Zostavax®)** Influenza (including H1N1), *intranasal form* Measles, mumps, and rubella Rotavirus Polio, *oral form* Typhoid, *oral form* Vaccinia (smallpox vaccine) Varicella Yellow fever
*No longer available in the US, where a recombinant herpes zoster vaccine (Shingrix®) is administered.

Table 128.8 Vaccines that contain live attenuated viruses or bacteria.

Indications

Etanercept has been approved for the treatment of moderate to severe plaque psoriasis in adults since 2004 and in children ages 4–17 years since 2016. Depending on the regimen (see below), ~30%–60% and ~15%–25% of patients achieve a 75% and 90% improvement in their Psoriasis Area and Severity Index (PASI) score, respectively[30]. Other approved indications for etanercept include rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis in adults as well as JIA in children ≥2 years of age.

Etanercept has been used to treat a variety of other mucocutaneous disorders, including toxic epidermal necrolysis, hidradenitis suppurativa, dermatomyositis, cutaneous lupus erythematosus, lichen planus, autoimmune bullous diseases (especially mucous membrane [cicatricial] pemphigoid), neutrophilic dermatoses (including pyoderma gangrenosum), multicentric reticulohistiocytosis, relapsing polychondritis, and GVHD[18,31,32]. Although successful treatment of sarcoidosis has been described in case reports and small series, etanercept therapy failed to improve systemic manifestations of sarcoidosis in RCTs[33].

Dosages
The approved dose for moderate to severe plaque psoriasis is 50 mg twice weekly for the first 3 months, followed by 50 mg weekly. Etanercept is available in 25 and 50 mg prefilled syringes, 50 mg autoinjectors, and 25 mg multiple-use vials. The recommended dose for pediatric psoriasis is 0.8 mg/kg (maximum 50 mg) weekly.

Specific side effects
Side effects shared with other TNF inhibitors are discussed above and summarized in Tables 128.5 and 128.7. Injection site reactions are the most common side effect of etanercept (Fig. 128.8) but in general are mild to moderate and diminish in frequency after the first month of treatment. Erythema, pruritus, pain, and swelling have been described, and "recall" reactions at sites of previous injections have been reported. These reactions do not progress to anaphylaxis.

Interactions
The concomitant use of etanercept and methotrexate is approved for the treatment of rheumatoid arthritis and psoriatic arthritis. Due to the potential for increased immunosuppression, combination of etanercept with other targeted immune modulators should generally be avoided. A study of anakinra plus etanercept for patients with rheumatoid arthritis found no increase in efficacy but a substantial increase in the frequency of infection[34]. Etanercept has been used together with narrowband UVB without an increase in adverse events[35].

Infliximab
Infliximab and its biosimilars are chimeric human–mouse monoclonal IgG1 antibodies, and their target is human TNF[36].

Indications
Infliximab is approved for the treatment of adults with chronic severe plaque psoriasis. Compared with the other TNF inhibitors, its onset of action tends to be faster and a higher proportion of patients (~75%–85% and ~50%–65%) achieve a 75% and 90% reduction in the PASI score, respectively[37]. Infliximab is also approved for the treatment of adults with psoriatic arthritis, Crohn disease (including associated fistulas), ulcerative colitis, rheumatoid arthritis, and ankylosing spondylitis, as well as children ≥6 years of age with Crohn disease and ulcerative colitis. Infliximab appears to be useful for pyoderma gangrenosum, whether or not it is associated with inflammatory bowel disease[38]. It has been effective as a treatment for sarcoidosis, granulomatous cheilitis, Behçet disease, various vasculitides, pityriasis rubra pilaris, reactive arthritis, subcorneal pustular dermatosis, hidradenitis suppurativa, GVHD, Sjögren syndrome, and multicentric reticulohistiocytosis[39].

Fig. 128.8 Etanercept injection site reaction. Similar reactions occur with nearly all subcutaneously injected biologic therapies.

Dosages
In patients with plaque psoriasis, the typical infliximab regimen is 5 mg/kg administered by slow intravenous infusion at 0, 2, and 6 weeks, and then every 8 weeks. However, doses ranging from 3 to 10 mg/kg have been utilized, and the frequency of administration as well as the dose can be adjusted when the response is inadequate. For Crohn disease, rheumatoid arthritis, and psoriatic arthritis, it is approved for concomitant administration with methotrexate, azathioprine, or low-dose prednisone. Loss of efficacy over time may be related to the development of neutralizing anti-chimeric antibodies and has been associated with the presence of anti-nuclear antibodies[40,41]; the concurrent administration of low-dose weekly methotrexate may help to prevent the formation of anti-chimeric antibodies.

Specific side effects
Side effects shared with other TNF inhibitors are discussed above and summarized in Tables 128.5 and 128.7. Infusion-related reactions are the most commonly reported side effect of infliximab, occurring in ~15% of patients. The incidence of severe reactions, in particular anaphylaxis, is ~1%. Associated symptoms include fever, chills, pruritus, urticaria, chest pain, hypotension, hypertension, and shortness of breath. Infusion reaction risk has been linked to the presence of human anti-chimeric antibodies. Risk of reactions may be lessened by a slower infusion rate or concomitant use of methotrexate, azathioprine, or corticosteroids.

Interactions
Infliximab should not be administered together with other targeted immune modulators due to the potential for additive immunosuppression; concomitant use with anakinra or abatacept has been associated with the development of severe infections.

Adalimumab
Adalimumab (Humira®) and its biosimilars are human recombinant IgG1 monoclonal antibodies with specificity for human TNF[42].

Indications
Adalimumab is approved for the treatment of moderate to severe plaque psoriasis in adults; ~65%–75% and ~40%–45% of patients achieve a 75% and 90% improvement in their PASI score, respectively[36]. It is also approved for the treatment of moderate to severe hidradenitis suppurativa in patients ≥12 years of age, with ~40%–60% of these individuals achieving a 50% reduction in the abscess/inflammatory nodule count with no increase in the draining fistula count[43]. Additional approved indications include psoriatic arthritis, rheumatoid arthritis, ankylosing spondylitis, uveitis, and Crohn disease in adults as well as JIA and Crohn disease in children ≥2 years and ≥6 years of age, respectively. There have also been reports of successful adalimumab therapy for pustular psoriasis[44], sarcoidosis, pyoderma gangrenosum, Behçet disease, other neutrophilic dermatoses, and dermatomyositis.

Dosages
Adalimumab is supplied in 10–80 mg prefilled syringes as well as 40 and 80 mg autoinjectors; it is administered subcutaneously. For the treatment of psoriasis in adults, a loading dose of 80 mg is typically given, followed by 40 mg on day 8 and then 40 mg every other week. The approved regimen for hidradenitis suppurativa in adults and adolescents weighing ≥60 kg is a loading dose of 160 mg, 80 mg on day 15, and then either 40 mg weekly or 80 mg every other week starting on day 29. For adolescent HS patients weighing 30–59 kg, a loading dose of 80 mg is followed by 40 mg every other week starting on day 8. Loss of efficacy of adalimumab over time related to the production of anti-adalimumab antibodies can occur and may be prevented by the concurrent administration of low-dose weekly methotrexate; loss of efficacy has also been associated with the development of anti-nuclear antibodies[20].

The concomitant use of adalimumab and methotrexate is approved for the treatment of psoriatic arthritis, rheumatoid arthritis, and JIA.

Side effects

Side effects shared with other TNF inhibitors, including risk of infection with mycobacteria (see Fig. 128.5) and fungi, are discussed above and summarized in Tables 128.5 and 128.7[45].

Interactions

The concomitant administration of other targeted immune modulators with adalimumab may increase the risk of infection and should be avoided[46].

Golimumab

Golimumab (Simponi®, Simponi ARIA®) is a human recombinant IgG1 monoclonal antibody with specificity for human TNF[42]. It is approved for the treatment of psoriatic arthritis, rheumatoid arthritis, ankylosing spondylitis, polyarticular JIA, and ulcerative colitis; it can be administered together with methotrexate. Golimumab may also be useful in the treatment of other conditions that respond to TNF inhibitors. For psoriatic arthritis, it is administered as a 50 mg subcutaneous injection (prefilled syringe or autoinjector) monthly in adults or via a 2 mg/kg intravenous infusion at weeks 0 and 4, and then every 8 weeks, in patients ≥2 years of age[47].

Certolizumab pegol

Certolizumab pegol (Cimzia®) is a pegylated Fab fragment of a humanized monoclonal antibody with specificity for human TNF. It is approved for the treatment of psoriasis in adults, with ~60%–75% and ~35%–50% of patients achieving a 75% and 90% improvement in their PASI score, respectively[48]. Certolizumab is also approved for psoriatic arthritis, rheumatoid arthritis, and Crohn disease. It is supplied in a 200 mg prefilled syringe and administered subcutaneously. For psoriasis, 400 mg is given every 2 weeks, with an option of switching to a 200 mg dose after 4 weeks in patients weighing ≤90 kg.

Interleukin-12/23 and Interleukin-23 Inhibitors

Ustekinumab (Stelara®) is a monoclonal antibody that targets both IL-12 and IL-23. Monoclonal antibodies that target IL-23 alone include guselkumab (Tremfya®), risankizumab (Skyrizi®), tildrakizumab (Ilumya®), and mirikizumab (approved in Japan). A review of their mechanisms of action as well as shared contraindications, side effects, interactions, and use in pregnancy is followed by a discussion of issues that relate specifically to individual FDA-approved drugs.

Mechanism of action

Ustekinumab binds to the p40 subunit that is shared by the heterodimeric IL-12 and IL-23 cytokines, whereas guselkumab, risankizumab, tildrakizumab, and mirikizumab target the p19 subunit that is specific to IL-23 (Fig. 128.9D). IL-12 has a critical role in the development of Th1 cells and NK cell activation, whereas IL-23 is necessary for the generation of Th17 cells (see Fig. 4.9).

Contraindications

Ustekinumab and IL-23 inhibitors are contraindicated in patients with known hypersensitivity to these agents, and they should be avoided in patients with serious active infections or malignancies.

Side effects (see Table 128.5)

The most common adverse events in clinical trials of ustekinumab and IL-23 inhibitors were upper respiratory tract infections. Injection site reactions occurred in <5% of patients, and dermatophyte infections were observed in ~1% of patients treated with guselkumab or risankizumab. Hypersensitivity reactions have also been reported, including anaphylaxis, angioedema, and urticaria.

Assessment for tuberculosis is recommended at baseline and, depending on risk factors, repeated annually during therapy (see Table 128.6). Patients with untreated latent tuberculosis should receive antituberculous therapy prior to beginning treatment. In patients treated with IL-23 inhibitors, preservation of IL-12 activity and the resultant Th1 response is thought to result in less risk of infection with *Mycobacterium* spp. and other intracellular pathogens.

Interactions

Live vaccines should be avoided (see Table 128.8), and patients (especially children) should be brought up to date with immunizations prior to initiating treatment. Other targeted immune modulators should not be administered together with ustekinumab and IL-23 inhibitors. The concomitant administration of other immunosuppressive agents might increase the risk of infection.

Use in pregnancy

Animal reproduction studies have not shown adverse fetal effects, with the exception of increased fetal loss in pregnant monkeys who received high doses of risankizumab. There are no adequate studies in pregnant women. Safety during lactation is unknown.

Ustekinumab

Ustekinumab (Stelara®) is a human IgG1 monoclonal antibody that binds with high affinity and specificity to the p40 subunit shared by the heterodimeric IL-12 and IL-23 cytokines (see Fig. 128.9D).

Indications

Ustekinumab is approved for the treatment of moderate to severe plaque psoriasis and psoriatic arthritis in adults and children ≥6 years of age, with ~65%–80% and ~40%–55% of patients achieving a 75% and 90% improvement in their PASI scores, respectively[49]. Ustekinumab is also approved for adults with Crohn disease and ulcerative colitis. In addition, there are reports of its benefit in the treatment of other dermatologic conditions, such as hidradenitis suppurativa and pyoderma gangrenosum.

Dosages

For the treatment of psoriasis in adults and children weighing 60–100 kg, ustekinumab is administered as a subcutaneous injection of 45 mg, with the dose increased to 90 mg for patients weighing >100 kg; 0.75 mg/kg is administered to children weighing <60 kg. It is given at weeks 0 and 4, and then every 12 weeks. Ustekinumab is available as a 45 or 90 mg prefilled syringe, a 45 mg single-dose vial, and a solution for intravenous infusion in patients with Crohn disease. Measurement of serum levels of ustekinumab and anti-ustekinumab antibodies is commercially available and may be of utility in patients with a suboptimal therapeutic response.

Specific side effects

Side effects shared with IL-23 inhibitors are discussed above. Ustekinumab is associated with a potential risk of severe and disseminated infections with mycobacteria and *Salmonella*, which also occur in patients with genetic deficiencies in the IL-12/IL-23 signaling pathway (see Fig. 60.2). An increase in candidal infections has been observed in patients with Crohn disease. A possible excess of major adverse cardiovascular events (MACEs) such as myocardial infarction or stroke was noted in patients who received anti-IL-12/23 therapy in individual clinical trials, but meta-analyses and a 5-year follow-up study did not find a significant increase in the risk of MACEs[50–52]. Although the effects of IL-12/23 inhibitors on vascular inflammation and thrombosis, especially early in the course of therapy, remain to be determined, cardiovascular risk factors should be assessed prior to initiating treatment. Other potential severe side effects of ustekinumab are listed in Table 128.5. Retiform purpura progressing to cutaneous necrosis on the leg was reported in a patient treated with ustekinumab[53].

Guselkumab

Guselkumab (Tremfya®) is a human IgG1 monoclonal antibody that binds with high affinity and specificity to the p19 subunit of IL-23. It is approved for the treatment of adults with moderate to severe plaque psoriasis or psoriatic arthritis, with ~85% and ~65%–70% of psoriasis patients achieving a 75% and 90% improvement in their PASI score, respectively. Guselkumab is supplied in a 100 mg prefilled syringe or autoinjector that is administered subcutaneously at weeks 0 and 4, and then every 8 weeks.

Tildrakizumab

Tildrakizumab (Ilumya®) is a humanized IgG1 monoclonal antibody that specifically binds to the p19 subunit of IL-23. It is approved for the treatment of moderate to severe plaque psoriasis in adults, with ~65%

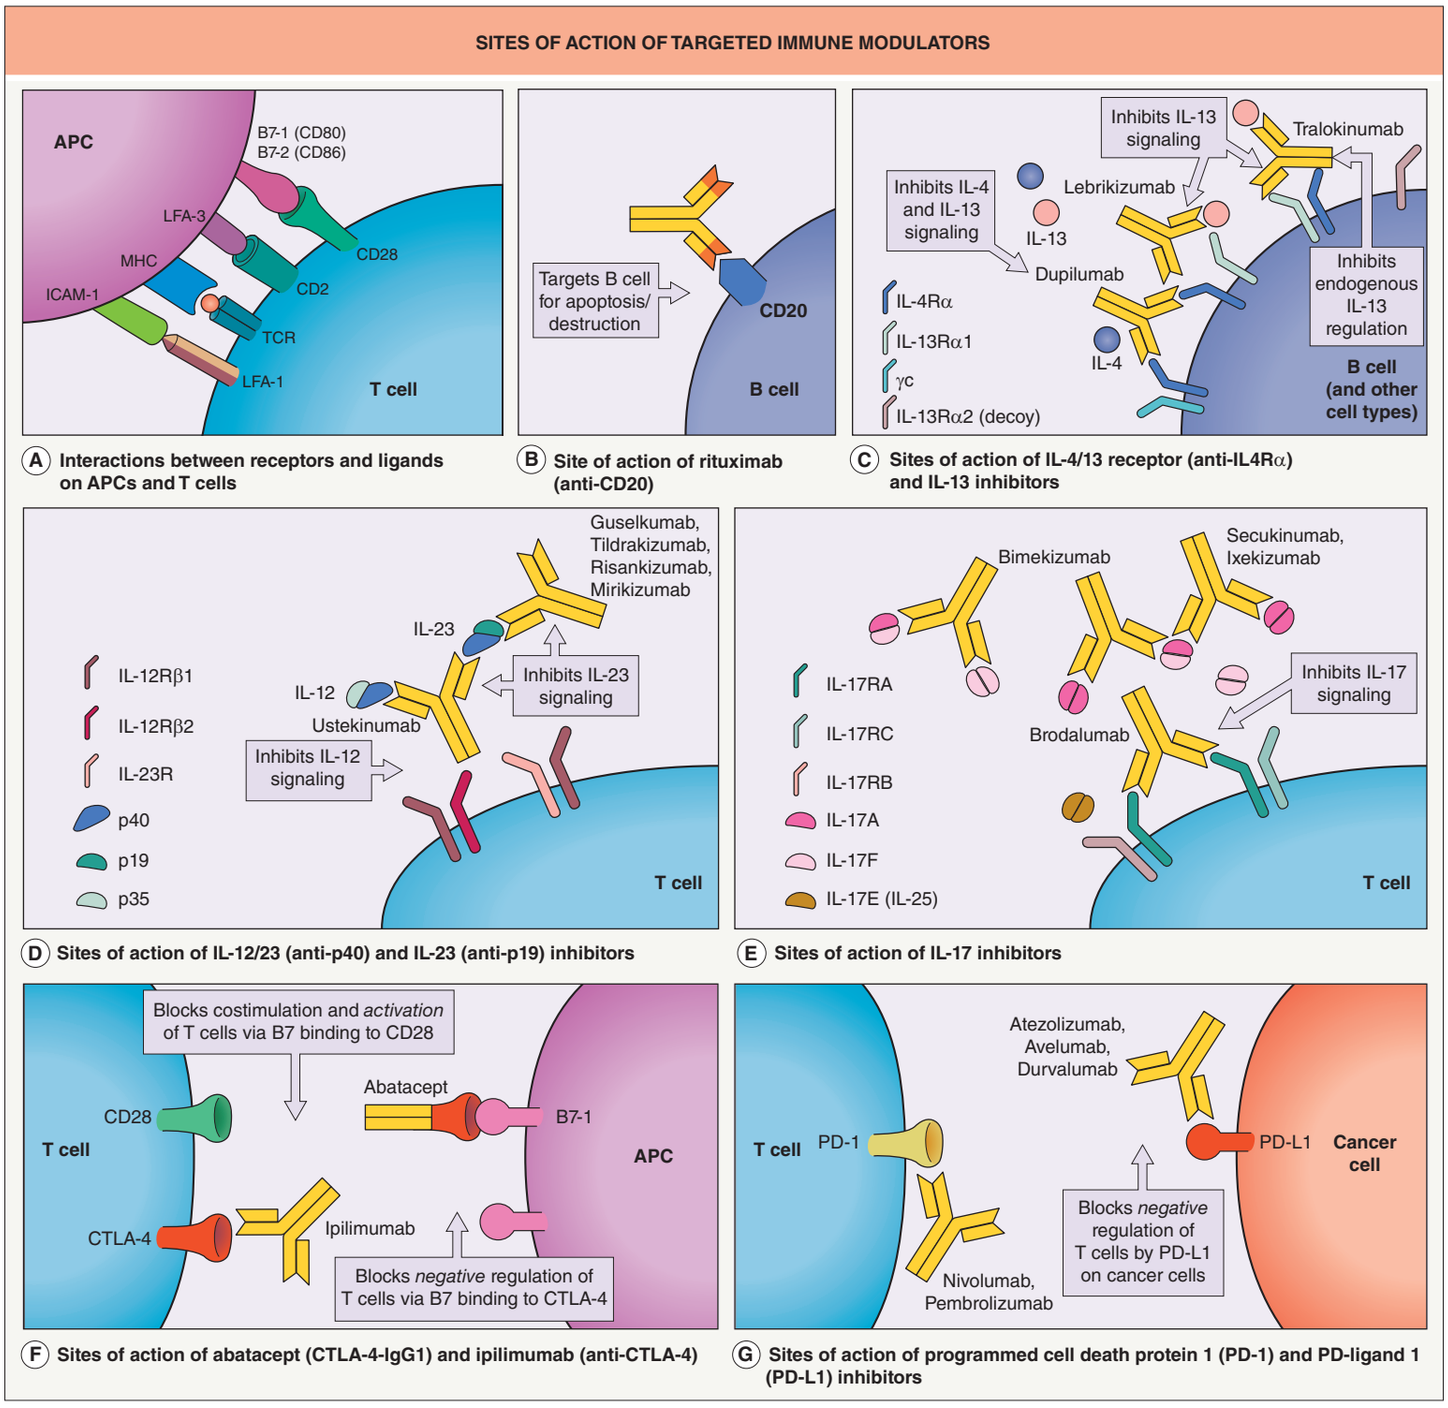

Fig. 128.9 Sites of action of targeted immune modulators. A Activation of T cells requires two signals. The first occurs when the major histocompatibility complex antigen interacts with the T cell receptor (TCR). A second costimulatory signal is required for T cell activation to occur. **B** Site of action of rituximab. **C** Sites of action of IL-4/13 receptor (anti-IL4Rα) and IL-13 inhibitors. **D** Sites of action of IL-12/23 (anti-p40) and IL-23 (anti-p19) inhibitors. **E** Sites of action of IL-17 inhibitors. **F** Sites of action of abatacept and ipilimumab. **G** Sites of action of programmed cell death protein 1 (PD-1) and PD-ligand 1 (PD-L1) inhibitors. APC, antigen-presenting cell; CTLA-4, cytotoxic T lymphocyte antigen 4; ICAM, intercellular adhesion molecule; IL, interleukin; LFA, lymphocyte function antigen; MHC, major histocompatibility complex; R, receptor.

and ~40% of patients achieving a 75% and 90% improvement in their PASI score, respectively. Tildrakizumab is supplied in a 100 mg prefilled syringe that is administered subcutaneously at weeks 0 and 4, and then every 12 weeks.

Risankizumab

Risankizumab (Skyrizi®) is a humanized IgG1 monoclonal antibody that binds with high affinity and specificity to the p19 subunit of IL-23. It is approved for the treatment of moderate to severe psoriasis, psoriatic arthritis, and Crohn disease in adults. Approximately 90% and 75% of psoriasis patients achieve a 75% and 90% improvement in their PASI score, respectively. Risankizumab is supplied in a 150 mg prefilled syringe or autoinjector that is administered subcutaneously at weeks 0 and 4, and then every 12 weeks.

Interleukin-17 Inhibitors

Currently, three IL-17 inhibitors are approved for the treatment of psoriasis: ixekizumab (Taltz®) and secukinumab (Cosentyx®), which target IL-17A, and brodalumab (Siliq™), which blocks the IL-17 receptor A (Fig. 128.9E). Bimekizumab (Bimzelx®), which targets both IL-17A and IL-17F, is approved in Europe, Canada, and Japan. A review of their

shared contraindications, major side effects, interactions, and use in pregnancy is followed by a discussion of issues that relate specifically to individual drugs.

Contraindications

Each IL-17 inhibitor is contraindicated in patients with a known hypersensitivity to that particular agent or components of its formulation. These medications should be used with caution in patients with chronic/recurrent infections or inflammatory bowel disease, with Crohn disease representing a contraindication for brodalumab (see below). Administration of an IL-17 inhibitor should be avoided or discontinued in patients with a serious active infection.

Major side effects

The most common adverse events in clinical trials of IL-17 inhibitors were nasopharyngitis/upper respiratory tract infections and (for ixekizumab) injection-site reactions[54–56]. Hypersensitivity reactions have also been reported, including anaphylaxis, angioedema, and urticaria. Mucocutaneous candidiasis, most often oral or vulvovaginal, develops in ~5% of patients[55,57]; this reflects the important role of IL-17 in defense against *Candida* (see Fig. 60.2)[58]. These infections are typically mild or moderate and resolve with standard treatment[55]. Neutropenia (<1500 cells/mm^3) occurs in ~1%–2% of patients, which is similar to the frequency in patients receiving etanercept[54,56]. Assessment for tuberculosis is required at baseline and, depending on risk factors, repeated annually during therapy (see Table 128.6). Patients with untreated or inadequately treated latent tuberculosis should receive antituberculous therapy prior to beginning treatment.

In 0.1%–0.5% of patients receiving IL-17 inhibitors, a new onset or exacerbation of Crohn disease or ulcerative colitis has been reported. An increased risk of adverse cardiovascular events was not observed in clinical trials. Cutaneous reactions that have been described in patients receiving IL-17 inhibitors are listed in Table 128.7.

Interactions

Live vaccines should be avoided (see Table 128.8), and patients (especially children) should be brought up to date with immunizations prior to initiating treatment. To avert a potential increased risk of infection, other targeted immune modulators should not be coadministered with IL-17 inhibitors.

Use in pregnancy

There are no adequate studies on IL-17 inhibitor use in pregnant women, although human IgG is known to cross the placenta. No evidence of harm to the fetus was observed in pregnant monkeys receiving up to 19–30 times the maximum recommended human doses of ixekizumab, secukinumab, and brodalumab; however, there were a few deaths of newborn monkeys in the ixekizumab group. Safety during lactation is unknown.

Ixekizumab

Mechanism of action

Ixekizumab (Taltz®) is a humanized IgG4 monoclonal antibody that binds and inhibits IL-17A, resulting in neutralization of IL-17A homodimers and IL-17A/F heterodimers (see Fig. 128.9E). In its hinge region, there is substitution of proline for serine which prevents the formation of half-antibodies (half-mers) that can undergo Fab-arm exchange with endogenous human IgG4.

Indications

Ixekizumab is approved for the treatment of moderate to severe plaque psoriasis in patients ≥6 years of age, with ~90% and ~70%–75% of patients achieving a 75% and 90% improvement in their PASI score, respectively, within 12 weeks of beginning treatment[54]. Ixekizumab is also indicated for the treatment of psoriatic arthritis and ankylosing spondylitis in adults.

Dosages

Ixekizumab is administered as a subcutaneous injection (prefilled syringe or autoinjector), with a loading dose of 160 mg followed by 80 mg every 2 weeks for 12 weeks and then every 4 weeks. Pediatric dosing is based on body weight: 160 mg loading and then 80 mg every 4 weeks if >50 kg; 80 mg loading and then 40 mg every 4 weeks if 25–50 kg; and 40 mg loading and then 20 mg every 4 weeks if <25 kg. It is supplied in 80 mg prefilled syringes and autoinjectors; currently 20 and 40 mg doses must be prepared and administered by a healthcare professional.

Secukinumab

Mechanism of action

Secukinumab (Cosentyx®) is a human IgG1κ monoclonal antibody that binds with high affinity and selectivity to IL-17A (see Fig. 128.9E).

Indications

Secukinumab is approved for moderate to severe plaque psoriasis in patients ≥6 years of age. Approximately 75%–85% and 65%–75% of adults treated with the 300 mg and 150 mg doses, respectively, achieve a 75% improvement in their PASI score, with ~65% of those who received 300 mg reaching 90% improvement by week 12[59]. Secukinumab is also approved for psoriatic arthritis in patients ≥2 years of age, enthesitis-related arthritis in patients ≥4 years of age, and ankylosing spondylitis in adults.

Dosages

Secukinumab is administered as a subcutaneous injection at weeks 0, 1, 2, 3, and 4; thereafter, it is given every 4 weeks. The standard dose for psoriasis in adults is 300 mg; doses of 150 mg and 75 mg are given to children weighing ≥50 kg (or selected adults weighing <90 kg) and <50 kg, respectively. It is available in prefilled syringes (75, 150, and 300 mg) and autoinjectors (150 and 300 mg).

Brodalumab

Mechanism of action

Brodalumab (Siliq™) is a human IgG2κ monoclonal antibody that selectively binds the IL-17 receptor A, inhibiting its interactions with IL-17A/F and IL-17E (also known as IL-25) (see Fig. 128.9E).

Indications

Brodalumab is approved for the treatment of moderate to severe plaque psoriasis in adults who have failed or become unresponsive to other systemic therapies. Approximately 80%–90% and 65%–75% of patients achieve a 75% and 90% reduction in their PASI score, respectively[57].

Dosages

Brodalumab is available in prefilled syringes and administered as a 210 mg subcutaneous injection every 2 weeks.

Additional contraindications and major side effects

Contraindications and major side effects shared with other IL-17 inhibitors are described above. Brodalumab is contraindicated in patients with Crohn disease. Suicidal ideation and completed suicides occurred during clinical trials of brodalumab[60]. As a result, this medication is only available through a restricted Risk Evaluation and Mitigation Strategy (REMS) program, which requires provider and pharmacy certification as well as a patient–prescriber agreement form.

Spesolimab-sbzo

Spesolimab-sbzo (Spevigo®) is a humanized IgG1 monoclonal antibody that binds to the IL-36 receptor, preventing downstream proinflammatory signaling. It is approved for the treatment of generalized pustular psoriasis flares in adults. A single 900 mg intravenous infusion is administered, which leads to a lack of visible pustules after 1 week in >50% of patients[61]; a repeat dose may be given 1 week later in patients without an inadequate response.

Contraindications

Spesolimab is contraindicated in patients with a history of hypersensitivity to this agent and should be avoided in patients with serious active infections.

Major side effects

The most common adverse reactions are asthenia and fatigue, nausea and vomiting, infection, headache, and pruritus. Hypersensitivity and

infusion-related reactions have occurred, including drug hypersensitivity with eosinophilia and systemic symptoms (DRESS). Assessment for tuberculosis is recommended prior to initiating treatment (see Table 128.5).

Interactions

Live vaccines are contraindicated and the response to vaccines may be muted (see Table 128.8).

Use in pregnancy

There are no adequate studies of spesolimab in pregnant women, and animal reproduction studies have not shown harm to the fetus. Its safety during lactation is unknown.

Interleukin-4/13 Receptor and Interleukin-13 Inhibitors

Dupilumab (Dupixent®) is a monoclonal antibody that targets the receptor which binds both IL-4 and IL-13. Monoclonal antibodies that target IL-13 include tralokinumab (Adbry™) and lebrikizumab (currently under FDA review for atopic dermatitis). A review of the mechanisms of action as well as shared contraindications, side effects, interactions, and use in pregnancy of these agents is followed by a discussion of issues that relate specifically to individual FDA-approved drugs.

Mechanisms of action

Dupilumab is a human IgG4 monoclonal antibody that specifically binds to the IL-4Rα subunit of the heterodimeric IL-4 and IL-13 receptor (Fig. 128.9C). This blocks signaling by these cytokines and the resultant Th2-mediated inflammation. Tralokinumab (Adbry™) is a human IgG4 monoclonal antibody that binds to IL-13, blocking its interaction with the IL-13Rα1 subunit of the IL-4/-13 receptor as well as IL-13Rα2, a decoy receptor. Lebrikizumab is a humanized IgG4 monoclonal antibody that also binds to soluble IL-13 but blocks its interaction with the IL-4Rα subunit, preventing heterodimerization with IL-13Rα1.

Contraindications

These agents are contraindicated in patients with known sensitivity to the drug or components of its formulation. Administration should be avoided or discontinued in patients with a serious active helminth infection.

Major side effects

The most common side effects are injection site reactions and conjunctivitis (see Table 128.5), with each occurring in ~10% of patients. Conjunctivitis typically develops in the first weeks to months of treatment, and manifestations of ocular surface disease may also include dry eyes, blepharitis, keratitis, eyelid dermatitis, and palpebral edema[62] (Fig. 128.10). Warm compresses, lubricant eye drops (i.e. artificial tears), and antihistamine/mast cell stabilizer eye drops (e.g. ketotifen) are often recommended for initial management; corticosteroid, cyclosporine, or lifitegrast eye drops and tacrolimus ointment represent additional treatment options.

Interactions

Live vaccines should be avoided (see Table 128.8), and patients (especially children) should be brought up to date with all immunizations prior to initiating treatment.

Use in pregnancy

There are no available data on use in pregnant women, although human IgG is known to cross the placenta. No evidence of fetal harm was observed in animal studies. Safety during lactation is unknown.

Dupilumab

Indications

Dupilumab is approved for the treatment of patients ≥6 months of age with moderate to severe atopic dermatitis that is not adequately controlled with topical therapy. It is also approved for prurigo nodularis in adults. Approximately 40%–50% of adolescents and adults treated with dupilumab alone and ~60%–70% of children or adults treated with dupilumab plus topical corticosteroids achieve a 75% improvement in their Eczema Area and Severity Index (EASI) score[63]. Non-dermatologic indications for dupilumab include asthma in patients ≥6 years of age, eosinophilic esophagitis in patients ≥12 years of age, and chronic rhinosinusitis with nasal polyposis in adults.

Fig. 128.10 Conjunctivitis and ectropion requiring surgical repair associated with dupilumab therapy for atopic dermatitis. The patient's facial and eyelid dermatitis flared on dupilumab. Of note, the conjunctivitis and ectropion recurred after rechallenge with dupilumab. *Courtesy Jonathan S. Leventhal, MD.*

Dosages

Administration via subcutaneous injection depends on age and weight: a 600 mg loading dose and then 300 mg every *2 weeks* in adults and children weighing ≥60 kg; a 400 mg loading dose and then 200 mg every *2 weeks* in children weighing 30–59 kg; a 600 mg loading dose and then 300 mg every *4 weeks* in children ≥6 years of age weighing 15–29 kg; 300 mg every *4 weeks* in children ≤5 years of age weighing 15–29 kg; and 200 mg every *4 weeks* in children ≤5 years of age weighing 5–14 kg. It is available in prefilled syringes (100, 200, and 300 mg) and autoinjectors (200 and 300 mg).

Specific side effects

In addition to the side effects noted above, facial ± neck erythema or dermatitis may develop in association with dupilumab therapy, with potential contributing factors including rosacea/demodicosis, allergic contact dermatitis, and *Malassezia*-related dermatitis[64]. Depending on the suspected etiology, treatment options include topical corticosteroids, topical calcineurin inhibitors, and topical or oral (e.g. itraconazole) antifungal agents. Dupilumab-associated psoriasis/psoriasiform eruptions, lichen planus/lichenoid eruptions, and eosinophilic granulomatosis with polyangiitis have also been reported.

Tralokinumab

Tralokinumab (Adbry™) is approved for the treatment of adults with moderate to severe atopic dermatitis that is not adequately controlled with topical therapy. Monotherapy and combination therapy with topical corticosteroids result in ~30% and 55% of patients achieving a 75% improvement in their EASI score, respectively[65,66]. A loading dose of 600 mg is followed by 300 mg every 2 weeks; a decrease in frequency to every 4 weeks may be considered in patients with clear or almost clear skin after 16 weeks of treatment. It is supplied in a 150 mg prefilled syringe.

Interleukin-1 Inhibitors

Currently, there are three approved IL-1 antagonists: anakinra, canakinumab, and rilonacept. Dermatologic uses of these medications include treatment of cryopyrin-associated periodic syndrome (CAPS) and the pustular eruptions and bone lesions (e.g. osteomyelitis) of the autosomal recessive *d*eficiency of the *I*L-1 *r*eceptor *a*ntagonist (DIRA) (see Tables 45.2 & 45.7). CAPS represents a spectrum of autosomal dominant disorders featuring urticarial lesions and variable extracutaneous manifestations associated with gain-of-function mutations in the

gene that encodes cryopyrin, a protein that functions in an "inflammasome" complex that releases IL-1β (see Fig. 4.2). A review of these agents' shared contraindications, major side effects, and interactions is followed by a discussion of issues that relate specifically to individual drugs.

Contraindications

Each IL-1 antagonist is contraindicated in patients with a known hypersensitivity to that particular agent or components of its formulation. Administration should not be initiated in patients with active infections, and discontinuation should be considered if a serious infection develops.

Major side effects

Adverse effects include an increased risk of serious infections, flu-like symptoms, and injection site reactions (see Table 128.5). Assessment for tuberculosis is required at baseline and typically repeated annually during therapy. Patients with untreated latent tuberculosis should receive antituberculous therapy prior to beginning treatment.

Interactions

Other immunosuppressive agents, particularly TNF inhibitors, should not be coadministered with IL-1 antagonists[34]. Live vaccines should also be avoided (see Table 128.8), and it is unknown whether vaccines have a full effect.

Anakinra

Mechanism of action

Anakinra (Kineret®) is a recombinant, non-glycosylated human IL-1 receptor antagonist. The drug binds to IL-1 type 1 receptors and thereby acts as a competitive inhibitor of IL-1, downregulating its inflammatory effects (see Fig. 45.13).

Indications

Anakinra is approved for the treatment of rheumatoid arthritis in adults as well as CAPS, in particular NOMID, in both children and adults[67,68] (see Table 45.2). In addition, anakinra has been reported to aid in the control of DIRA (see above and Table 45.7), generalized pustular psoriasis/deficiency of the IL-36 receptor antagonist (DITRA), SAPHO syndrome, Schnitzler syndrome, hidradenitis suppurativa, pyoderma gangrenosum, and *p*yogenic *a*rthritis–*p*yoderma gangrenosum–*a*cne (PAPA) syndrome[69–71].

Dosages

Anakinra is administered via *daily* subcutaneous injection at a dose of 100 mg in adults with rheumatoid arthritis and a starting dose of 1–2 mg/kg in children with NOMID, followed by titration to a maximum dose of 8 mg/kg daily as needed to control active inflammation. It is available in 100 mg graduated prefilled syringes.

Additional contraindications

In addition to the shared contraindications for IL-1 antagonists noted above, anakinra should be used with caution in patients with renal impairment; every other day administration is recommended for NOMID patients with a creatinine clearance <30 mL/min.

Additional major side effects

In addition to infections, neutropenia and thrombocytopenia represent potentially serious reactions. Complete blood counts should be performed monthly for 3 months and then quarterly (see Table 128.6). Injection site reactions are usually mild and tend to abate with continued therapy.

Use in pregnancy

In animal studies, anakinra has not shown evidence of harm to the fetus. Adequate studies in pregnant women have not been conducted, and its safety during lactation is unknown.

Canakinumab

Mechanism of action

Canakinumab (Ilaris®) is a human IgG1κ monoclonal antibody that binds and neutralizes IL-1β (see Fig. 45.13).

Indications

Canakinumab is approved for the treatment of the following conditions: CAPS in patients ≥4 years of age (see above and Table 45.2); TNF receptor-associated periodic syndrome (TRAPS), hyperimmunoglobulinemia D syndrome (HIDS), and familial Mediterranean fever (FMF) in adult and pediatric patients (see Table 45.2); and systemic JIA in patients ≥2 years of age. Canakinumab has also been successfully used to treat DIRA, generalized pustular psoriasis, Schnitzler syndrome, hidradenitis suppurativa, pyoderma gangrenosum, and PAPA syndrome[70,72,73].

Dosages

Canakinumab is given every 4–8 weeks as a subcutaneous injection of 150–300 mg in patients who weigh >40 kg and 2–4 mg/kg in patients who weigh 15–40 kg. In general, the doses are lower and the drug is administered less frequently in patients with CAPS as compared to those with TRAPS, HIDS, or FMF. It is available in 150 mg single-dose vials.

Use in pregnancy

Canakinumab has been associated with delayed skeletal development in animal reproduction studies. Adequate studies in pregnant women have not been conducted, and it should be used with caution in nursing women[74].

Rilonacept

Mechanism of action

Rilonacept (Arcalyst®) is a dimeric fusion protein composed of the extracellular portion of the IL-1 receptor and the Fc portion of IgG1. It blocks IL-1β signaling by acting as a soluble decoy receptor, preventing interaction of IL-1β with cell surface receptors (see Fig. 45.13). Rilonacept has less affinity for IL-1α and the IL-1 receptor antagonist.

Indications

Rilonacept is approved for the treatment of CAPS in patients ≥12 years of age. It has also been reported to be of benefit in patients with Schnitzler syndrome.

Dosages

Rilonacept is administered via subcutaneous injection, with a loading dose of 320 mg in adults or 4.4 mg/kg in pediatric patients, followed by weekly injections of 160 mg or 2.2 mg/kg.

Use in pregnancy

Rilonacept has been associated with minor skeletal anomalies in animal reproduction studies. Adequate studies in pregnant women have not been conducted, and it should be used with caution in nursing women.

Rituximab

Rituximab (Rituxan®) and its biosimilars are chimeric monoclonal antibodies directed against the CD20 antigen present on the surface of mature B cells[75].

Mechanism of action

Rituximab binds to CD20 on the surface of mature B cells and causes apoptosis of these cells (see Fig. 128.9B). It targets and selectively depletes $CD20^+$ B cells without affecting stem cells or existing plasma cells. Possible mechanisms of cell lysis include complement-dependent cytotoxicity and antibody-dependent cell-mediated cytotoxicity. In patients with pemphigus vulgaris, downregulation of desmoglein-3-specific $CD4^+$ T cells as well as depletion of B cells and decreased anti-desmoglein-3 antibody levels has been observed[76].

Indications

Rituximab is approved for the treatment of the following disorders: pemphigus vulgaris, B cell non-Hodgkin lymphoma (NHL), chronic lymphocytic leukemia, and rheumatoid arthritis in adults; granulomatosis with polyangiitis and microscopic polyangiitis in patients ≥2 years of age; and mature B cell NHL and mature B cell acute leukemia in children ≥6 months of age[77,78]. It has been successfully used to treat primary cutaneous B cell lymphoma[79]. In addition to its approved indications, rituximab has demonstrated efficacy in other autoimmune

bullous dermatoses (e.g. bullous pemphigoid, mucous membrane pemphigoid[80], paraneoplastic pemphigus), SLE, cutaneous lupus erythematosus[81], dermatomyositis[82], chronic GVHD[83], cryoglobulinemic vasculitis, and other forms of cutaneous small vessel vasculitis[84].

Dosages

The dosing regimen for pemphigus vulgaris is 1 g administered intravenously at weeks 0 and 2, followed by 500 mg at 12 months and then every 6 months. For lymphomas, rituximab 375 mg/m^2 is given intravenously weekly for 48 weeks. Rituximab is approved for concomitant use with methotrexate in patients with rheumatoid arthritis, and with chemotherapy in patients with B cell lymphoma. Efficacy may be reduced in patients who develop anti-rituximab antibodies[85].

Contraindications

Rituximab is contraindicated in patients allergic to the drug or its components, hepatitis B carriers, and patients with cardiac arrhythmias, angina pectoris, a high tumor burden, or active infection.

Major side effects (see Table 128.5)

In clinical trials, the most common adverse events were infusion reactions and infections, with no significant change in average immunoglobulin levels. Deaths within 24 hours of rituximab infusion have been attributed to reaction-related sequelae including hypoxia, acute respiratory distress syndrome, myocardial infarction, ventricular fibrillation, and cardiogenic shock. Approximately 80% of these deaths occurred in association with the first infusion. Acute kidney failure requiring dialysis has occurred in the setting of tumor lysis syndrome following treatment with rituximab, with instances of fatal outcome. Severe mucocutaneous reactions, including Stevens–Johnson syndrome/toxic epidermal necrolysis, have occasionally been noted in patients given rituximab. Rarely patients have developed paraneoplastic pemphigus during treatment, but it is not clear whether this phenomenon is drug-related or disease-related.

Hypogammaglobulinemia and late-onset neutropenia (≥4 weeks after infusion) develop in ~1%–30% of patients, with incidence related to factors such as age and the underlying disease (more frequent with hematologic disorders than pemphigus). Progressive multifocal leukoencephalopathy and hepatitis B virus activation potentially leading to fulminant hepatitis have also been reported.

Interactions

Live vaccines are contraindicated and the response to vaccines may be muted, as recently witnessed with COVID mRNA vaccines (see Table 128.8). Combination with other targeted immune modulators, particularly natalizumab, may increase the risk of infection. Combination with cisplatin increases the risk of nephrotoxicity.

Use in pregnancy

There are no adequate studies of rituximab in pregnant women, and its safety during lactation is unknown. B cell lymphopenia can occur in infants exposed to rituximab *in utero*.

Omalizumab

Omalizumab (Xolair®) is a recombinant humanized monoclonal antibody that targets IgE.

Mechanism of action

Omalizumab is a humanized IgG1 monoclonal antibody that selectively binds to and decreases serum levels of free human IgE. It also downregulates the number of high-affinity IgE receptors on mast cells, basophils, and dendritic cells[86,87]. These two mechanisms limit the release of inflammatory mediators and, via its effects on dendritic cells, decrease antigen presentation to T cells.

Indications

Omalizumab is approved for the treatment of patients ≥12 years of age with chronic spontaneous urticaria (CSU), patients ≥6 years of age with asthma, and adults with chronic rhinosinusitis with nasal polyps[88,89]. In addition, it has variable utility in the treatment of atopic dermatitis[90], eosinophilic granulomatosis with polyangiitis, bullous pemphigoid, and mastocytosis.

Dosages

Omalizumab is administered as a subcutaneous injection of 150 or 300 mg every 4 weeks for CSU, with dosing independent of serum IgE level or body weight. Patients with asthma receive 75–375 mg every 2–4 weeks, with dosing determined by the baseline serum total IgE level and body weight.

Contraindications

There are no contraindications other than previous hypersensitivity to omalizumab.

Major side effects (see Table 128.5)

The most common serious adverse event is anaphylaxis, which occurs in 0.1%–0.2% of asthma patients and has rarely been reported in CSU patients. A possible increased overall risk of malignancy was noted in clinical trials in asthma patients – 0.5% with omalizumab vs 0.2% with placebo; however, subsequent larger longitudinal studies failed to demonstrate an increased risk of malignancy[91]. Injection site reactions occur in 10%–15% of patients.

Interactions

No specific interactions with other medications have been noted.

Use in pregnancy

Omalizumab has not shown evidence of fetal harm in animal studies, and adequate studies in pregnant women have not been conducted. It is excreted into the breast milk of monkeys, and caution is advised when administering it to nursing women.

Janus Kinase (JAK) Inhibitors

Oral Janus kinase (JAK) inhibitors include abrocitinib (Cibinqo™), baricitinib (Olumiant®), deucravacitinib (Sotyktu™), ritlecitinib (Litfulo™), ruxolitinib (Jakafi®), tofacitinib (Xeljanz®), and upadacitinib (Rinvoq®). These agents are currently approved for the treatment of dermatologic disorders including atopic dermatitis, psoriasis, alopecia areata, and graft-versus-host disease. Other skin conditions for which successful oral JAK inhibitor therapy has been reported include dermatomyositis, STAT1-related chronic mucocutaneous candidiasis, and interferonopathies (see Table 45.7). A review of the mechanism of action, contraindications, side effects, and use in pregnancy of JAK inhibitors is followed by a discussion of indications, dosing, and interactions of individual FDA-approved drugs. *Topical* JAK inhibitors such as ruxolitinib 1.5% cream (Opzelura™), which is approved for the treatment of atopic dermatitis and vitiligo, are discussed in Chapter 129.

Mechanism of action

There are four known JAK enzymes: JAK1, JAK2, JAK3, and tyrosine kinase 2 (TYK2). These tyrosine kinases are expressed primarily in hematopoietic cells and play a key role in the transduction of cytokine-mediated signals, with the latter leading to activated transcription of inflammatory proteins (Fig. 128.11). Examples of JAK-dependent cytokines include: IFN-γ – JAK1/2; IL-2, IL-4 – JAK1/3; IFN-α/β – JAK1/TYK2; and IL-12/23 – JAK2/TYK2. These cytokines are implicated in the pathogenesis of inflammatory and autoimmune skin diseases such as atopic dermatitis, psoriasis, alopecia areata, and vitiligo[92].

Contraindications

Use of JAK inhibitors should be avoided in patients with a serious active infection, thrombotic disorders, severe hepatic impairment, lymphopenia (<500 cells/mm^3), neutropenia (<1000 cells/mm^3), anemia (hemoglobin <8–9 g/dL), or (especially with abrocitinib and ruxolitinib) thrombocytopenia (<50 000 cells/mm^3). Caution is advised in patients at increased risk of gastrointestinal perforation, especially when considering treatment with baricitinib, tofacitinib, or upadacitinib.

Major side effects

Serious bacterial, mycobacterial, invasive fungal, viral (e.g. human papillomavirus, herpes zoster, herpes simplex virus; Fig. 128.12), and other opportunistic infections have occurred in patients receiving JAK inhibitors. Assessment for tuberculosis at baseline and monitoring during therapy is required. Patients with untreated latent tuberculosis should receive antituberculous therapy before beginning treatment.

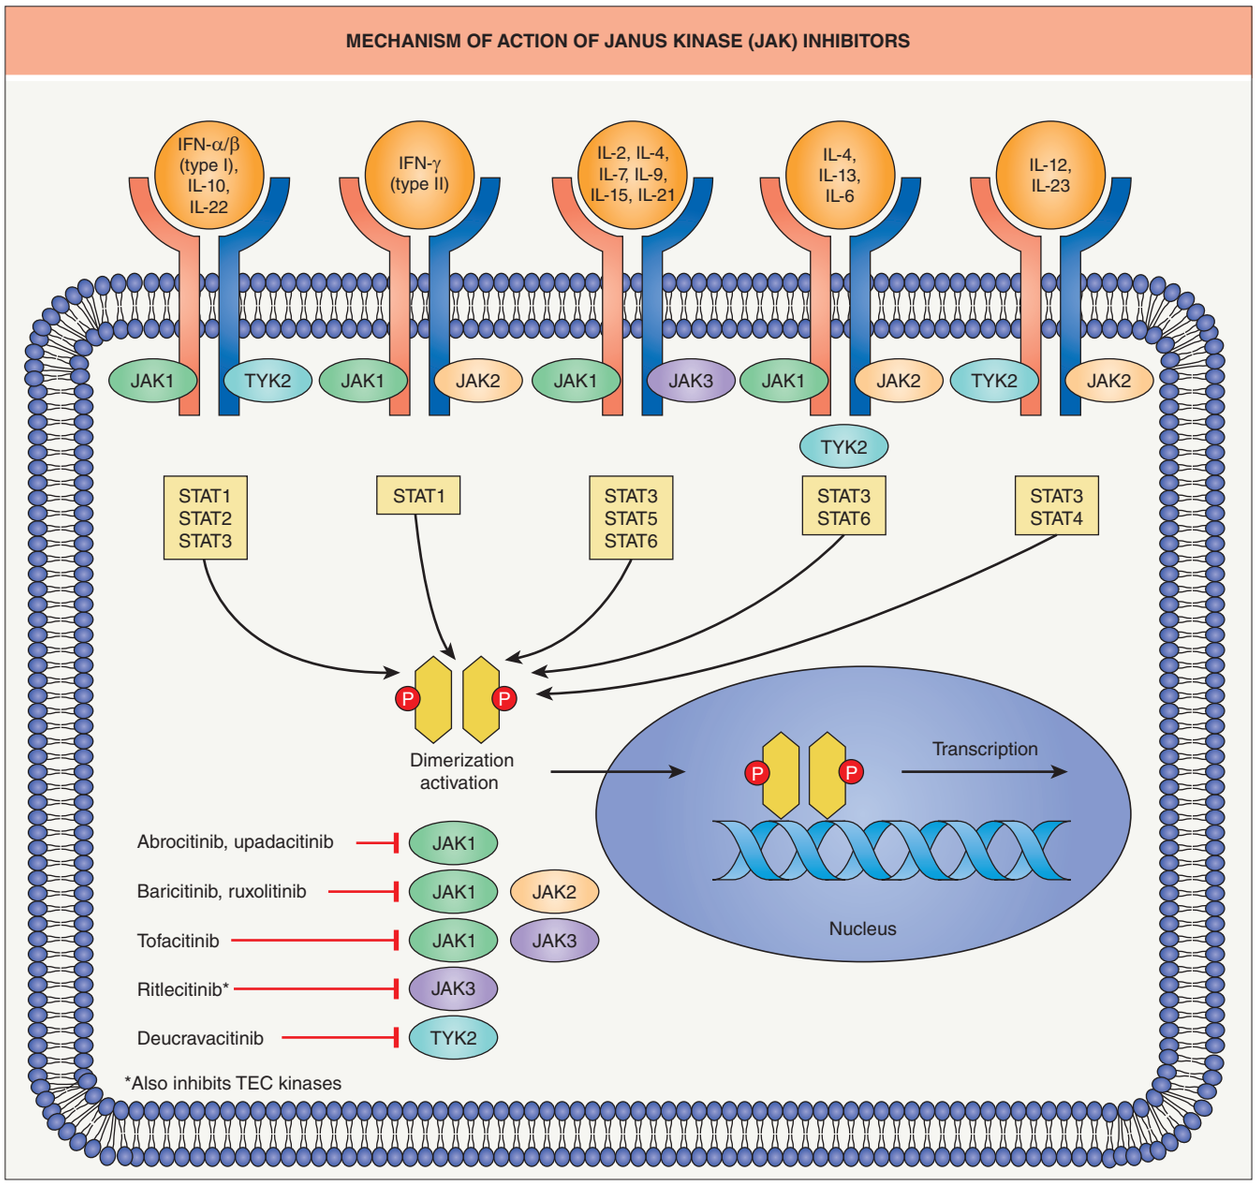

Fig. 128.11 Mechanism of action of Janus kinase (JAK) inhibitors. Different combinations of receptor-associated JAKs and STAT (signal transducer and activator of transcription) proteins transduce cytokine signals. Upon phosphorylation by JAKs, the STATs dimerize, translocate to the nucleus, and activate target genes. IL, interleukin; IFN, interferon.

Fig. 128.12 Eczema herpeticum. Vesicular facial eruption in patient on oral ruxolitinib for chronic graft-versus-host disease. Note the central delling. *Courtesy Edward Cowen, MD.*

Neutropenia, lymphopenia, anemia, thrombocytopenia (primarily for abrocitinib and ruxolitinib), hyperlipidemia, and elevated liver enzyme levels have been observed in patients treated with JAK inhibitors. Monitoring of the complete blood count (CBC), liver enzyme levels, and lipid profile at baseline, in 1–2 months, and every 3 months thereafter during therapy is recommended (see Table 128.6).

Additional adverse effects of JAK inhibitors include acne, thrombosis, major cardiovascular events, and gastrointestinal perforation (primarily for baricitinib, tofacitinib, and upadacitinib). Although an RCT found a higher rate of malignancies in rheumatoid arthritis patients treated with tofacitinib as compared to those who received TNF inhibitors, meta-analyses have not shown an increased risk of malignancy after a mean follow-up time of ~300 person-months when tofacitinib was compared to placebo or other therapies in patients with RA[93]. Keratinocyte and Merkel cell carcinomas have occurred in patients treated with JAK inhibitors. Progressive multifocal leukoencephalopathy (PML) has been observed in patients treated with ruxolitinib for myelofibrosis. Consultation with an oncologist should be considered when planning JAK inhibitor therapy in patients with a recent history of malignancy.

Interactions

Oral JAK inhibitors should not be administered to patients receiving other targeted immune modulators or immunosuppressive agents such as cyclosporine due to an increased risk of infection. Live vaccines are contraindicated and the response to vaccines may be impaired. It is recommended that patients be brought up to date with all immunizations prior to initiating treatment with a JAK inhibitor.

Use in pregnancy

High doses of JAK inhibitors have been associated with reduced fetal body weight, increased fetal mortality, and skeletal malformations in

animal reproduction studies. Adequate studies in pregnant women have not been conducted, and use in nursing mothers is not recommended.

Abrocitinib

The Janus kinase 1 (JAK1)-selective inhibitor abrocitinib (Cibinqo™) is approved for the treatment of refractory, moderate to severe **atopic dermatitis** in patients ≥12 years of age, with ~40%–60% (higher response rates with higher doses) of patients achieving a 75% improvement in the EASI score. The initial dose of abrocitinib for atopic dermatitis is 100 mg daily, which can be increased to 200 mg daily if an adequate response is not achieved after 12 weeks of treatment. Coadministration of abrocitinib with antiplatelet drugs (with the exception of low-dose aspirin) can increase the risk of bleeding and is contraindicated during the first 3 months of treatment. Coadministration with P-glycoprotein substrates (e.g. digoxin) can also increase plasma concentrations of the latter.

Baricitinib

The JAK1/2 inhibitor baricitinib (Olumiant®) is approved for the treatment of adults with severe **alopecia areata** (≥50% scalp hair loss), with ~15%–25% and ~30%–40% of patients who received a daily dose of 2 or 4 mg, respectively, for 36 weeks achieving ≥80% scalp coverage[94]. Baricitinib is also approved for adults with rheumatoid arthritis. The usual baricitinib starting dose for patients with alopecia areata is 2 mg daily, with 4 mg daily recommended for those who fail to respond to this dose or have nearly complete/complete hair loss; the dose can be decreased to 2 mg daily when an adequate response is achieved. Inhibitors of organic anion transporter 3 (OAT3; e.g. probenecid) can increase the blood levels of baricitinib.

Deucravacitinib

Deucravacitinib (Sotyktu™) is a TYK2 inhibitor approved for adults with moderate to severe **plaque psoriasis**, with ~50%–60% and ~30%–40% of patients achieving a 75% and 90% improvement in their PASI score, respectively. The dose is 6 mg daily. Increased serum creatine phosphokinase levels were noted in ~3% of patients in clinical trials.

Ritlecitinib

The JAK3 and TEC kinase inhibitor ritlecinib (Litfulo™) is approved for the treatment of severe **alopecia areata** in individuals ≥12 years of age, with ~25% of patients who received a daily dose of 50 mg for 24 weeks achieving ≥80% scalp coverage[94a]. Treatment should not be initiated in patients with a platelet count <100 000/mm^3 or absolute lymphocyte count <500/mm^3.

Ruxolitinib

The JAK1/2 inhibitor ruxolitinib (Jakafi®) is approved for patients ≥12 years of age with acute or chronic **graft-versus-host disease** (GVHD) as well as adults with polycythemia vera and myelofibrosis. The starting doses of ruxolitinib for acute and chronic GVHD are 5 and 10 mg twice daily, respectively. In a study of 12 adults with moderate to severe alopecia areata, 75% had >50% improvement in their Severity of Alopecia Tool (SALT) score after treatment with ruxolitinib 20 mg twice daily for 3–6 months, but hair loss recurred upon its discontinuation[95]. Fluconazole and strong inhibitors of CYP3A4 (e.g. itraconazole) increase blood levels of ruxolitinib and so avoidance or dose modification of these inhibitors is required.

Tofacitinib

The JAK1/3 inhibitor tofacitinib (Xeljanz®) is FDA-approved for children ≥2 years of age with polyarticular idiopathic arthritis as well as adults with rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, and ulcerative colitis. In an open-label study of 66 adults with severe alopecia areata treated with tofacitinib 5 mg twice daily for 3 months, 32% had >50% improvement in their SALT score; however, drug cessation led to disease relapse in a median of 8 weeks[96]. Fluconazole and strong inhibitors of CYP3A4 (e.g. itraconazole) increase blood levels of tofacitinib and require dose modifications.

Upadacitinib

The JAK1-selective inhibitor upadacitinib (Rinvoq®) is approved for the treatment of refractory, moderate to severe **atopic dermatitis** in patients ≥12 years of age, with ~65%–75% of patients achieving a 75% improvement in the EASI score. Upadacitinib is also approved for adults with psoriatic arthritis, rheumatoid arthritis, ankylosing spondylitis, ulcerative colitis, and Crohn disease. The initial dose of upadacitinib for atopic dermatitis is 15 mg daily, which can be increased to 30 mg daily in patients who do not have an adequate response. Strong inhibitors of CYP3A4 (e.g. itraconazole) increase blood levels of upadacitinib and require dose modifications.

Targeted Immune Modulators Under Investigation and Other Targeted Therapies

Development of targeted immune modulators for use in dermatology continues. Table 128.9 is a partial listing of the drugs that are currently under investigation for dermatologic disorders. Additional drugs that are being developed for non-cutaneous inflammatory diseases might be effective for skin disorders (Table 128.10).

INTRAVENOUS IMMUNE GLOBULIN (IVIg)

Key features

- IVIg is useful for inflammatory disorders, including some cutaneous diseases
- Doses for inflammatory disorders are empiric, but have generally been 2 g/kg/month for chronic diseases, and 3 g/kg total for acute conditions
- There are only a few skin disorders for which there is a high level of evidence indicating effectiveness of IVIg

IVIg is a sterile solution of globulins extracted from pooled plasma donated by 100 000–200 000 individuals per production cycle. Processing results in a product that is predominantly IgG, having eliminated all but trace amounts of IgA and other soluble immunologically active particles. It has a half-life of 3 to 5 weeks.

TARGETED IMMUNE MODULATORS FOR UNDER DEVELOPMENT FOR DERMATOLOGIC INDICATIONS

Name	Mechanism of action (disease)	Phase
Injectable agents under development		
Amlitelimab	OX40 ligand inhibitor (atopic dermatitis)	II
Cendakimab	IL-13 inhibitor (atopic dermatitis)	II
Eblasakimab	IL-13 receptor α1 inhibitor (atopic dermatitis)	II
Gumokinab	IL-17A inhibitor (psoriasis)	
IBI112	IL-23 inhibitor (psoriasis)	II
IMO-8400	TLR7/8/9 antagonist (psoriasis)	II
Imsidolimab	IL-36 receptor (generalized pustular psoriasis)	III
Izokibep	IL-17A inhibitor (hidradenitis suppurativa, psoriasis)	II
Neihulizumab	P selectin glycoprotein ligand 1 (PSGL-1) inhibitor (GVHD)	II
Nemolizumab	IL-31 receptor A inhibitor (prurigo nodularis)	III
Rocatinlimab	OX40 inhibitor (atopic dermatitis)	III
Vixarelimab	Oncostatin M receptor β inhibitor (prurigo nodularis)	II
Vunakizumab	IL-17A inhibitor (psoriasis)	III
Oral agents under development		
Jaktinib	JAK1/2 inhibitor (psoriasis, alopecia areata)	II
Piclidenoson	Adenosine A3 receptor inhibitor (psoriasis)	III
PN-235	IL-23 receptor inhibitor (psoriasis)	II
RIST4721	CXCR2 inhibitor (palmoplantar pustulosis)	II

Table 128.9 Targeted immune modulators for psoriasis under development. IL, interleukin; JAK, Janus kinase.

OTHER TARGETED ("BIOLOGIC") AGENTS USED IN MEDICINE		
Drug (Trade name®)	**Target**	**Selected FDA-approved indications**
Abatacept (Orencia)	B7–1 (CD80)	Rheumatoid arthritis, juvenile idiopathic arthritis, adult psoriatic arthritis
Abciximab (ReoPro)	Glycoprotein IIb/IIIa	Cardiovascular disease
Aducanumab (Aduhelm)	Amyloid beta	Alzheimer disease
Alemtuzumab (Campath)	CD52	B cell CLL
Alirocumab (Praluent)	PCSK9	Hypercholesterolemia
Amivantamab (Rybrevant)	EGF, MET	Non-small cell lung cancer
Anifrolumab (Saphnelo)	Type I interferon receptor	Systemic lupus erythematosus
Ansuvimab (Ebanga)	Ebola	Ebola
Atezolizumab (Tecentriq)	PD-L1	Urothelial cancer, non-small cell lung cancer, breast cancer, hepatocellular cancer
Atoltivimab, maftivimab, odesivimab (Inmazeb)	Ebola	Ebola
Avelumab (Bavencio)	PD-L1	Metastatic Merkel cell carcinoma, urothelial carcinoma, renal cell carcinoma
Basiliximab (Simulect)	IL-2 receptor α (CD25)	Solid organ transplantation; off-label use for GVHD
Belimumab (Benlysta)	B lymphocyte stimulator	Systemic lupus erythematosus (LE); off-label use for cutaneous LE
Benralizumab (Fasenra)	IL-5 receptor α	Asthma
Bevacizumab (Avastin)	VEGF	Colorectal cancer, non-squamous/non-small cell lung cancer, other malignancies
Bezlotoxumab (Zinplava)	*Clostridium difficile* toxins	*C. difficile* diarrhea
Blinatumomab (Blincyto)	CD19 & CD3 (BiTE)	B cell ALL
Brentuximab vedotin (Adcetris)	CD30	Anaplastic large cell and Hodgkin lymphomas, peripheral T cell lymphoma, refractory mycosis fungoides
Brolucizumab (Beovu; intravitreal agent)	VEGF	Age-related macular degeneration
Burosumab (Crysvita)	FGF23	X-linked hypophosphatemia
Caplacizumab (Cablivi)	Von Willebrand factor	Thrombotic thrombocytopenic purpura
Cemiplimab (Libtayo)	PD-1	Cutaneous SCC and basal cell carcinoma
Cetuximab (Erbitux; IgG1)	EGFR	Head and neck SCC, colorectal cancer
Crizanlizumab (Adakveo)	P-selectin	Sickle cell disease
Daratumumab (Darzalex)	CD38	Multiple myeloma
Denosumab (Prolia, Xgeva)	RANK ligand	Osteoporosis, bone metastases
Dinutuximab (Unituxin)	Glycolipid GD2	Neuroblastoma
Dostarlimab (Jemperli)	PD-1	Endometrial cancer
Durvalumab (Imfinzi)	PD-L1	Advanced/metastatic urothelial carcinoma, lung cancer
Eculizumab (Soliris)	Complement component 5	Paroxysmal nocturnal hemoglobinuria, atypical hemolytic uremic syndrome, generalized myasthenia gravis, neuromyelitis optica spectrum disorder
Elotuzumab (Empliciti)	SLAMF7 (CD319)	Multiple myeloma
Emapalumab (Gamifant)	Interferon-δ	Hemophagocytic lymphohistiocytosis
Emicizumab (Hemlibra)	Factors IXa and X	Hemophilia A
Enfortumab vedotin (Padcev)	Nectin-4	Bladder cancer
Epcoritamab (Epkinly)	CD20 & CD3 (BiTE)	Diffuse large B cell lymphoma
Eptinezumab (Vyepti)	CGRP	Migraine
Erenumab (Aimovig)	CGRP	Migraine
Evinacumab (Evkeeza)	ANGPTL3	Familial hypercholesterolemia
Evolocumab (Repatha)	PCSK9	Hyperlipidemia
Faricimab (Vabysmo; intravitreal agent)	VEGF, Ang-2	Neovascular age-related macular degeneration
Fremanezumab (Ajovy)	CGRP	Migraine
Galcanezumab (Emgality)	CGRP	Migraine
Glofitamab (Columvi)	CD20 & CD3 (BiTE)	Diffuse large B cell lymphoma
Ibalizumab (Trogarzo)	CD4	Human immunodeficiency virus infection
Ibritumomab tiuxetan (Zevalin)*	CD20	Non-Hodgkin lymphoma
Inebilizumab (Uplizna)	CD19	Neuromyelitis optica
Ipilimumab (Yervoy)	CTLA-4 (CD152)	Unresectable/metastatic melanoma or adjuvant treatment of melanoma with lymph node involvement (Fig. 128.9F), other cancers

Table 128.10 Other targeted ("biologic") agents used in medicine.

OTHER TARGETED ("BIOLOGIC") AGENTS USED IN MEDICINE		
Drug (Trade name®)	**Target**	**Selected FDA-approved indications**
Isatuximab (Sarclisa)	CD38	Multiple myeloma
Lanadelumab (Takhzyro)	Kallikrein	Hereditary angioedema
Lecanemab (Leqembi)	Amyloid beta	Alzheimer disease
Loncastuximab tesirine (Zynlonta)	CD19	Large B cell lymphoma
Margetuximab (Margenza)	HER2	$HER2^+$ breast cancer
Mepolizumab (Nucala)	IL-5	Asthma
Mirvetuximab soravtansine (Elahere)	Folate receptor alpha (plus microtubule inhibitor)	Ovarian cancer
Mogamulizumab (Poteligeo)	CCR4	Non-Hodgkin lymphoma, cutaneous T-cell lymphoma
Mosunetuzumab (Lunsumio)	CD20 & CD3 (BiTE)	Follicular lymphoma
Muromonab (Orthoclone OKT3)	CD3	Acute allograft rejection (renal, cardiac, hepatic)
Natalizumab (Tysabri)	α-4 integrin	Multiple sclerosis, Crohn disease
Naxitamab (Danyelza)	GD2	Neuroblastoma
Necitumumab (Portrazza)	EGFR	Advanced squamous non-small cell lung cancer
Nirsevimab (Beyfortus)	RSV	RSV disease
Nivolumab (Opdivo)	PD-1	Unresectable/metastatic melanoma, squamous cell head/neck cancer, non-small cell lung cancer, other malignancies
Nivolumab plus relatlimab (Opdualag)	PD-1 and LAG-3	Unresectable/metastatic melanoma
Obiltoxaximab (Anthim)	*Bacillus anthracis* spores	Anthrax
Obinutuzumab (Gazyva)	CD20	CLL, follicular lymphoma
Ocrelizumab (Ocrevus)	CD20	Multiple sclerosis
Ofatumumab (Arzerra, Kesimpta)	CD20	B cell CLL, multiple sclerosis
Olaratumab (Lartruvo)	Platelet-derived growth factor receptor-α	Soft tissue sarcoma
Palivizumab (Synagis)	Respiratory syncytial virus (RSV)	RSV infections
Panitumumab (Vectibix)	EGFR	Metastatic colorectal cancer
Pembrolizumab (Keytruda)	PD-1	Unresectable/metastatic melanoma, Merkel cell carcinoma, squamous cell head/neck cancer, non-small cell lung cancer, other malignancies
Pertuzumab (Perjeta)**	HER2	$HER2^+$ breast cancer
Polatuzumab vedotin (Polivy)	CD79b	Diffuse large B cell lymphoma
Ramucirumab (Cyramza)	VEGFR2	Advanced gastric carcinoma; metastatic colorectal and non-small cell lung cancers
Ranibizumab (Lucentis; intravitreal agent)	VEGF	Age-related macular degeneration, diabetic retinopathy/macular edema
Raxibacumab	*Bacillus anthracis* spores	Anthrax
Ravulizumab (Ultomiris)	C5	Paroxysmal nocturnal hemoglobinuria
Reslizumab (Cinqair)	IL-5	Asthma
Retifanlimab (Zynyz)	PD-1	Metastatic/recurrent advanced Merkel cell carcinoma
Romosozumab (Evenity)	Sclerostin	Osteoporosis
Rozanolixizumab (Rystiggo)	Neonatal Fc receptor	Myasthenia gravis
Sacituzumab govitecan (Trodelvy)	Trop-2	Breast cancer
Sarilumab (Kevzara)	IL-6 receptor	Rheumatoid arthritis
Satralizumab (Enspryng)	IL-6 receptor	Neuromyelitis optica
Siltuximab (Sylvant)	IL-6	Multicentric Castleman disease
Sutimlimab (Enjaymo)	C1s	Cold agglutinin disease
Tafasitamab (Monjuvi)	CD19	Large B cell lymphoma
Talquetamab (Talvey)	GPRC5D & CD3 (BiTE)	Multiple myeloma
Tebentafusp (Kimmtrak)	gp100 & HLA-directed CD3 (BiTE)	Uveal melanoma
Teclistamab (Tecvayli)	BCMA & CD3 (BiTE)	Multiple myeloma
Teprotumumab (Tepezza)	IGF-1R	Thyroid eye disease
Teplizumab (Tzield)	CD3	Type 1 diabetes mellitus
Tezepelumab (Tezspire)	TSLP	Asthma

Table 128.10 Other targeted ("biologic") agents used in medicine.

Continued

OTHER TARGETED ("BIOLOGIC") AGENTS USED IN MEDICINE		
Drug (Trade name®)	**Target**	**Selected FDA-approved indications**
Tisotumab vedotin (Tivdak)	Tissue factor	Cervical cancer
Tocilizumab (atlizumab; Actemra)	IL-6 receptor	Rheumatoid arthritis, juvenile idiopathic arthritis, giant cell arteritis
Trastuzumab (Herceptin)**	HER2	HER2-overexpressing breast and metastatic gastric cancers
Tremelimumab (Imjudo)	CTLA-4	Hepatocellular carcinoma
Ublituximab (Briumvi)	CD20	Multiple sclerosis
Tyrosine kinase inhibitors (see Table 21.16)		
Abemaciclib (Verzenio)	CDK4/6	Advanced/metastatic breast cancer
Acalabrutinib (Calquence)	Bruton tyrosine kinase	Mantle cell lymphoma
Adagrasib (Krazati)	KRAS with G12C mutation	Non-small cell lung cancer
Afatinib (Gilotrif)	EGFR, HER2	Non-small cell lung cancer
Alectinib (Alecensa)	ALK	ALK^+ non-small cell lung cancer
Alpelisib (Piqray)	PI3K	Breast cancer
Asciminib (Scemblix)	Abl	CML
Avapritinib (Ayvakit)	KIT, PDGFR	Gastrointestinal stromal tumor
Axitinib (Inlyta)	VEGFR1-3, KIT, PDGFR	Renal cell cancer
Binimetinib (Mektovi)	MEK	Unresectable/metastatic melanoma (in combination with encorafenib)
Bosutinib (Bosulif)	Abl, Src	CML
Brigatinib (Alunbrig)	ALK, EGFR	ALK^+ non-small cell lung cancer
Cabozantinib (Cometriq)	VEGFR2, MET	Metastatic medullary thyroid cancer, renal cell carcinoma, hepatocellular carcinoma
Capmatinib (Tabrecta)	MET	Non-small cell lung cancer
Ceritinib (Zykadia)	ALK	ALK^+ non-small cell lung cancer
Cobimetinib (Cotellic)	MEK1/2	Unresectable/metastatic melanoma (in combination with vemurafenib)
Copanlisib (Aliqopa)	PI3K	Follicular lymphoma
Crizotinib (Xalkori)	ALK	ALK^+ non-small cell lung cancer
Dabrafenib (Tafinlar)	BRAF serine/threonine kinase with V600E/K mutation	Unresectable/metastatic melanoma with the BRAF V600E/K mutation
Dacomitinib (Vizimpro)	EGFR	Non-small cell lung cancer
Dasatinib (Sprycel)	KIT, Abl	CML, Philadelphia chromosome-positive ALL
Duvelisib (Copiktra)	PI3K	CLL, small lymphocytic lymphoma, follicular lymphoma
Encorafenib (Braftovi)	BRAF serine/threonine kinase with V600E/K mutation	Unresectable/metastatic melanoma with the BRAF V600E/K mutation
Entrectinib (Rozlytrek)	TRKs, ROS1, ALK	Non-small cell lung cancer, solid tumors with NTRK gene fusion
Erdafitinib (Balversa)	FGFR1/2/3/4, RET, PDGFR	Bladder cancer
Erlotinib (Tarceva)	EGFR	Non-small cell lung and pancreatic cancer
Fedratinib (Inrebic)	JAK2	Myelofibrosis
Fostamatinib (Tavalisse)	SYK	Immune thrombocytopenia
Futibatinib (Lytgobi)	FGFR2	Cholangiocarcinoma
Gefitinib (Iressa)	EGFR	Non-small cell lung cancer
Gilteritinib (Xospata)	FLT3	AML
Ibrutinib (Imbruvica)	Bruton tyrosine kinase	Mantle cell lymphoma, Waldenstrom macroglobulinemia, marginal zone lymphoma, chronic GVHD
Infigratinib (Truseltiq)	FGFR1/2/3	Cholangiocarcinoma
Imatinib (Gleevec, Glivec)	KIT, Abl, PDGFR	CML, ALL, myelodysplastic/myeloproliferative diseases, GIST, DFSP (see Ch. 116), systemic mastocytosis (see Ch. 118), hypereosinophilic syndrome (see Fig. 26.6); off-label use for sclerodermatous conditions (e.g. morphea, chronic GVHD)
Inotuzumab ozogamicin (Besponsa)	CD22	ALL
Lapatinib (Tykerb, Tycerb)	EGFR, HER2	Metastatic breast cancer
Larotrectinib (Vitrakvi)	TRKs	Solid tumors with NTRK gene fusion
Leniolisib (Joenja)	PI3Kδ	Activated phosphoinositide 3-kinase delta (PI3Kδ) syndrome

Table 128.10 Other targeted ("biologic") agents used in medicine.

OTHER TARGETED ("BIOLOGIC") AGENTS USED IN MEDICINE		
Drug (Trade name®)	**Target**	**Selected FDA-approved indications**
Lenvatinib (Lenvima)	VEGFR1–3	Thyroid cancer, renal cell cancer, hepatocellular cancer, endometrial cancer
Lorlatinib (Lorbrena)	ALK, ROS1	Non-small cell lung cancer
Mobocertinib (Exkivity)	EGFR	Non-small cell lung cancer
Neratinib (Nerlynx)	EGFR, HER2/4	$HER2^+$ breast cancer
Nilotinib (Tasigna)	KIT, Abl, PDGFR	CML
Niraparib (Zejula)	PARP	Ovarian, fallopian tube, and peritoneal cancers
Obinutuzumab (Gazyva)	CD20	CLL, follicular lymphoma
Osimertinib (Tagrisso)	EGFR	Non-small cell lung cancer
Pacritinib (Vonjo)	JAK2, FLT3	Myelofibrosis
Pazopanib (Votrient)	VEGFR1-3, PDGFR, KIT	Renal cell carcinoma, soft tissue sarcoma
Palbociclib (Ibrance)	CDK4/6	Advanced/metastatic breast cancer
Pexidartinib (Turalio)	CSF1R, KIT, FLT3	Giant cell tumor
Pemigatinib (Pemazyre)	FGFR2	Cholangiocarcinoma
Pirtobrutinib (Jaypirca)	Bruton tyrosine kinase	Mantle cell lymphoma
Ponatinib (Iclusig)	Abl, VEGFR, PDGFR, FGFR, KIT, others	CML, Philadelphia chromosome-positive ALL
Pralsetinib (Gavreto)	RET	Non-small cell lung cancer, thyroid cancer
Quizartinib (Vanflyta)	FLT3, KIT, PDGFRs, others	AML
Regorafenib (Stivarga)	VEGFR2, TIE2, others	Advanced/metastatic colorectal cancer, GIST, hepatocellular cancer
Ribociclib (Kisqali)	CDK4/6	Advanced/metastatic breast cancer
Ripretinib (Qinlock)	KIT, PDGFR	Gastrointestinal stromal tumor
Selpercatinib (Retevmo)	RET	Non-small cell lung cancer, thyroid cancer
Selumetinib (Koselugo)	MEK1/2	Plexiform neurofibromas in neurofibromatosis type 1
Sorafenib (Nexavar)	VEGFR1&2, PDGFR, BRAF	Renal cell, hepatocellular, and thyroid carcinomas
Sotorasib (Lumakras)	KRAS with G12C mutation	Non-small cell lung cancer
Sunitinib (Sutent)	VEGFR1&2, PDGFR, KIT, FLT3	Renal cell carcinoma, GIST, pancreatic neuroendocrine tumors
Tepotinib (Tepmetko)	MET	Non-small cell lung cancer
Tivozanib (Fotivda)	VEGF	Renal cell carcinoma
Trametinib (Mekinist)	MEK1/2	Unresectable/metastatic melanoma (in combination with dabrafenib), anaplastic thyroid cancer, non-small cell lung cancer
Tucatinib (Tukysa)	HER2	$HER2^+$ breast cancer
Umbralisib (Ukoniq)	PI3Kδ, CK1ε	Marginal zone lymphoma, follicular lymphoma
Vandetanib (Caprelsa)	VEGFR, EGFR, RET	Metastatic medullary thyroid cancer
Vemurafenib (Zelboraf)	BRAF serine/threonine kinase with V600E mutation	Unresectable or metastatic melanoma with the BRAF V600E mutation, Erdheim–Chester disease
Zanubrutinib (Brukinsa)	Bruton tyrosine kinase	Mantle cell lymphoma, CLL
Hedgehog pathway inhibitor		
Sonidegib (Odomzo)	Smoothened receptor	Advanced recurrent or unresectable basal cell carcinoma
Vismodegib (Erivedge)	Smoothened receptor	Unresectable or metastatic basal cell carcinoma

*Radioactive forms are used, with ibritumomab tiuxetan conjugated to yttrium-90 or indium-111.
**Conjugated forms include ado-trastuzumab emtansine (Kadcyla), fam-trastuzumab deruxtecan (Enhertu), and pertuzumab/trastuzumab/hyaluronidase (Phesgo).

Table 128.10 Other targeted ("biologic") agents used in medicine. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; ANGPTL3, angiopoietin-like protein 3; ATLL, adult T cell leukemia–lymphoma; BCMA, B cell maturation antigen; BiTE, bi-specific T-cell engager; CDK, cyclin-dependent kinase; CLL, chronic lymphocytic leukemia; CK1, casein kinase 1; CGRP, calcitonin gene-related peptide; CML, chronic myelogenous leukemia; CSF1R, colony-stimulating factor-1 receptor; CTLA-4, cytotoxic T lymphocyte antigen-4; DFSP, dermatofibrosarcoma protuberans; EGFR, epidermal growth factor receptor; FGFR2, fibroblast growth factor receptor 2; FLT3, FMS-like tyrosine kinase 3; GIST, gastrointestinal stromal tumors; GPRC5D, G-protein coupled receptor family C group 5 member D; GVHD, graft-versus-host disease; IGF-1R, insulin-like growth factor 1 receptor; IL, interleukin; LAG-3, lymphocyte activation gene 3; MEK, mitogen-activated protein kinase kinase; MET, mesenchymal–epithelial transition; PCSK9, proprotein convertase subtilisin/kexin type 9; PD-1, programmed cell death protein 1; PD-L1, programmed cell death ligand 1; PDGFR, platelet-derived growth factor receptor; PI3K, phosphoinositide 3-kinase; RANK, receptor activator of nuclear factor κB; SCC, squamous cell carcinoma; TRK, tropomyosin receptor kinase; TSLP, thymic stromal lymphopoietin; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor.

IVIg is used in the treatment of immunodeficiency syndromes, hypogammaglobulinemia (e.g. due to myeloma), inflammatory disorders, and infectious diseases[97]. It is occasionally administered as prophylaxis to susceptible individuals exposed to particular infectious agents, such as nonimmune, immunocompromised patients exposed to varicella–zoster virus. Clinical studies, most of which were uncontrolled, and anecdotal reports suggest that IVIg is useful for some cutaneous conditions[98–100] (Table 128.11), but randomized clinical trials, barring those for dermatomyositis, are lacking.

USES OF IVIg IN DERMATOLOGY			
Indication	**Summary of evidence**	**Dosing**	**Comments**
Dermatomyositis	Benefit established	2 g/kg (over 2 days) Initially given every month, maintenance schedule individualized	Beneficial in patients intolerant of prednisone or immunosuppressives
Kawasaki disease	Benefit established	2 g/kg (over 6–12 hours)	
Toxic epidermal necrolysis	Case series, anecdotal evidence	1 g/kg/day for 3 days	Benefit controversial
Pemphigus variants	Case series, anecdotal evidence	2 g/kg (over 2–3 days) Initially given every month, maintenance schedule individualized	Adjunctive or second-line therapy
Bullous pemphigoid	Case series, anecdotal evidence	2 g/kg (over 2–3 days) Initially given every month, maintenance schedule individualized	Adjunctive or second-line therapy
Mucous membrane (cicatricial) pemphigoid	Case series, anecdotal evidence	2–3 g/kg (over 3 days) Initially given every 2–6 weeks, maintenance schedule individualized	Adjunctive or second-line therapy
Epidermolysis bullosa acquisita	Anecdotal evidence	2 g/kg (over 2–3 days) Initially given every month, maintenance schedule individualized	Adjunctive or second-line therapy
Necrotizing fasciitis	Uncertain benefit	2 g/kg (over 6–12 hours); repeat 1–2 g/kg in 2–5 days if disease progresses	Adjunctive for progressive disease
Pyoderma gangrenosum	Uncertain benefit	2 g/kg (over 2 days) Initially given every month, maintenance schedule individualized	May be considered
Atopic dermatitis	Uncertain benefit (inconsistent results in controlled studies)	2 g/kg (over 1–2 days) Monthly	

Table 128.11 Uses of IVIg in dermatology. *Adapted from Mydlarski PR, Mittman N, Shear NH. Intravenous immunoglobulin: use in dermatology. Skin Therapy Lett 2004;9:1–6.*

SELECTED PREPARATIONS OF IVIg THAT ARE AVAILABLE IN THE US				
	Gammagard®S/D	**Privigen®**	**Gamunex®-C**	**Carimune® NF**
Form	Lyophilized	Liquid	Liquid	Lyophilized
Concentration	5% (also 10%)	10%	10%	3%–12%
Maximum infusion rate	4.0 mL/kg/h	4.8 mL/kg/h	4.8 mL/kg/h	2.5 mL/kg/h
Time to infuse 70 g	5.3 h	2 h	2 h	6.6 h
pH	6.8	4.8	4.25	6.4–6.8
Osmolarity (mOsm/L)	636	320	260	192–1074
Sugar content	2% glucose	None	None	1.67 g sucrose/g of protein
Sodium content	0.85%	Trace	Trace	<20 mg/g of protein
IgA (mcg/mL)	<2.2	<25	46	720

Table 128.12 Selected preparations of IVIg that are available in the US. Subcutaneous immunoglobulin preparations are also available. Information on additional products is provided at: https://primaryimmune.org/publication/characteristics-ig-products-used-treat-pi-licensed-use-us.

Mechanism of Action

The immunomodulatory effects of IVIg may be exerted through one or more of the following mechanisms: (1) functional blockade of Fc receptors; (2) inhibition of complement-mediated damage; (3) alteration of cytokine and cytokine antagonist profiles; (4) reduction of circulating antibodies via anti-idiotype antibodies; and (5) neutralization of toxins that trigger autoantibody production[97,101]. In toxic epidermal necrolysis, IVIg is believed to block Fas (CD95)-mediated keratinocyte death by inhibiting Fas–Fas ligand interactions (see Ch. 20).

Indications

IVIg is approved for treatment of primary and secondary immunodeficiency diseases. Table 128.11 lists dermatologic disorders for which IVIg represents a therapeutic option.

Dosages

At least nine different preparations of IVIg are available in the US[102]. The products differ in their sugar content, sodium content, osmolarity, pH, and IgA levels (Table 128.12). The doses recommended vary depending upon the disease state being treated (see Table 128.11).

Contraindications

Preparations containing IgA are contraindicated in patients with a history of hypersensitivity to IVIg, the presence of anti-IgA antibodies, or a profound IgA deficiency; the latter may be associated with the development of anti-IgA antibodies and a risk of anaphylaxis.

Major Side Effects

Major toxicity includes the potential for anaphylaxis, aseptic meningitis, thromboembolic events, hyperviscosity syndromes, dyshidrotic eczema (pompholyx; Fig. 128.13), cardiac collapse, and pulmonary edema. These risks vary with the preparation selected and the patient being treated. For example, renal failure represents a potential complication of sucrose-containing products, which can lead to "osmotic nephrosis". Pretreatment with acetaminophen and diphenhydramine may lessen infusion reactions, and decreasing the rapidity of the infusion lessens

Fig. 128.13 New-onset dyshidrotic eczema in an adult receiving monthly IVIg.
Courtesy Jean L. Bolognia, MD.

the risk of thromboembolic events, aseptic meningitis, and renal or cardiovascular events.

Interactions

Individuals receiving IVIg may have a suboptimal response to vaccination with live viruses.

Use in Pregnancy

There does not appear to be an excessive risk in pregnancy or lactation associated with the use of IVIg.

Additional tables on Mechanisms of action for interferons, Interpretation of hepatitis B and C serologic test results, and Examples of biosimilars of monoclonal antibodies used in dermatology, available in our eBook (see inside front cover for access code).

129 Other Topical Medications

Mark Marchitto, Matthew Fox, Yolanda R. Helfrich and Sewon Kang

Chapter Contents

General Principles of Topical Therapy 2295
Antipruritic Agents 2296
Keratolytics and Humectants 2296
Skin-Lightening Agents 2297
Agents that Affect Hair Growth 2298
Immunomodulatory Agents 2300
Chemotherapeutic Agents 2303
Vitamin D Analogues 2304
Miscellaneous Agents 2305

Key features

- Absorption of topical medications depends upon several factors, including cutaneous barrier function, the anatomic site, the active agent, and characteristics of the vehicle
- In neonates, there is a greater risk of systemic toxicity with use of topical medications
- Combination or rotational therapy using topical agents may result in increased efficacy and decreased risk of side effects

INTRODUCTION

Topical medications are fundamental in the armamentarium of dermatologic therapeutics, offering the ability to deliver treatment directly to the skin while limiting systemic side effects. However, topical therapy can be time-consuming and messy, and it may not be practical for generalized skin disorders or effective for conditions with deeper involvement. Choosing an appropriate topical regimen requires consideration of the disease process and involved site(s) as well as the vehicle, application strategy, and duration of use of the selected agent. This chapter reviews general principles of topical therapy and topical medications not discussed elsewhere in the textbook. Table 129.1 lists topical medications covered in other chapters.

GENERAL PRINCIPLES OF TOPICAL THERAPY

Topical formulations consist of an active ingredient in a non-active base (vehicle). To be effective, topical medications must gain entry into the skin and reach the desired target site, e.g. the epidermis below the stratum corneum or the dermis, in adequate concentrations. Successful topical therapy therefore requires percutaneous absorption, which depends upon factors related to the skin being treated as well as the agent and its vehicle (Table 129.2). The role of the stratum corneum in skin barrier function, including percutaneous absorption of medications, is discussed in Chapter 124.

Quantity of Application

In general, topical medications should be applied to the skin as a thin layer. A thicker layer of medication does not result in enhanced penetration or additional therapeutic benefit. One gram of cream covers a ~10 cm × 10 cm area of skin, and the same amount of ointment spreads nearly 10% further.

TOPICAL MEDICATIONS DISCUSSED IN OTHER CHAPTERS	
Topical medications	**Chapter(s)**

Wound healing agents	105, 141
Tirbanibulin for actinic keratoses	109
Hemostatic agents	151

Table 129.1 Topical medications discussed in other chapters.

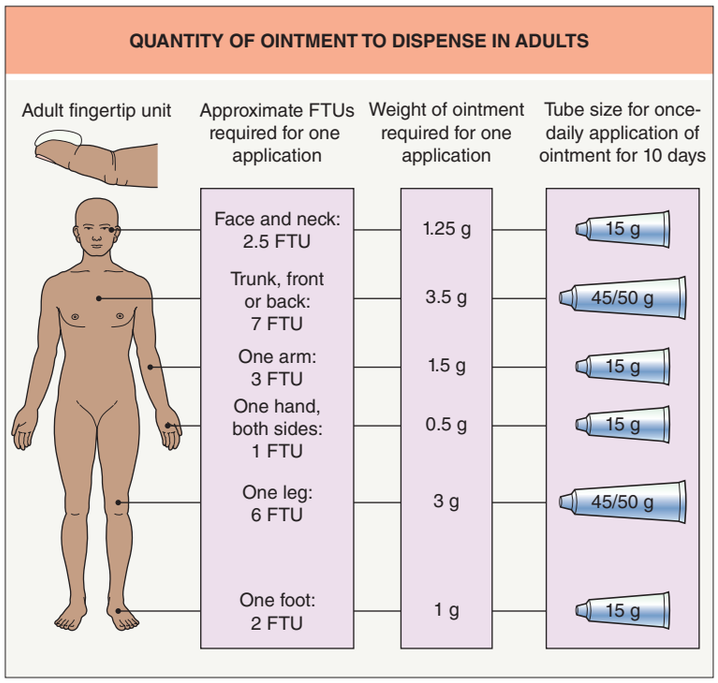
FACTORS THAT AFFECT PERCUTANEOUS ABSORPTION
Characteristics of the patient/skin

• Patient age
  • Suboptimal skin barrier function in neonates, especially if premature (see Table 129.4)
• Diseases, physical injuries, or chemical exposures that disrupt skin barrier function (e.g. Netherton syndrome)
• A thicker stratum corneum decreases absorption
• Skin hydration and/or occlusion increase absorption (e.g. in a skin fold)
• Anatomic location (approximate ratio of absorption compared to the forearm)
  • *Higher absorption:* scrotum (40), face (10), axilla (4), scalp (3)
  • *Intermediate absorption*: trunk (1.5), arm (1)
  • *Lower absorption*: palm (0.8), ankle (0.4), sole (0.1)

Properties of the medication/its application

• Drug/prodrug properties that increase absorption
  • Smaller molecular size and/or lower frictional coefficient
  • Increased lipophilicity
  • Increased concentration and/or solubility
• Vehicle composition
• Application under occlusion increases absorption (e.g. ointment, occlusive dressing)

Table 129.2 Factors that affect percutaneous absorption.



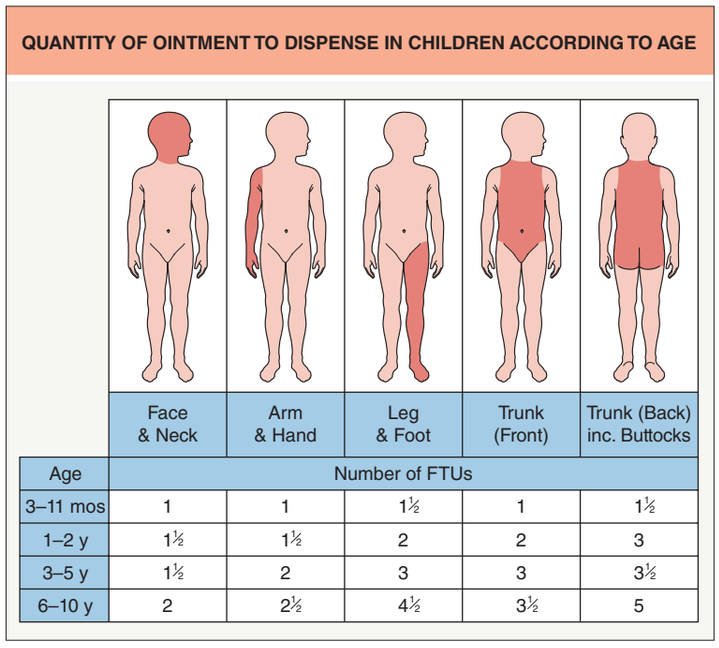


Fig. 129.1 Quantity of ointment to dispense in adults. FTU, fingertip unit. *Redrawn from Long CC, Finlay AY. The finger-tip unit – a new practical measure. Clin Exp Dermatol 1991;16:444–7.*

Age	Face & Neck	Arm & Hand	Leg & Foot	Trunk (Front)	Trunk (Back) inc. Buttocks
	Number of FTUs				
3–11 mos	1	1	1½	1	1½
1–2 y	1½	1½	2	2	3
3–5 y	1½	2	3	3	3½
6–10 y	2	2½	4½	3½	5

Fig. 129.2 Quantity of ointment to dispense in children, according to age. FTU, fingertip unit (in an adult). *Redrawn from Long CC, Mills CM, Finlay AY. A practical guide to topical therapy in children. Br J Dermatol 1998;138:293–6.*

A practical guide to quantifying the amount of ointment necessary to treat different areas of the body is the "fingertip unit" (FTU), which represents the amount of ointment dispensed from a 5 mm-diameter nozzle that extends from the distal crease to the tip of the index finger in an adult[1]. One FTU is equal to ~0.5 g, and the quantities required to treat various areas of the body in adults and children are presented in Figs. 129.1 and 129.2. The appropriate amount to treat the entire body of an adult man is ~20 g, therefore requiring ~250 g per week if applied twice daily. Because ~0.5 FTU (0.25 g) can treat an area equivalent to one side of an extended ("flat") hand, estimating the number of "flat hand areas" of affected skin assists in determining the amount of medication needed. For example, four "flat hand areas" would require 1 g per application and ~15 g per week if applied twice daily.

Formulations and Vehicles

A classification of topical formulations and clinical guidelines for vehicle selection are presented in Fig. 129.3. A discussion of how vehicles affect drug delivery is found in Chapter 124.

Topical Therapy During Pregnancy and Lactation

The decision to use topical medications during pregnancy and lactation should be based on the potential risk of the medication and the extent to which the condition affects the health of the woman. Use of the following topical medications during pregnancy (not a comprehensive list) is generally contraindicated: podophyllin, anthralin, lindane, chemotherapeutics (e.g. carmustine, mechlorethamine hydrochloride [nitrogen mustard], 5-fluorouracil), tazarotene, and peels with phenol or salicylic acid. In 2015, the US Food and Drug Administration (FDA) replaced pregnancy risk categories with narrative sections addressing pregnancy and lactation, which include risk summaries as well as information on pregnancy exposure registries, clinical considerations, and available data. Table 129.3 lists topical medications with minimal risk during pregnancy and lactation.

Topical Therapy in Neonates

Although the stratum corneum provides competent skin barrier function in full-term newborns under basal conditions (see Ch. 2), it undergoes structural and functional maturation during the first few weeks to months of life. Several factors result in an increased risk of systemic toxicity from topically applied medications during the neonatal period (the first 30 days of life) (Table 129.4). Systemic toxicity has been reported in neonates exposed to topical corticosteroids, salicylic acid, lindane, hexachlorophene, chlorhexidine, and propylene glycol (Table 129.5).

Combination and Rotational Topical Therapy

The advantages of using a single topical agent include improved compliance and sometimes lower cost. However, combination or rotational therapy may be employed to provide additive/synergistic effects via different mechanisms of action or to decrease potential side effects by reducing exposure to one or both agents, especially if they have different adverse-effect profiles. Examples of this strategy for topical therapy include various combinations of benzoyl peroxide, retinoids, and antibiotics to treat acne; use of a corticosteroid together with a vitamin D analogue or tazarotene to treat psoriasis; and rotating use of a corticosteroid and calcineurin inhibitor to treat atopic dermatitis.

ANTIPRURITIC AGENTS

Pruritus involves multiple components of the nervous system, including skin surface receptors, peripheral (especially unmyelinated C fibers) and central nerves, and specific brain regions (see Ch. 5). Treatment of the associated dermatologic condition, e.g. by applying topical corticosteroids to inflamed skin and moisturization of dry skin, or the underlying systemic cause remains the most effective method of alleviating itch. Topical antipruritic agents may help reduce the urge to scratch, potentially improving the efficacy of skin disease-specific therapies. Mechanisms of action of topical antipruritics include substituting a different sensation for itching, anesthetizing cutaneous nerve endings, and blocking molecular mediators of pruritus[2]. Unfortunately, a relative lack of comparative studies has made antipruritics difficult to evaluate. Commonly used agents are outlined in Table 129.6 (also see Table 5.5).

KERATOLYTICS AND HUMECTANTS

Keratolytic agents reduce the thickness of the stratum corneum via elimination of squames. This can be beneficial in diseases characterized by reduced desquamation or accelerated epidermal proliferation.

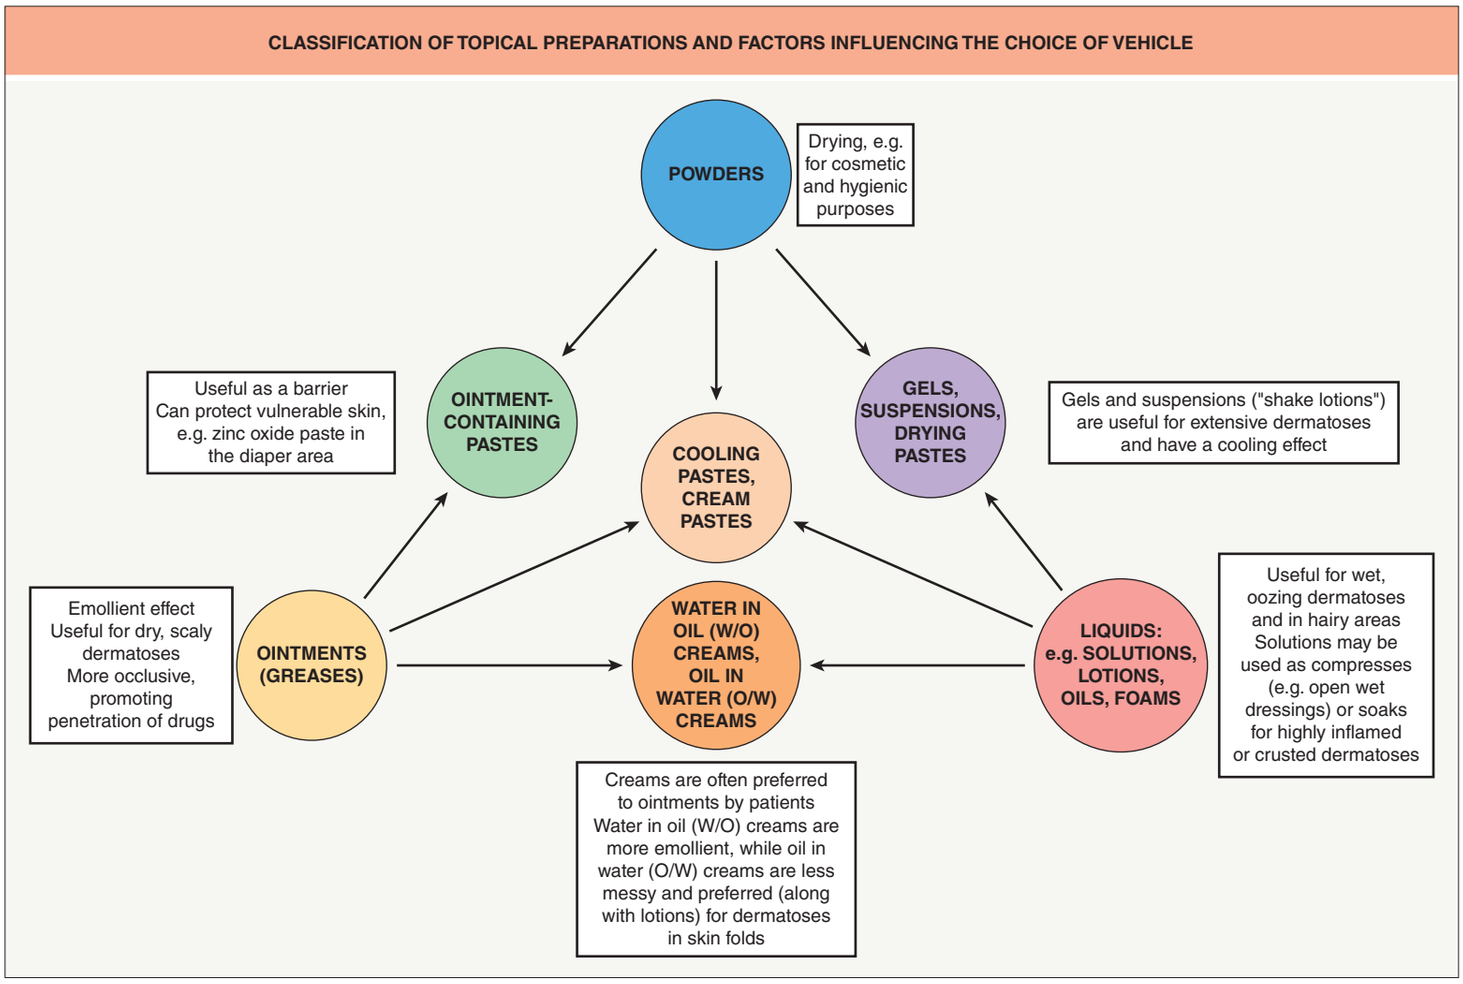

Fig. 129.3 Classification of topical preparations and factors influencing the choice of vehicle. Monophasic preparations are in primary colors. Diphasic preparations, which represent a combination of two monophasic preparations, are in secondary colors. Cooling pastes and cream pastes are triphasic preparations. Ointments, creams, gels, and pastes (highly concentrated suspensions) are semi-solids. Creams and lotions may be emulsions, i.e. contain mixtures of ≥2 liquids that are normally immiscible, brought together by emulsifiers. Foams and aerosol sprays represent liquids with pressurized gaseous propellants, and paints are alcohol-based solutions. Preparations containing alcohol or salicylic acid can lead to stinging and burning when applied to fissured or eroded skin. Vehicles may also contain preservatives, absorption promoters, and fragrances. *Adapted from Polano MK. Principles of formulation. Topical Skin Therapeutics. New York: Churchill Livingstone; 1984.*

Keratolytics and humectants are reviewed in Table 129.7, and their use in cosmeceutical products and chemical peels is discussed in Chapters 153 and 154.

SKIN-LIGHTENING AGENTS

Hydroquinone

Introduction, dosages, and indications

Hydroquinone (1,4-dihydroxybenzene) is used to treat melasma and other disorders of hyperpigmentation (see Ch. 67)[3]. In the US, 2% formulations are available over the counter, while 3% solution and 4% cream or gel require a prescription. Although twice-daily application is commonly recommended, irritant contact dermatitis can limit frequency of application. Some products contain hydroquinone combined with a sunscreen or with tretinoin (0.05%–0.1%) and a class 5–7 corticosteroid[4].

Mechanism of action

Hydroquinone reduces skin pigmentation by competing with tyrosine as a substrate for tyrosinase (the initial enzyme in melanin biosynthesis; see Ch. 65) and via selective damage to melanosomes and melanocytes via production of reactive oxygen radicals[3].

Side effects

Irritant or (less often) allergic contact dermatitis can develop. Exogenous ochronosis occasionally occurs with prolonged use of higher concentrations of hydroquinone. A variety of neoplasms have been noted to develop in rodents that received large systemic doses of the medication, but the relevance to topical therapy in humans has not been determined[3]. Concern regarding potential adverse effects related to misuse of hydroquinone led to its removal from Japanese and European markets.

Use in pregnancy

Animal reproduction studies have not consistently shown adverse fetal effects, and there are no adequate studies in pregnant women. Because of the potential for substantial systemic absorption (~30%–50%), it is recommended that hydroquinone use be avoided during pregnancy.

Monobenzyl Ether of Hydroquinone

Monobenzyl ether of hydroquinone (MBEH) 20% is infrequently used to depigment remaining uninvolved skin in patients with extensive, treatment-resistant vitiligo so as to achieve a uniform appearance (see Ch. 66). It is thought to act via competitive inhibition of tyrosinase and free radical-mediated damage of melanocytes. Depigmentation is typically long-lasting, but repigmentation (especially in a perifollicular distribution) can occur following sun exposure. Both irritant and allergic contact dermatitis are possible side effects[5].

Mequinol

Mequinol (4-hydroxyanisole) is a skin-lightening agent. A solution composed of mequinol 2% and tretinoin 0.01% is FDA-approved for

TOPICAL MEDICATIONS WITH MINIMAL RISK DURING PREGNANCY AND LACTATION	
Pregnancy	**Lactation**
Azelaic acid	Acyclovir
Ciclopirox	Bacitracin
Clindamycin	Benzoyl peroxide
Clotrimazole	Butoconazole
Erythromycin	Calcipotriene
Metronidazole*	Ciclopirox
Mupirocin	Clotrimazole
Naftifine	Erythromycin
Nystatin†	Hydroquinone
Oxiconazole	Ketoconazole
Permethrin	Metronidazole
Retapamulin	Mupirocin
Terbinafine	Nystatin
	Oxiconazole
	Terbinafine

*The CDC no longer recommends avoidance of oral metronidazole during the first trimester.
†Intravaginal topical application not advised close to term because of risk of contamination if membranes have ruptured; pregnancy category A for pastilles.

Table 129.3 Topical medications with minimal risk during pregnancy and lactation. Minimal risk refers to medications where there is no evidence of fetal risk in humans based on data from human or (if no adequate human data) animal studies. The medications listed were previously designated as FDA pregnancy category B.

FACTORS THAT INCREASE THE RISK OF SYSTEMIC TOXICITY FROM TOPICAL MEDICATIONS IN NEONATES
• Increased ratio of surface area to body weight (fourfold greater than in adults)
• Suboptimal epidermal barrier function due to the neonatal stratum corneum being on average ~30% thinner and having a higher pH (neutral instead of acidic), less hydration, and smaller corneocytes (reflecting more rapid cell turnover)
• Decreased hepatic metabolism of drugs
• Decreased renal excretion of drugs
• Increased distribution of drug, including into the CNS due to a more permeable blood–brain barrier
• Decreased plasma protein binding

Table 129.4 Factors that increase the risk of systemic toxicity from topical medications in neonates.

POTENTIAL SYSTEMIC SIDE EFFECTS OF TOPICAL MEDICATIONS	
Medication	**Systemic side effect**
Androgens	Virilization in women, children*, and fetuses
Boric acid	Generalized erythema, fever, vomiting, mental status change
Calcipotriene (calcipotriol)	Hypercalcemia, hypercalciuria
Carmustine (BCNU)	Bone marrow suppression
Chlorhexidine	Nausea, signs of ethanol intoxication
Clindamycin	Diarrhea, pseudomembranous colitis (controversial)
Corticosteroids	Iatrogenic Cushing syndrome, inhibition of hypothalamic–pituitary axis
Dimethylsulfoxide	Nausea, abdominal pain
Epinephrine (adrenaline)	Tachycardia
Estrogens	Pseudoprecocious puberty, gynecomastia, hypogonadism in men
Gentamicin	Ototoxicity
Hexachlorophene	Neurotoxicity, coma, death
Iodine	Hypothyroidism
Lidocaine and other topical anesthetics	With overdose (>5 mg/kg of lidocaine absorbed): *early/lower levels* – paresthesias (e.g. perioral tingling), tinnitus, dysgeusia (e.g. metallic taste), lightheadedness, tremors; *late/higher levels* – seizures, hypotension, arrhythmias, cardiopulmonary arrest (see Ch. 143)
Lindane	CNS toxicity
Malathion	CNS toxicity, hyperglycemia
Mechlorethamine (nitrogen mustard)	Myelosuppression
Mercury	CNS and renal toxicity, acrodynia
Minoxidil	Cardiac toxicity
Neomycin	Ototoxicity, nephrotoxicity
Phenol	Cardiac arrhythmia, death
Podophyllin	Gastrointestinal (nausea, vomiting), neurologic (mental status changes, peripheral polyneuropathy) and hematologic (thrombocytopenia, leukopenia) effects
Prilocaine–lidocaine (EMLA®)	Methemoglobinemia (perioral/acral cyanosis, vascular "mottling") related to prilocaine; see lidocaine above
Propylene glycol	Hyperosmolality, with or without lactic acidosis
Salicylic acid	Tinnitus (early sign), gastrointestinal symptoms (e.g. nausea, vomiting), CNS toxicity (e.g. confusion, delirium, seizures), metabolic acidosis with respiratory compensation (i.e. tachypnea), hypoglycemia, coma, death
Silver (silver nitrate, silver sulfadiazine)	Leukopenia, argyria

*May occur from passive transfer of paternal topical testosterone.

Table 129.5 Potential systemic side effects of topical medications. For most, the risk of these side effects is either theoretical or exists only in instances where the medication is applied to neonates or in quantities greatly exceeding normal exposure. CNS, central nervous system.

treatment of solar lentigines (formerly pregnancy category X). However, the latter product is no longer commercially available in the US. Mequinol is a substrate of tyrosinase and may serve as a competitive inhibitor of melanin biosynthesis[3].

AGENTS THAT AFFECT HAIR GROWTH

Both unwanted excessive hair and hair loss are common dermatologic complaints. Minoxidil, bimatoprost, and eflornithine are reviewed here, and topical immunotherapy with diphencyprone (DPCP) or squaric acid dibutyl ester (SADBE) for alopecia areata is covered in Chapter 69. The use of anthralin for alopecia areata is discussed below.

Minoxidil

Introduction, dosages, and indications

Originally developed as an antihypertensive agent, minoxidil has been known for decades to promote hair growth. Available in 2% and 5% solutions and a 5% foam, topical minoxidil is FDA-approved for the treatment of androgenetic alopecia in both men and women (see Ch. 69). It is also used for other forms of hair loss, including alopecia areata. Minoxidil is typically applied once or twice daily to the scalp[6].

Mechanism of action

Minoxidil causes premature termination of the telogen phase, lengthens the anagen phase, and can increase follicle size, particularly

TOPICAL AGENTS USED TO ALLEVIATE PRURITUS			
Agent	**Classification/derivation**	**Mechanism of action**	**Uses and side effects**
Pramoxine 1% (gel, lotion); in combination with 0.5%–2.5% hydrocortisone in lotion, cream, ointment, or foam	Ester anesthetic	Blocks transmission of sensory nerve impulses; hypoalgesic effect on cold pain, but not heat pain[90]; duration of effect is 2–4 hours	• Beneficial for uremic pruritus[91] and histamine-induced itch; uses include pruritus ani, notalgia paresthetica, and nonspecific mild pruritus • Allergic contact dermatitis is extremely uncommon
Menthol (up to 16% in a variety of lotions, creams, ointments, and gels)	Cyclic terpene alcohol derived from plants in the *Mentha* genus	Activates TRPM8 cation channels, which also respond to cold thermal stimuli[92,93]; possible central itch modulation via Aδ fiber and/or κ-opioid receptor activation[94]	• Provides a cooling sensation • Inconsistent antipruritic results in controlled studies • Irritation, especially of inflamed or eroded skin; rare allergic contact dermatitis
Phenol	Originally a distillation product of coal tar	Thought to act directly on cold receptors	• Cooling and antipruritic effects; found in throat sprays and lozenges • Should not be used in pregnant women or infants <6 months of age • Irritation, especially of inflamed or eroded skin
Camphor (0.25%–0.5%; various preparations)	Ketone originally derived from the camphor laurel tree (*Cinnamomum camphora*)	Local anesthetic effect	• Cooling sensation may relieve mild pruritus • Irritation, especially of inflamed or eroded skin
Capsaicin (0.025%–0.1% cream, lotion, gel, or stick; 0.025%, 8% patch)	Natural alkaloid; derived from Solanaceae family members, including hot chili peppers of the *Capsicum* genus	Activates the TRPV1 vanilloid receptor, which also responds to temperatures >43°C (109°F); repeated release of substance P from C neurons eventually leads to depletion of this neuropeptide (and reduced transmission of heat, pain, and itch)[95]	• Applied three to five times daily or via a single 1-hour application of the 8% patch • Initially evokes a sensation of warmth/burning[96], with onset of the therapeutic effect ~1 week after initiation • Transdermal patch is FDA-approved for treatment of postherpetic neuralgia • Uses include notalgia paresthetica, brachioradial pruritus, renal pruritus, prurigo nodularis, psoriatic pruritus, and itch associated with a burning sensation • Burning, stinging, and/or erythema at the application site occur in >50% of patients[97] • Hand washing after application helps to prevent contact with (and irritation of) non-affected skin, eyes, and other mucosal surfaces • Animal reproduction studies have not shown adverse fetal effects; no adequate studies in pregnant women
Doxepin 5% cream	Tricyclic compound	Potent histamine antagonist (H1 and H2); sedation via anticholinergic properties	• Applied four times daily for up to 7 days • Shown to relieve pruritus in patients with atopic dermatitis, lichen simplex chronicus, and nummular eczema[98,99] • Drowsiness due to systemic absorption occurs in ~25% of patients[100] • Occasionally irritant or (less often) allergic contact dermatitis; systemic contact dermatitis with subsequent administration of oral doxepin has been described • Contraindicated in patients with untreated narrow angle glaucoma or urinary retention and those receiving MAO inhibitors • Animal reproduction studies have not shown adverse fetal effects, and no adequate studies in pregnant women; use during lactation is not recommended
Diphenhydramine (2% cream, lotion, gel, or spray)	Antihistamine	H1 histamine antagonist; localized anesthetic effect via blockage of sodium channels	• Use is *not recommended* due to lack of efficacy as an antipruritic agent and potency as a topical sensitizer, which can lead to allergic contact dermatitis

Table 129.6 Topical agents used to alleviate pruritus. Calamine lotion is listed in Table 129.11. MAO, monoamine oxidase; TRPM8, transient receptor potential melastatin 8; TRPV1, transient receptor potential vanilloid 1.

of miniaturized follicles[6,7]. Stimulation of vascular endothelial growth factor and prostaglandin synthesis may also play a role[7]. Although oral minoxidil relaxes vascular smooth muscle by opening ATP-dependent potassium channels, this mechanism has not been definitively linked to stimulation of hair growth[7].

Side effects

While generally well-tolerated, topical minoxidil can cause dryness, irritation, and (uncommonly) allergic contact dermatitis; components of the solution formulation, in particular propylene glycol, may be responsible for these side effects. Topical minoxidil can also lead to unwanted hair growth at adjacent sites inadvertently exposed to medication (e.g. the face or ears). Systemic side effects such as headache and peripheral edema are occasionally observed.

Use in pregnancy

Animal reproduction studies with *oral* minoxidil have shown adverse effects with regard to ability to conceive and survival of offspring, but there are no adequate studies in pregnant women.

Bimatoprost

Introduction, dosages, and indications

Bimatoprost is a synthetic prostaglandin $F_{2\alpha}$ analogue that was initially utilized for the treatment of glaucoma. Following observations of thickening and elongation of the eyelashes in glaucoma patients treated with bimatoprost 0.03% ophthalmic solution (Fig. 129.4), this agent was explored as a treatment for eyelash hypotrichosis and, in 2008, FDA-approved for this indication. When bimatoprost is applied nightly to the skin of the

TOPICAL KERATOLYTICS AND HUMECTANTS				
Agent	**Dosage**	**Mechanism of action**	**Indications**	**Side effects**
Keratolytics				
Salicylic acid (2-hydroxybenzoic acid)	0.5%–40% lotion, ointment, gel, foam, solution, shampoo, cleanser, pad, plaster; OTC or prescription	Alters corneocyte adhesion, likely via disruption of desmosomal proteins; possible mild anti-inflammatory effects	0.5%–2%: comedolytic for acne 2%–10%: hyperkeratotic dermatoses 10%–40%: corns, calluses, verrucae, focal hyperkeratosis; increases penetration of other topical agents 20%–30%: chemical peels	Irritation, burning, peeling, erosions (depending on the site and concentration); allergic contact dermatitis (uncommon); systemic absorption from extensive application, especially in neonates/infants, can lead to salicylism (see Table 129.5)
α-hydroxy acids: glycolic, lactic > mandelic, tartaric, malic, and citric acids	Various concentrations and pH levels; cleanser, shampoo, lotion, cream, gel, solution, mask	Diminish strength of intercellular bonding, thereby weakening corneocyte cohesion and leading to exfoliation; act at lower, newly forming levels of the stratum corneum; higher concentrations may have dermal effects (e.g. thickening)	Xerosis, ichthyoses, other hyperkeratotic dermatoses, acne, rosacea, photoaging; chemical peels	Irritation and burning, especially when applied to inflamed or eroded/fissured skin
Humectants				
Propylene glycol	10%–70%* solution or gel	Humectant, occlusive, and keratolytic agent*	Ichthyoses, keratodermas, other hyperkeratotic dermatoses	Irritation, burning
Urea	10%–50% cream, lotion, solution, gel, or foam; OTC or prescription (higher concentrations)	Due to its hygroscopic properties; absorption of water into the stratum corneum results in increased hydration, desquamation of corneocytes, enhanced barrier function, and decreased sensitizing effects of topical irritants	Xerosis, hyperkeratotic dermatoses (e.g. keratoderma climactericum, ichthyosis, psoriasis), nail avulsion; increases penetration of other topical medications	Irritation and burning, especially when applied to inflamed or eroded/fissured skin
*Often employed at lower concentrations as a preservative and penetration enhancer in vehicles.				

Table 129.7 Topical keratolytics and humectants[101–108]. Considering the low systemic absorption with topical application, use of these agents to a limited area is considered to be safe during pregnancy. Use of these agents in cosmeceutical products and chemical peels is discussed in Chapters 153 and 154, respectively.

Fig. 129.4 Unilateral trichomegaly. Bimatoprost ophthalmic solution (0.03%) was applied to one eye to treat glaucoma. *Courtesy Jean L. Bolognia, MD.*

upper eyelid margin, increased eyelash length, fullness, and darkness are noted within 16 weeks in ~75% of patients[8–11]; upon discontinuation of treatment, return toward baseline typically begins within 4 weeks.

Bimatoprost was also found to improve eyebrow hypotrichosis in a randomized, vehicle controlled trial[12]. Its potential utility for various forms of scalp alopecia (e.g. androgenetic) has also been investigated.

Mechanism of action

In animal studies, bimatoprost and other prostaglandin $F_{2\alpha}$ analogues (e.g. latanoprost) prolonged the anagen phase, increased the proportion of anagen follicles, and enlarged the dermal papilla and hair bulb during early anagen[13].

Side effects

Bimatoprost ophthalmic solution can cause pruritus and irritation of the eye, conjunctival hyperemia, and hyperpigmentation of the eyelid skin and iris, with the latter likely to be permanent[8,12]. Decreased intraocular pressure may occur but is generally not of clinical significance.

Use in pregnancy

Animal reproduction studies with high *oral* doses of bimatoprost have shown risk of spontaneous abortion and other adverse outcomes (e.g. early delivery), but systemic absorption is limited with topical use; there are no adequate studies in pregnant women.

Eflornithine

Eflornithine 13.9% cream is FDA-approved for the treatment of excessive and unwanted facial hair in women; it was discontinued by the original manufacturer in 2023. It irreversibly inhibits ornithine decarboxylase in the skin, leading to decreased polyamine synthesis and arrest of follicular matrix cell proliferation[14]. Twice-daily application for 24 weeks has been shown to significantly decrease facial hair[14], and use of eflornithine together with laser hair removal may result in more rapid and complete reduction in facial hair than laser treatment alone[15]. Eflornithine is usually well tolerated, with occasional burning or acneiform eruptions at sites of application[14]. Adverse fetal effects have been observed in animal reproduction studies when there was ingestion of eflornithine from topical application sites.

IMMUNOMODULATORY AGENTS

Imiquimod

Introduction, dosages, and indications

Imiquimod stimulates innate and adaptive immune response pathways, resulting in antiviral, antitumor, and immunoregulatory properties. Commercially available as 2.5%, 3.75%, and 5% creams, it

is FDA-approved for the treatment of: (1) anogenital warts[16]; (2) actinic keratoses (AKs) on the face or scalp[17,18]; and (3) superficial basal cell carcinoma (BCC) measuring up to 2 cm in diameter on the trunk, neck, or extremities (excluding the hands and feet)[19]. Off-label cutaneous uses with variable efficacy include treatment of common warts[20], Bowen disease (squamous cell carcinoma *in situ*)[21], nodular BCC, lentigo maligna, melanoma metastases, T cell lymphoma, Paget disease, and leishmaniasis as well as prevention of keloid recurrence following surgical excision[22–24]. Although imiquimod has been utilized to treat molluscum contagiosum, unpublished randomized controlled trials (RCTs) showed no difference in its efficacy compared to that of placebo[25].

FDA-approved regimens for imiquimod application are as follows: (1) *for anogenital warts* – 5% cream three times weekly for up to 16 weeks, or 3.75% cream daily for up to 8 weeks (~50% and ~30% clearance, respectively); (2) *for AKs* – 5% cream twice weekly for 16 weeks, or 2.5%–3.75% cream daily for two 2-week cycles separated by 2 weeks without treatment (~50% and ~35% clearance, respectively); and (3) *for superficial BCC* – 5% cream five times weekly for 6 weeks (~75% clearance). The frequency of application and duration of therapy for off-label uses vary.

Mechanism of action

The mechanism of action is depicted in Fig. 129.5[26]. In animal models, imiquimod's antiviral and antitumor activity is explained at least in part by the effects of IFN-α[27].

Side effects

The most common adverse reactions to imiquimod cream are erythema, edema, scaling, erosion, and ulceration at the site of application (Figs. 129.6 & 129.7). These reactions tend to be more intense and frequent in patients with actinic damage. Development of erosive pustular dermatosis of the scalp has been associated with the use of imiquimod for AKs of the scalp[28], and reactions with histologic findings mimicking those of lupus erythematosus have been described. Flu-like symptoms such as fatigue, fever, headache, diarrhea, and myalgias occur in ~1%–2% of patients, but systemic immune alterations have not been described.

Use in pregnancy

Animal reproduction studies with *systemic* imiquimod administration have shown adverse fetal effects, but percutaneous absorption of imiquimod cream is minimal. There are no adequate studies in pregnant women.

Topical Calcineurin Inhibitors (TCIs)

Introduction, dosages, and indications

Tacrolimus ointment and pimecrolimus cream are anti-inflammatory agents that allow treatment of eczematous and other inflammatory dermatoses without the side effects of topical corticosteroids. Tacrolimus 0.1% and 0.03% ointments are indicated for treatment of "moderate to severe" atopic dermatitis in patients ≥16 and ≥2 years of age, respectively, while pimecrolimus 1% cream is indicated for treatment of "mild to moderate" atopic dermatitis in individuals ≥2 years of age. Pimecrolimus has also been studied extensively in infants 3–23 months of age, and the American Academy of Dermatology's current guidelines recommend off-label use of pimecrolimus 1% cream and tacrolimus 0.03% ointment for children <2 years of age with mild to severe atopic dermatitis[29].

TCIs are also frequently used to treat other inflammatory skin conditions, especially when there is facial (including the eyelids) and intertriginous involvement. Examples include eczematous and seborrheic dermatitis as well as psoriasis, lichen planus (oral and genital), vitiligo, pyoderma gangrenosum, perioral dermatitis, granulomatous rosacea, cutaneous Crohn disease, lichen sclerosus, and cutaneous lesions of dermatomyositis, lupus erythematosus, and chronic graft-versus-host disease (GVHD)[30].

Mechanism of action

The mechanism of action is depicted in Fig. 129.8.

Contraindications

The TCI labels were revised in 2006 to include a boxed warning regarding a theoretical concern for risk of malignancy. However, there has been no short-term or long-term (>20 years) evidence of

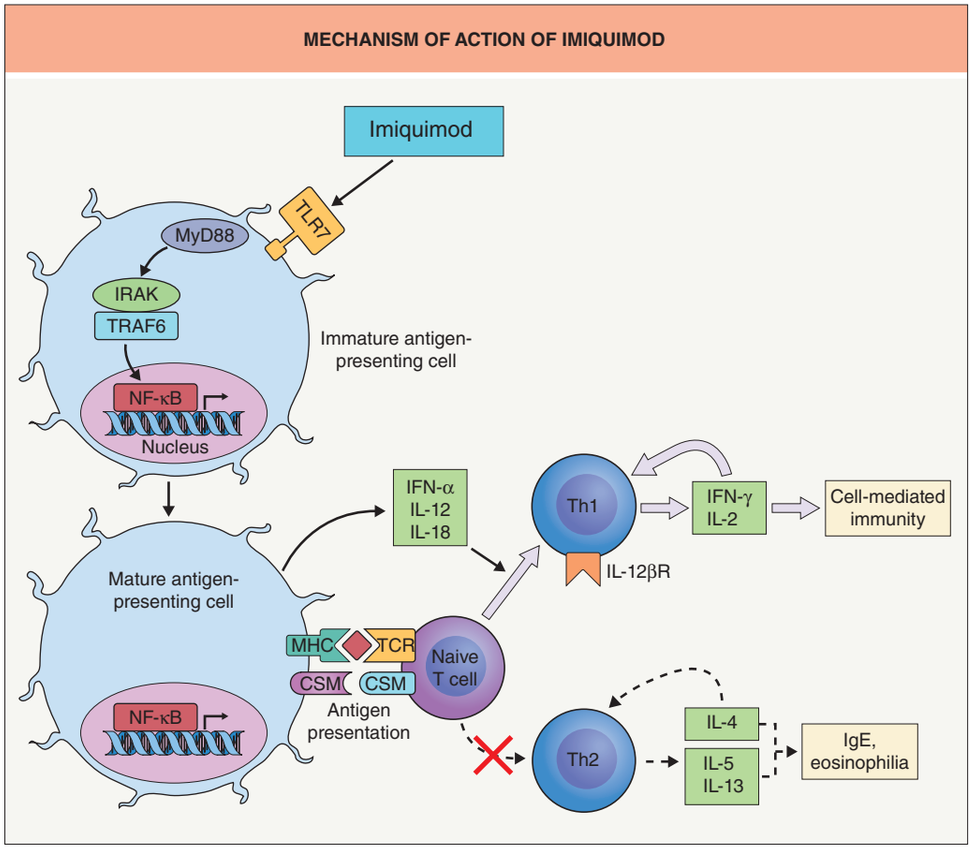

Fig. 129.5 Mechanism of action of imiquimod. Binding of imiquimod to Toll-like receptor 7 (TLR7) on antigen-presenting cells (e.g. Langerhans cells, other dendritic cells, macrophages) leads to interaction of the cytoplasmic portion of the receptor with MyD88. This facilitates association of MyD88 with interleukin (IL)-1 receptor-associated kinase (IRAK), which in turn activates TNF receptor-activated 6 (TRAF6) and ultimately results in stimulation of nuclear factor-κB-mediated signaling. Imiquimod thereby promotes antigen-presenting cell maturation and secretion of interferon (IFN)-α, IL-12, IL-18, and other cytokines, which induce IFN-γ production by naive T cells and result in enhancement of cell-mediated immunity via a Th1-type response. CSM, costimulatory molecule; MHC, major histocompatibility complex; TCR, T cell receptor.

Fig. 129.6 Reaction to topical imiquimod treatment of an actinic keratosis. **A** Inflammation and erosions developed after application of imiquimod to an actinic keratosis and actinically damaged skin. **B** Following discontinuation of imiquimod, the inflammation subsided and the actinic keratosis had cleared. Note the residual hypopigmentation. *Courtesy J. Mark Jackson, MD and Jeffrey P. Callen, MD.*

Fig. 129.7 Inflammation at the site of application of imiquimod to an amelanotic lentigo maligna. The patient had residual disease despite multiple surgical procedures including skin graft placement. The inflammation did not occur until the tenth month of application. Three years later, the lesion recurred, but only within the graft. *Courtesy Jean L. Bolognia, MD.*

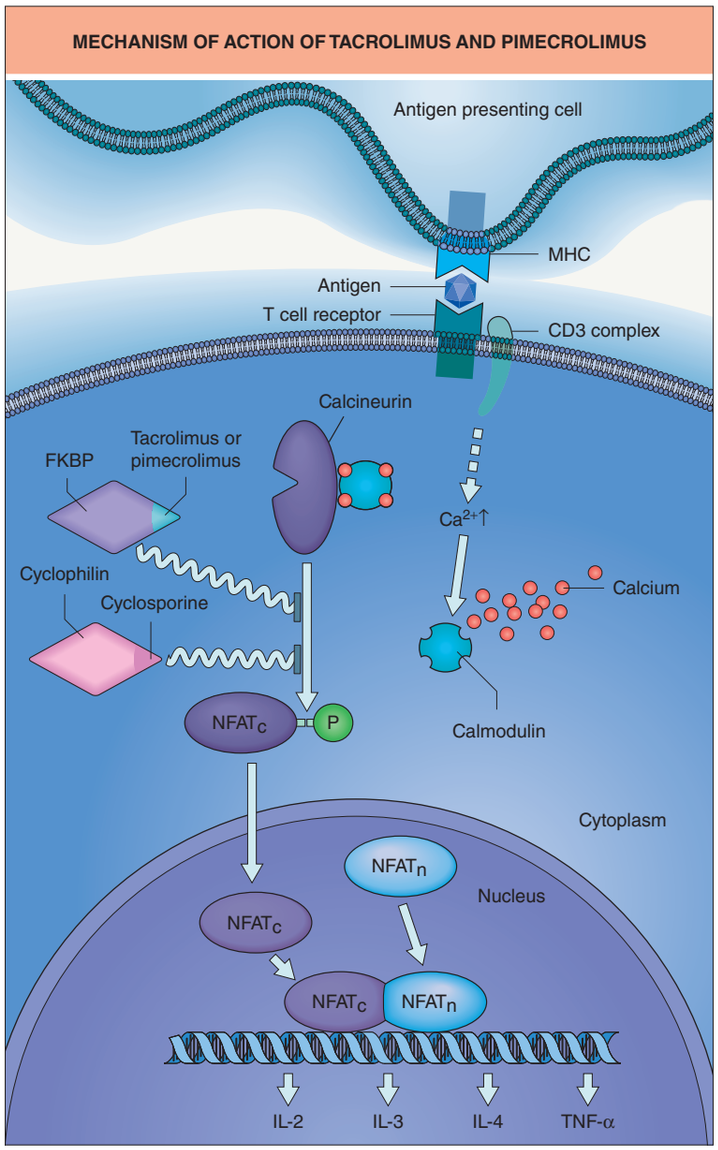

Fig. 129.8 Mechanism of action of tacrolimus and pimecrolimus. Both tacrolimus and pimecrolimus bind to the FK506-binding protein (FKBP), forming complexes that inhibit calcineurin[89]. Calcineurin normally dephosphorylates the cytoplasmic subunit of nuclear factor of activated T cells (NFAT), which then translocates to the nucleus and forms a complex that promotes transcription of proinflammatory cytokines, including the T cell mitogen IL-2. *From Nghiem P, Pearson G, Langley RG. Tacrolimus and pimecrolimus: from clever prokaryotes to inhibiting calcineurin and treating atopic dermatitis. J Am Acad Dermatol 2002:46:228–41.*

systemic immunosuppression or an increased risk for malignancy in clinical studies, systematic reviews, or post-marketing surveillance of either medication[31–34]. A task force of international experts concluded that the boxed warning is not justified and recommended its removal[33].

Because TCIs shorten the time to skin tumor formation in animal photocarcinogenicity studies, the package inserts recommend that patients minimize or avoid natural or artificial sunlight exposure. TCIs generally have negligible systemic absorption even with use on extensive areas of dermatitis, although low systemic levels have been observed following application to ulcers or eroded mucosal surfaces[35,36]. A rare exception is patients with Netherton syndrome, who have significant absorption of topical tacrolimus (but less so for pimecrolimus) that necessitates monitoring of blood levels or avoidance of TCI therapy[32,37].

Major side effects

Burning, stinging, or a sensation of warmth at sites of application are the most common side effects of TCIs. A local flushing reaction in association with alcohol consumption can also occur. There are scattered reports of allergic contact dermatitis and a rosacea-like granulomatous reaction on the face due to topical tacrolimus. *Staphylococcus aureus* colonization of the skin is actually reduced in atopic dermatitis patients treated with TCIs.

Use in pregnancy

Animal studies with *systemically* administered tacrolimus indicate harmful fetal effects only at doses that are toxic to the mother. There are no adequate studies in pregnant women.

Topical Janus Kinase (JAK) Inhibitors

Introduction, dosages, and indications

Janus kinase (JAK) inhibitors function by impeding proinflammatory cytokine-mediated signaling via the JAK-signal transducer and activator of transcription (STAT) pathway (see Ch. 128)[38]. Ruxolitinib 1.5% cream, a JAK1/2-selective inhibitor, is FDA-approved for the treatment of mild to moderate atopic dermatitis (short-term or non-continuous chronic use) and vitiligo in patients ≥12 years of age. Clear/almost clear skin and a ≥2-grade improvement were achieved by ~50% of individuals with mild to moderate atopic dermatitis treated with ruxolitinib 1.5% cream twice daily for 8 weeks[39], and >75% improvement of facial vitiligo was seen in ~30% of patients treated twice daily for 24 weeks[40].

Delgocitinib 0.25% or 0.5% ointment represents a pan-JAK inhibitor that is approved in Japan for the treatment of atopic dermatitis in adult and pediatric patients[41]. Tofacitinib 2% cream, a JAK1/3 inhibitor, has also demonstrated efficacy for atopic dermatitis in a randomized controlled study[42]. Additional dermatologic conditions for which topical JAK inhibitors have shown benefit include hand eczema, psoriasis, cutaneous lupus erythematosus, and alopecia areata[43–46].

Mechanism of action

The mechanism of action of JAK inhibitors is depicted in Fig. 128.11.

Major side effects

The most common side effects of topical JAK inhibitors include pruritus, erythema, and acne at application sites. However, the JAK inhibitor class-wide black box warning notes potential increased risks of serious infection, death, cancer, cardiovascular events, and thrombosis (see Ch. 128).

Use in pregnancy

Animal reproduction studies with high *oral* doses of tofacitinib and ruxolitinib have shown harmful fetal effects. There are no adequate studies in pregnant women.

Topical Phosphodiesterase-4 Inhibitors

Phosphodiesterase-4 (PDE-4) inhibitors function by inhibiting the degradation of cyclic AMP, which leads to decreased production of proinflammatory cytokines such as tumor necrosis factor (TNF), interferon-γ, and interleukins (ILs)-2, -4, -12, -23, and -31 (see Fig. 130.4). Crisaborole 2% ointment is a PDE-4 inhibitor that is FDA-approved for the treatment of mild to moderate AD in patients ≥3 months of age, with ~30% of these patients achieving clear/almost clear skin with a ≥2-grade improvement after 4 weeks of twice daily treatment[47]. Another PDE-4 inhibitor, roflumilast 0.3% cream, was recently FDA-approved for the treatment of plaque psoriasis (including in intertriginous sites) in patients ≥12 years of age; ~40% of such individuals achieved clear/almost clear skin with a ≥2-grade improvement after 8 weeks of once daily treatment[48]. The most common side effect of these medications is stinging or burning in the area of application. In animal reproduction studies, *oral* administration of crisaborole has not shown adverse fetal effects, but high *oral* doses of rofluminast have resulted in fetal harm. There are no adequate studies in pregnant women.

Aryl Hydrocarbon Receptor Agonists

Tapinarof is an aryl hydrocarbon receptor agonist that decreases expression of IL-17 and increases production of skin-barrier proteins such as filaggrin and loricrin as well as antioxidant enzymes. Tapinarof 1% cream is FDA-approved for the treatment of plaque psoriasis in adults, with ~40% of these patients achieving clear or almost clear skin after 12 weeks of once daily treatment[49]. Topical tapinarof is currently under investigation as a treatment for atopic dermatitis. The most common side effects include folliculitis and contact dermatitis. Animal reproduction studies have not shown harmful fetal effects, and there are no adequate studies in pregnant women.

CHEMOTHERAPEUTIC AGENTS

5-Fluorouracil

Mechanism of action

5-Fluorouracil (5-FU) is a pyrimidine analogue that interferes with DNA synthesis by irreversibly inhibiting thymidylate synthetase, which prevents cellular proliferation and results in cell death, preferentially affecting rapidly dividing cells[50]. It is also incorporated into DNA and RNA, leading to DNA breakage and decreased protein synthesis, and it disrupts the exosome complex that degrades RNA.

Indications and dosages

Topical 5-FU is used primarily to treat AKs[51], especially when there are numerous lesions, and sites of severe actinic damage without clinically evident AK lesions. In a randomized controlled trial, a ≥75% reduction in the number of AKs in a 25–100 cm^2 area on the head 12 months after completing therapy was achieved by a higher proportion of patients treated with 5-FU 5% cream (75%) than those who received imiquimod 5% cream (54%), methyl aminolevulinate photodynamic therapy (38%), or ingenol mebutate 0.015% gel (29%)[52]. 5-FU is less effective for hypertrophic AKs, owing to decreased percutaneous absorption through the thickened stratum corneum. Additional dermatologic applications of topical 5-FU include treatment of actinic cheilitis, SCC *in situ* (Bowen disease), superficial BCC, cutaneous and genital warts, porokeratoses, nail psoriasis, and extramammary Paget disease[51]; in addition, intralesional 5-FU may be of benefit for keloids. Topical 5-FU can also improve the appearance of photoaged skin via epidermal injury and subsequent dermal remodeling, similar to that seen following laser therapy[53].

5-FU is available as a cream (0.5%, 1%, and 5%) and solution (2% and 5%). Regimens vary depending on the concentration and vehicle as well as the indication and anatomic location. For example, duration of treatment is usually longer on the extremities than on the face. 5-FU is typically applied once or twice daily for 2 to 6 weeks. Pretreatment with a topical retinoid for 2 weeks can increase efficacy on the extremities and trunk. Application of topical calcipotriene (calcipotriol) 0.005% ointment together with 5-FU 5% cream (e.g. both twice daily for 4 days) induces thymic stromal lymphopoietin (TSLP) production and optimizes $CD4^+$ T cell-mediated immunity, resulting in a synergistic effect against AKs[54]. An office-based technique utilized for severely photodamaged extremities is weekly application of 5-FU (~10–20 g/extremity) that is then occluded by a zinc oxide-impregnated wrap.

Side effects

During treatment of AKs and photodamage, the skin progresses through stages of erythema (sometimes painful and associated with edema), crusted erosions, and re-epithelialization. The principal side effects are related to this localized inflammatory response (Fig. 129.9), which is occasionally followed by residual pigmentary changes. A mid-potency topical corticosteroid can be applied for symptomatic relief once peak inflammation has been attained. Systemic adverse events are rare, and systemic levels of 5-FU after topical application are very low[51].

Contraindications and use in pregnancy

Use of 5-FU is contraindicated in patients with a history of hypersensitivity to this agent and those with dihydropyrimidine dehydrogenase deficiency. 5-FU is potentially teratogenic (formerly pregnancy category X), and its use during pregnancy and lactation is contraindicated.

Mechlorethamine Hydrochloride

Introduction, dosages, and indications

Mechlorethamine hydrochloride (HCl), a form of nitrogen mustard, was introduced in 1959 and is used to treat limited or generalized patch/plaque-stage mycosis fungoides (MF). Concentrations ranging from 10 to 40 mg/dl (0.01%–0.04% w/w) can be compounded in an ointment or (less often) aqueous solution. Mechlorethamine 0.016% w/w gel is FDA-approved for stage 1 A/1B MF. Topical mechlorethamine

Fig. 129.9 Reactions to topical 5-fluorouracil. **A** Inflammation with erythema and crusting at sites of actinic keratoses on the forehead. **B** More severe inflammatory response with diffuse erythema and crusting in a patient treated for actinic keratoses. **C** Inflammation of actinic keratoses and areas of photodamage. **D** Large red–purple patches at sites of application on the upper chest in a patient with severe photodamage. *D, Courtesy Jean L. Bolognia, MD.*

is typically applied daily to affected areas until clearance is achieved, which typically takes 10–12 months with an ointment, 1–4 months with a solution, and 6–12 months with the gel[55]. Less often the entire body is treated, excluding the genitalia and applying sparingly to the skin folds.

Older studies suggested that treatment with mechlorethamine ointment or solution could result in a complete response (CR) rate of ~35%–75% in patients with patch/plaque-stage MF[56]. However, in a more recent 12-month randomized trial, the CR rate was 14% for 0.02% gel and 12% for an Aquaphor®-based 0.02% ointment; response rates rose to 59% and 48%, respectively, when partial responses were included[57].

Mechanism of action

Mechlorethamine is an alkylating agent (i.e. donates alkyl groups to DNA), with cytotoxicity that preferentially affects rapidly dividing cells. Immunostimulatory effects have also been postulated to have a role in treatment of patients with MF[56].

Side effects

Irritant and/or allergic contact dermatitis occurs in at least half of patients and may result in interruption of treatment. However, irritant reactions may improve with continued use, and patients can be desensitized if necessary. Other potential side effects include pruritus, xerosis, bacterial skin infections, vesiculation, ulceration, hyperpigmentation, urticaria, anaphylaxis, and (with prolonged use) development of SCC[56].

Use in pregnancy

Mechlorethamine can cause adverse fetal effects, and its use during pregnancy or lactation is contraindicated.

Carmustine

Introduction, dosages, and indications

Topical nitrosoureas have been utilized in the treatment of MF since 1972[58], but their use is declining. Carmustine (1,3-bis [2-chloroethyl]-1-nitrosourea; BCNU) currently represents a second- or third-line therapeutic option for MF, due to the potential for hematologic complications secondary to systemic absorption. It is available as an aqueous solution and ointment. Carmustine is applied once or twice daily until clearance of the treated areas occurs, which typically requires 1–4 months with the aqueous solution and 6–12 months with the ointment. A complete response is achieved in 85% of patients with limited patch/plaque-type disease (T1) and ~50% of those with generalized patch/plaque-type disease (T2)[56,59].

Mechanism of action

Carmustine is a nitrosourea alkylating agent that produces alkylation and subsequent cross-linking of DNA, thereby disrupting DNA synthesis and resulting in cytotoxicity that preferentially affects dividing cells[56].

Side effects

Erythema, tenderness, bullae, and persistent telangiectasias can develop at application sites[56]. Allergic contact dermatitis occurs less frequently than with mechlorethamine. However, higher levels of systemic absorption (5%–30% of the administered dose) can lead to side effects such as mild to moderate myelosuppression[60].

Use in pregnancy

Carmustine can cause adverse fetal effects, and its use during pregnancy or lactation is contraindicated.

VITAMIN D ANALOGUES

Mechanism of action

The skin serves as both a site of vitamin D biosynthesis (see Fig. 51.11) and a target organ for its ultimate activity. The cutaneous effects of 1,25-dihydroxyvitamin D_3 (calcitriol, the active form of vitamin D) include inhibiting proliferation and promoting differentiation of keratinocytes, as well as decreasing production of inflammatory mediators such as IL-2, IL-6, IL-8, interferon-γ, and chemokines[61]. Vitamin D exerts its regulatory functions by binding to vitamin D receptors (VDRs) on keratinocytes, melanocytes, Langerhans cells, macrophages, T cells, and fibroblasts.

Topical agents and their indications

Several topical vitamin D analogues are available for clinical use: calcipotriene, calcitriol, tacalcitol, and maxacalcitol; their formulations and dosing are outlined in Table 129.8. The primary indication for these agents is the treatment of psoriasis[62–66], but they have been used to treat other skin conditions such as vitiligo, morphea, ichthyoses, and Hailey–Hailey disease. Application of a vitamin D analogue in combination with a high-potency topical corticosteroid in patients with psoriasis can have greater efficacy and more rapid onset of action than either agent alone, as well as less irritation than the vitamin D analogue alone[63]. Additive benefits can also occur when vitamin D analogues are used together with acitretin, cyclosporine, or phototherapy for psoriasis or with phototherapy for vitiligo; the vitamin D analogue should be applied after phototherapy sessions to avoid degradation by UV light.

Side effects

The most common side effects are irritation, burning, and stinging at the application site, which limits use of vitamin D analogues on the face and in intertriginous areas. Allergic contact dermatitis has been described with calcipotriene. The systemic effects of vitamin D and its analogues include releasing calcium from the bone, increasing renal tubular reabsorption and intestinal absorption of calcium, and decreasing parathyroid hormone release. Use of excessive amounts of topical vitamin D analogues can lead to hypercalcemia and hypercalciuria. Parathyroid hormone levels should be monitored if use exceeds recommended amounts (see Table 129.8). Patients with renal disease and those receiving medications that can increase the serum calcium level (e.g. thiazide diuretics, high doses of oral vitamin D) may be at increased risk of developing hypercalcemia.

Use in pregnancy

Animal reproduction studies with *systemically* administered calcipotriene and calcitriol have demonstrated fetal skeletal abnormalities. There are no adequate studies in pregnant women.

MISCELLANEOUS AGENTS

Topical Sirolimus (Rapamycin)

Introduction, dosages, and indications

Sirolimus (rapamycin) is a *m*ammalian (*m*echanistic) *t*arget of *r*apamycin (mTOR) inhibitor with antiproliferative and immunomodulatory effects. Uses of *systemic* sirolimus include rejection prophylaxis and probable reduction of cutaneous SCC risk in solid organ transplant recipients; prophylaxis and treatment of GVHD; and treatment of lymphangioleiomyomatosis and other tumors associated with tuberous sclerosis complex (TSC; see Ch. 61), Kaposi sarcoma, kaposiform hemangioendothelioma, and lymphatic malformations[67]. *Topical* sirolimus has been utilized to treat angiofibromas, other TSC-related skin lesions, superficial lymphatic malformations, port-wine birthmarks (together with pulsed dye laser therapy), psoriasis, epidermal and sebaceous nevi, acanthosis nigricans, and confluent and reticulated papillomatosis (CARP)[68–77]. Sirolimus 0.2% gel is FDA-approved for the treatment of facial angiofibromas in patients ≥6 years of age with TSC. Application of sirolimus 0.1%–1% ointment, gel, cream, or solution (e.g. Rapamune® 1 mg/ml [0.1%]) once or twice daily to the facial angiofibromas of TSC usually leads to flattening and reduced erythema within 3 months, with better results in children than adults[69–74].

TOPICAL VITAMIN D_3 AND ITS ANALOGUES

Agent	Available formulations	Maximum weekly dose
Calcipotriene (calcipotriol) 0.005% (50 mcg/g)	Cream, ointment, solution, foam; combined with betamethasone dipropionate 0.064% in an ointment, suspension, and foam	100 g
Calcitriol [1,25$(OH)_2D_3$] 3 mcg/g	Ointment	200 g
Tacalcitol [1,24$(OH)_2D_3$] 4 mcg/g*	Ointment, lotion	70 g
Maxacalcitol 25 mcg/g*	Ointment, lotion	70 g

*Not available in the US.

Table 129.8 Topical vitamin D_3 and its analogues. These agents are typically applied twice daily. In general, treatment of >30% of the body surface area is not recommended. Calcipotriene is the US Adopted Name (USAN) and calcipotriol is the International Nonproprietary Name (INN).

Mechanism of action

Sirolimus binds to the FK506 binding protein FKBP12, forming a complex that inhibits mTOR (see Fig. 61.12). This leads to reduced proliferation and protein synthesis of T lymphocytes and other immune cells as well as decreased vascular endothelial growth factor (VEGF) production.

Side effects

Local skin irritation is more common with a gel or solution formulation than with an ointment[69,70]. Little to no systemic absorption has been observed with topical therapy[70–74].

Use in pregnancy

Animal reproduction studies with *oral* sirolimus have demonstrated adverse fetal effects. There are no adequate studies in pregnant women.

Diclofenac Sodium

Diclofenac sodium 3% in a gel vehicle containing hyaluronic acid is FDA-approved for treatment of AKs. This NSAID inhibits cyclooxygenase (COX)-2 and (to a lesser degree) COX-1. Its mechanism of action against AKs is thought to involve induction of apoptosis, alteration of cellular proliferation, and inhibition of angiogenesis. Twice-daily application for 60–90 days results in AK clearance rates of up to 30%–50%, with potential side effects including irritant, allergic, and photoallergic contact dermatitis. Animal reproduction studies have failed to demonstrate fetal risk, and there are no adequate studies in pregnant women.

Ingenol Mebutate

Ingenol mebutate, a diterpene ester from the *Euphorbia peplus* plant, was FDA-approved as a topical treatment for AKs[78–80]. However, this medication has been withdrawn from the market in the US and Europe due to its association with an increased risk of keratinocyte carcinoma. Application of ingenol mebutate 0.015% or 0.05% gel to areas with AKs on the face/scalp or trunk/extremities, respectively, once daily for 2–3 consecutive days led to a clearance rate of ~40%. This agent induces cell death in proliferating keratinocytes via disruption of the plasma membrane and mitochondria; it also triggers an inflammatory response that eradicates residual tumor cells[78–80]. Erythema, scaling, and crusting develop in most patients[78]; less frequently, swelling, vesiculation, ulceration, and dyspigmentation occur. Animal reproduction studies have demonstrated adverse fetal effects, and there are no adequate studies in pregnant women.

Tar

Introduction and indications

Topical tar has served as a skin-directed therapy for >2000 years, since the Greek physician Dioscorides applied "asphalt" to manage several cutaneous diseases[81]. Among the various types of tar (e.g. wood, bituminous [shale], petroleum, coal), coal tar is most often used as a dermatologic treatment. Currently, tar is utilized primarily in the management of psoriasis and several forms of dermatitis (e.g. seborrheic, nummular, atopic, hand), most commonly in conjunction with other therapeutic modalities. The classic Goeckerman regimen employs topical tar in combination with UVB radiation for the treatment of psoriasis[82].

Dosages

Coal tar in concentrations of 0.5% to 10% is available and can be compounded in a broad range of vehicles, including ointment, lotion, gel, foam, solution, oil, shampoo, and soap. *Liquor carbonis detergens* is a distillate of crude coal tar that is typically used in concentrations of 3%–10%.

Mechanism of action

Coal tar is thought to suppress DNA synthesis, which may lead to normalization of epidermal differentiation in conditions such as psoriasis[81]. It appears to have anti-inflammatory, antimicrobial, and antipruritic effects. In animal studies, tar has been found to decrease sebum secretion. Coal tar (but not other forms of tar) has a photosensitizing effect in the 330–550 nm range of the UVA and visible light spectra[81].

Side effects

The unpleasant odor, messiness, and staining potential of topical tar limit its use. Acneiform eruptions, folliculitis, and irritant contact dermatitis (including pustules within plaques of psoriasis) may occur at application sites, and "tar smarts" can develop following exposure to UVA radiation. Ever since Sir Percivall Pott described an increased risk of scrotal cancer in chimney sweepers in 1775, tar has been implicated as a potential carcinogen[81]. However, the evidence that topical tar formulations used in the treatment of skin disease result in an increased risk of skin cancer is inconclusive.

Use in pregnancy

Animal reproduction studies have shown adverse fetal effects, and there are no adequate studies in pregnant women. Use in the first trimester is not recommended.

Anthralin

Introduction, dosages, and indications

Anthralin, the synthetic form of the chrysarobin found in the bark of the South American araroba tree, has been used to treat dermatologic conditions for >80 years[83]. It is available in 0.5% and 1% creams. Although no longer commonly used for psoriasis, short-contact anthralin therapy, with gradual increases in the application time ± concentration, continues to be employed to treat alopecia areata via induction of an irritant effect (Table 129.9)[83].

Mechanism of action

Anthralin induces a brisk inflammatory response at sites of application, which may result from generation of extracellular oxygen free radicals[83]. Inhibition of mitochondrial respiration and cell growth are thought to reduce keratinocyte proliferation and lead to antipsoriatic effects.

Side effects

Use of anthralin is limited by irritation at application sites (depending on the concentration and contact time) and staining of skin, clothing, and household items (e.g. bed sheets, furniture). Staining and irritation can be ameliorated by application of triethanolamine 10% cream to treatment sites after removal of the anthralin-containing product.

SAMPLE PROTOCOL FOR SHORT-CONTACT ANTHRALIN THERAPY FOR ALOPECIA AREATA
• Anthralin 0.5% cream is applied sparingly to affected areas of the scalp daily, followed by washing with shampoo/soap and water • An initial application time of 10 minutes is increased in 10-minute increments every 4–5 days until slight irritation (e.g. erythema, scaling, pruritus) occurs • If excessive irritation develops, treatment is withheld for several days and resumed at the last tolerated application time • If there is no irritation with a 60-minute contact time, 1% anthralin is applied for 10 minutes and application times increased as above • If there is no irritation with 1% anthralin applied for 60 minutes, overnight application is considered • Initial responses are typically seen within 12 weeks; cosmetically acceptable responses require a mean of 24 weeks
Additional information
• Brownish staining of treated areas of the scalp and hair is expected • To prevent staining of clothing, bedding, and furniture, patients should wash their hands thoroughly after applying anthralin and avoid touching fabrics with their scalp until it has been washed off • Avoid getting anthralin into the eyes; do not apply to eyelids or eyelashes • Special care should be taken in sensitive areas (areas of scalp near the ears, eyebrows)

Table 129.9 Sample protocol for short-contact anthralin therapy for alopecia areata. *Courtesy Julie V. Schaffer, MD and Jean L. Bolognia, MD.*

Use in pregnancy

There are no adequate studies in animals or pregnant women.

Podophyllin and Podophyllotoxin

Introduction, dosages, and indications

Podophyllin resin is a crude extract from the May apple plant (*Podophyllum peltatum* or *Podophyllum emodi*) that has been employed for decades to treat condylomata acuminata. However, the concentration of its most active ingredient is not standardized in the 10%–25% solutions that are applied in the physician's office weekly and washed off 1 to 4 hours later[84]. In contrast, podophyllotoxin is available in a stable and standardized 0.5% solution and gel as well as a 0.15% cream. These compounds lack the mutagens that are found in podophyllin and can be applied by the patient, usually twice daily for three consecutive days each week for 4–6 weeks. Reported clearance rates for condylomata acuminata range from 30%–60% with podophyllin and from 45%–75% with podophyllotoxin[84].

Mechanism of action

Podophyllin and podophyllotoxin act by arresting mitosis through reversible binding to tubulin.

Side effects

Common adverse effects associated with both podophyllin and podophyllotoxin include burning, erythema, and skin breakdown at application sites. The extent of irritation may be reduced by application of petrolatum to unaffected surrounding skin. Because of its percutaneous absorption, application of large amounts of podophyllin can result in systemic toxicity (see Table 129.5).

Use in pregnancy

Use of podophyllin during pregnancy is contraindicated due to its teratogenic effects. However, a study of pregnant women treated with podophyllotoxin did not show an increased risk of adverse fetal outcomes.

Cantharidin

Introduction, dosages, and indications

Cantharidin is a vesicant derived from "blister beetles" in the Coleoptera order and Meloidae family. It has been used since the 1950s to treat warts and molluscum contagiosum (MC). Although cantharidin met the safety requirements outlined by the Food, Drug, and Cosmetic Act of 1938, it lost its FDA approval in 1962 when its manufacturers failed to submit required efficacy data[85]. A 0.7% concentration of cantharidin is available in a film-forming solution. VP-102, a drug-delivery device containing cantharidin 0.7% plus gentian violet, was FDA approved for the in-office treatment of MC in 2023. This formulation, was shown in randomized controlled studies to result in complete MC clearance in ~50% of patients treated at 3-week intervals for 12 weeks[86]. Another formulation that is primarily used for warts combines 1% cantharidin with 2% podophyllin and 30% salicylic acid.

A thin film of cantharidin is typically applied to lesions in the office. Occlusion may be used after drying, especially for treatment of warts. The residual film is washed off thoroughly with soap and water or rubbing alcohol by the patient (or a parent) 2 to 6 hours after application, or in 24 hours for VP-102. Blisters typically form over the next 12–24 hours, followed by superficial erosions; healing of treated areas (with temporary residual erythema) occurs over a period of 4–7 days[85]. Benefits of cantharidin use include painless application (particularly advantageous in young children) and a lack of scarring.

Mechanism of action

Cantharidin acts via release of neutral serine proteases that cause desmosomal plaque degeneration, leading to detachment of desmosomes from

tonofilaments; resultant acantholysis is intraepidermal and therefore non-scarring[85].

Side effects

The blisters and erosions that form after cantharidin treatment can be painful or pruritic, and postinflammatory hypopigmentation may take several months to resolve. Use of cantharidin to treat warts occasionally results in a "doughnut wart" due to clearance in the center but not at the periphery of the lesion. Cantharidin poisoning has been described following ingestion, with sequelae including blistering and erosions in the mouth and gastrointestinal tract as well as dysuria, hematuria, and renal failure. Standard in-office application of cantharidin, however, does not generally cause systemic effects.

Sulfur

Introduction

Sulfur, a yellow non-metallic element, has been employed as a treatment for seborrheic dermatitis, rosacea, acne, tinea versicolor, and scabies. Sulfur is typically used in concentrations of 2%–10%, often in combination with a second agent, e.g. 2% sulfur plus 2% salicylic acid in shampoos (for seborrheic dermatitis) or 5% sulfur plus 10% sodium sulfacetamide in a cream, suspension, or gel (for rosacea, acne, and seborrheic dermatitis; see Ch. 127). Application of 5%–10% sulfur ointment to the entire body for 2–3 consecutive nights represents a classic scabies treatment; however, it is inferior to topical permethrin therapy.

Mechanism of action

Sulfur has antibacterial, antifungal, and keratolytic properties.

Side effects

An offensive odor similar to that of rotten eggs limits the use of sulfur in the absence of masking fragrances. Side effects are generally mild and include dryness and pruritus.

Contraindications

Topical sulfur is contraindicated in patients with a sensitivity to sulfur.

Use in pregnancy

Topical sulfur (5%–10%) has been used to treat scabies in young infants and pregnant or lactating women, but safety data are lacking.

Azelaic Acid

Introduction and indications

Azelaic acid, a naturally occurring dicarboxylic acid, is used in the treatment of rosacea, acne, melasma, and postinflammatory hyperpigmentation.

Mechanism of action

Azelaic acid inhibits the production of free radical oxygen by neutrophils. This reduces oxidative tissue injury at sites of inflammation and decreases melanin production. Studies have also demonstrated selective cytotoxic and antiproliferative effects on hyperactive and abnormally proliferating melanocytes, with little effect on normal melanocytes. It may act as a competitive inhibitor of tyrosinase, further explaining its skin-lightening effects[87,88]. In addition, azelaic acid has antimicrobial activity against *Cutibacterium* (formerly *Propionibacterium*) *acnes* and *Staphylococcus epidermidis* as well as moderate anticomedogenic properties via modification of epidermal keratinization.

Dosages

Azelaic acid, which is applied twice daily, is available by prescription in a 20% cream and 15% gel as well as in 10%–14% over-the-counter formulations.

Side effects

Azelaic acid may cause mild to moderate irritant contact dermatitis (e.g. dryness, peeling, erythema), which often subsides after 2 to 4 weeks of treatment.

Use in pregnancy

Azelaic acid is considered safe to use during pregnancy.

Topical Immunotherapy

A sample protocol for topical immunotherapy with squaric acid dibutyl ester (SADBE) for cutaneous warts is outlined in Table 129.10, and use of SADBE or diphencyprone for alopecia areata is discussed in Chapter 69.

The Old and the New

Topical agents of historical interest are presented in Table 129.11. Many newer barrier-repair creams and moisturizers have purported benefit in

SAMPLE PROTOCOL FOR TOPICAL IMMUNOTHERAPY WITH SQUARIC ACID DIBUTYL ESTER FOR CUTANEOUS WARTS
• Sensitize with a 2% SADBE solution in acetone applied to a small (e.g. 2 cm × 2 cm) area on the inner aspect of the upper arm or medial thigh; cover with a dressing and do not wash for 24 hours • After 1 week (2 weeks if the initial reaction was severe), apply 0.2% SADBE solution to non-facial warts; cover with a light dressing and wash after 12–24 hours • Apply approximately twice weekly to warts; can increase or decrease the length of time between treatments depending on the duration of the reaction, with repeat application once the erythematous/eczematous reaction has subsided • If there is no inflammation or response of the warts after 2–4 weeks, increase the concentration to 0.5% (and subsequently to 1% and 2% as needed); decrease concentration (e.g. from 0.2% to 0.1%) and/or amount applied if excessive inflammation, e.g. more than mild erythema and pruritus • Responses are usually seen within 3 months, with complete clearance in 60%–80% of patients after a mean of 6–8 weeks
Additional information
• The acetone solution should be applied using a cotton-tip applicator • SADBE should be refrigerated and protected from light • Side effects include severe or widespread eczematous reactions (which can be treated with topical or, if required, systemic corticosteroids), lymphadenopathy, and postinflammatory pigment alterations (especially in patients with darkly pigmented skin)

Table 129.10 Sample protocol for topical immunotherapy with squaric acid dibutyl ester (SADBE) for cutaneous warts. This is not an FDA-approved medication.

TRADITIONAL TOPICAL MEDICATIONS		
Agent	**Components**	**Classic uses**
1-2-3 paste	Burow's solution, petrolatum, zinc oxide	In the diaper area as a protective barrier to treat and prevent irritant dermatitis Hand eczema, erosions, ulcerations
Aqueous silver nitrate 10% solution*	Silver nitrate	Small recalcitrant ulcerations Excess granulation tissue, bleeding – silver nitrate applicators ("sticks")
Black cat*	Acetone, collodion, crude coal tar	Psoriasis, lichen simplex chronicus, nummular eczema, hypertrophic lichen planus
Burow's solution	Aluminum acetate	Weeping, macerated, and/or infectious skin conditions, especially in intertriginous and acral sites (e.g. acute allergic contact dermatitis, tinea pedis/cruris, candidiasis)

Table 129.11 Traditional topical medications.

Continued

TRADITIONAL TOPICAL MEDICATIONS		
Agent	**Components**	**Classic uses**
Calamine lotion	Zinc oxide, ferric oxide, glycerin, bentonite magma, calcium hydroxide solution (lime water)	Acute and subacute pruritic dermatoses, especially acute allergic contact dermatitis
Castellani paint (carbol fuchsin)	Phenol, resorcinol, basic fuchsin (without the latter in colorless version)	Fissures, primarily on digits in the setting of chronic hand dermatitis Cutaneous candidiasis, tinea pedis/cruris, pustular dermatoses of the hands and feet
Chrysarobin*	Chrysarobin, chloroform	Chronic paronychia
Fluffy tannic acid powder*	Fluffy tannic acid, bentonite, kaolin	Hyperhidrosis, contact dermatitis of the hands/feet
Gentian violet solution	Gentian violet	Candidiasis, tinea pedis/cruris
P&S® liquid	Mineral oil, glycerin, phenol	Psoriasis/sebopsoriasis with excessive hyperkeratosis (especially of the scalp)
Potassium permanganate	$KMnO_4$	Weeping, macerated, and/or infectious skin conditions, especially in intertriginous and acral sites (e.g. tinea cruris/pedis, candidiasis)
Schamberg lotion*	Menthol, phenol, zinc oxide, calcium hydroxide solution, olive oil	Acute and subacute pruritic dermatoses
Whitfield ointment	Benzoic acid (6%), salicylic acid (3%)	Tinea pedis
*Primarily of historical interest.		

Table 129.11 Traditional topical medications.

EXAMPLES OF NEWER PRESCRIPTION BARRIER-REPAIR/ MOISTURIZING AGENTS	
Agent	**Active ingredients**
Atopiclair®/Pruclair™ cream	Glycyrrhetinic acid (licorice root), *Vitis vinifera* (grape vine) extract, *Butyrospermum parkii* (shea butter), hyaluronic acid, telmesteine
Eletone® cream	70% oil (mineral oil, white petrolatum) dispersed in 30% water
EpiCeram® emulsion	3:1:1 molar ratio of ceramide, cholesterol and free fatty acids (e.g. capric, linoleic, palmitic acids)
Hylatopic® (Plus) emollient foam cream, and lotion	*Theobroma grandiflorum* seed butter, hyaluronic acid, ceramide (latter in "Plus" version)
MimyX®/PruMyx™ cream	Palmitamide monoethanolamine, palm glycerides, hydrogenated lecithin, squalane, olive oil
Neosalus® foam	Dimethicone, stearic acid
Promiseb™ cream	Glycyrrhetinic acid, *Vitis vinifera* extract, *Butyrospermum parkii*, piroctone olamine, hydrogenated castor oil, telmesteine
Tetrix™ cream	Aluminum magnesium hydroxide stearate, cyclomethicone, dimethicone, hexyl laurate

Table 129.12 Examples of prescription barrier-repair/moisturizing agents. These agents are FDA-approved as "medical devices" and available by prescription. Over-the-counter barrier-repair moisturizers containing ceramides or "pseudoceramides" and filaggrin breakdown products are also available.

the management of various dermatoses, such as atopic dermatitis and irritant contact dermatitis; examples of these agents and their active ingredients are listed in Table 129.12.

TRADITIONAL FDA CLASSIFICATION SYSTEM OF PHARMACEUTICAL PREGNANCY CATEGORIES	
Category	**Description**
A	Controlled studies show no risk. Adequate well-controlled studies in pregnant women have failed to demonstrate risk to the fetus.
B	No evidence of risk in humans. Either animal studies show risk, but human studies do not; or, if no adequate human studies have been done, animal findings are negative.
C	Risk cannot be ruled out. Human studies are lacking, and animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk.
D	Positive evidence for risk. Human studies, or investigational or post-marketing data, show risk to fetus. Nevertheless, potential benefits may outweigh potential risk.
X	Contraindicated in pregnancy. Studies in animals or humans, or investigational or post-marketing reports, have shown fetal risk, which clearly outweighs any possible benefit to the patient.

eTable 129.1 Traditional FDA classification system of pharmaceutical pregnancy categories. In 2015, the FDA replaced these pregnancy risk categories with narrative sections addressing pregnancy and lactation, which include risk summaries as well as information on pregnancy exposure registries, clinical considerations, and available data. The new format is used for prescription drugs approved from June 30, 2015 onward and is being phased in for other drugs approved since 2001. FDA, Food and Drug Administration.

INTRODUCTION

This chapter is designed to be a broad overview of selected systemic therapies for dermatologic diseases. It provides an historical perspective for each drug, a discussion of its mechanism of action and side effects, and touches on indications and clinical use. This information should serve as a starting point, allowing the reader to readily compare and contrast treatment options. It is not a substitute for the in-depth knowledge and experience necessary to implement these therapies, nor is it a complete library of systemic drugs used in dermatology. Several systemic medications are reviewed in other chapters (Table 130.1) and not discussed here.

Systemic drugs discussed in this chapter may be subdivided into broad categories, such as immunosuppressive/anti-inflammatory, cytotoxic, and antiproliferative (Table 130.2). Drugs in a single category act in a relatively similar fashion and generally have similar important side effects. For example, immunosuppressive drugs suppress the body's ability to recognize or eliminate infections and neoplastic cells. Patients may be at increased risk for opportunistic infections and selected lymphoproliferative malignancies as well as squamous cell carcinomas. Given this increased risk for infection, patients with either an active infection or one that may reactivate (e.g. latent tuberculosis, hepatitis B viral infection) should be cautiously given these drugs, with prior (when possible) or concomitant administration of antimicrobial or antiviral medications.

Most of the drugs discussed herein lack Food and Drug Administration (FDA) approval for dermatologic indications. However, in most instances, their use is based on the mechanism of action of the drug and the presumed pathogenesis of the disease, combined with published case series, case reports, and a limited number of clinical trials.

When choosing therapy for a patient, certain broad general principles apply. First, the physician should be aware of all common therapeutic modalities available that are likely to yield optimal results. Certain systemic medications will not be utilized frequently enough for a given clinician to become comfortable with their use; therefore, patients requiring more specialized drugs should be referred to colleagues experienced with their use. Patients should be advised of all reasonable therapeutic choices as well as the risk–benefit profile of each modality. Non-compliance is a relative contraindication for all medications discussed in this chapter.

Prior to initiation of several of these medications, based upon potential side effects, the patient should have a complete history and physical examination, with specific emphasis on organ systems that may be affected by the particular drug. Tuberculin skin testing and/or interferon-gamma release assays (IGRAs; e.g. QuantiFERON-TB Gold Plus, T-SPOT.*TB*) should be performed prior to using immunosuppressive medications, specifically corticosteroids (particularly when a prolonged course is anticipated) and systemic immunomodulators ("biologics"; see Ch. 128). Consultation with appropriate generalists or specialists in selected situations may be required prior to initiating therapy as well as for periodic screening for treatment complications. Table 130.3 outlines suggested monitoring guidelines for systemic medications discussed in this chapter. Some tests may need to be performed more frequently in high-risk patients or in patients with abnormal results. Additionally, each outpatient visit should include an appropriate review of systems and physical examination.

The use of each drug during pregnancy and lactation is reviewed. Wherever possible, this has been referenced with the eleventh edition of *Drugs in Pregnancy and Lactation* by Briggs and colleagues. Additionally, in 2015, under the Pregnancy and Lactation Labeling Rule (PLLR), the FDA abolished the letter rating system for drug safety in pregnant women and during lactation; the letters have been replaced by narrative-based labeling with three subsections: (1) pregnancy; (2) lactation; and (3) females and males of reproductive potential[1]. In general, one should be circumspect in prescribing systemic medications to those with childbearing potential. It is not adequate to merely ask patients if they are utilizing birth control; each patient must be made acutely aware of the risks associated with medication use during pregnancy and risks of continuing therapy if one becomes pregnant.

SYSTEMIC MEDICATIONS COVERED IN OTHER CHAPTERS	
Antihistamines	Ch. 18
Antimicrobials	Ch. 127
Cytokines, including G-CSF, GM-CSF, interferons	Ch. 128
Glucocorticosteroids	Ch. 125
Interleukin (IL)-1 and IL-1R antagonists, including anakinra, canakinumab, rilonacept	Chs. 45 & 128
Intravenous immunoglobulin (IVIg)	Ch. 128
Ivermectin	Ch. 84
JAK inhibitors, e.g. tofacitinib	Ch. 128
Psoralens	Ch. 134
Psychotropic agents, including pimozide, atypical antipsychotic agents	Ch. 7
Retinoids, including acitretin, bexarotene, isotretinoin	Chs. 8, 36, & 126
Spironolactone	Ch. 36
Systemic immunomodulators, including rituximab, TNF inhibitors, IL-12/23, IL-23, IL-17 inhibitors	Ch. 128

Table 130.1 Systemic medications covered in other chapters. IL-1R, interleukin-1 receptor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; JAK, Janus kinase.

CATEGORIES OF SYSTEMIC DRUGS USED IN DERMATOLOGY BASED UPON MECHANISM OF ACTION			
Immunosuppressive/Anti-inflammatory	**Cytotoxic**	**Antiproliferative**	**Miscellaneous**
Apremilast Azathioprine Mycophenolate mofetil Cyclosporine Lenalidomide Tacrolimus Thalidomide	Cyclophosphamide Bleomycin	Methotrexate* Hydroxyurea	Dapsone Antimalarials Saturated solution of potassium iodide (SSKI)
*Also immunosuppressive/anti-inflammatory.			

Table 130.2 Categories of systemic drugs used in dermatology based upon mechanism of action.

MONITORING GUIDELINES FOR SYSTEMIC MEDICATIONS			
Drug	**Initial screening**	**Follow-up monitoring**	**Special considerations**
Antimalarials	***Ocular***: During the first year, a baseline examination* to exclude pre-existing maculopathy ***Laboratory***: CBC CMP G6PD (selected cases) ECG (at-risk patients)**	***Ocular***: After 5 years of continuous use with appropriate doses, annual screening* (unless high-risk patient or symptoms develop[5]; see Table 130.4) ***Laboratory***: Periodic CBC and CMP	• G6PD testing before antimalarial therapy is controversial and is probably most important with the use of primaquine • Urine or serum porphyrins should be measured when porphyria is clinically suspected • Retinopathy risk is greatest for those on treatment for at least 5 years (especially with chloroquine) and if maximum daily safe maintenance dose has been exceeded
Azathioprine	CBC CMP UA Consider pregnancy test for women of childbearing potential TPMT level, if available Tuberculosis screening† (should be considered depending on clinical situation)	CBC every 2 weeks for 2 months, then every 2–3 months if stable LFTs every 2 weeks for 2 months, then every 2–3 months if stable	• 25% dose reduction is necessary if GFR 10–50 ml/min; 50% dose reduction if GFR <10 ml/min • Frequency of laboratory studies is based on baseline TPMT determination (see Table 130.6); if TPMT is not known, hematologic parameters should be more closely monitored • Discontinue therapy, at least temporarily, if WBC declines to <3500–4000 cells/mm^3 or if hemoglobin <10 g/dl • Yearly skin examination and age-appropriate cancer screening, including yearly gynecologic examination in women
Cyclophosphamide	CBC CMP UA Pregnancy test for women of childbearing potential	CBC every week for 2–3 months, then every 2 weeks if stable. After 3–6 months, may decrease to every 3 months if stable UA every week for 2–3 months, then every 2 weeks if stable. After 3–6 months may decrease to every 3 months if stable CMP monthly for 3–6 months, then every 3 months if stable	• Discontinue temporarily or lower dose if WBC declines to <3500–4000 cells/mm^3 or PLT count to <100 000 cells/mm^3 • Stop treatment if red blood cells appear in urine; refer to urologist if hematuria persists • Yearly physical examination and CBC as well as age-appropriate cancer screening
Cyclosporine	At least 2 baseline blood pressure readings At least 2 baseline serum creatinine levels CMP (must include BUN, magnesium, potassium and uric acid) CBC UA with microscopic examination Fasting lipid profile (TG, cholesterol, HDL)	CBC at 1 month, then every 2–4 months CMP (must include BUN, creatinine, uric acid, potassium, magnesium) every 2 weeks for 1–2 months, then monthly or every 3 months if stable UA with microscopic examination every month if abnormal; otherwise yearly Fasting lipid panel every 2–4 weeks for 1–2 months, then every 3 months if stable	• Blood pressure must be monitored every 2 weeks for first 3 months and then monthly if stable • Lower dose by 25%–50% if serum creatinine remains elevated (over 2 weeks) by >25% of baseline • Lower dose by 25%–50%, or discontinue, if at any time serum creatinine is elevated by ≥50% of baseline • Consider creatinine clearance if >6 months of therapy • Skin examination at least yearly and age-appropriate cancer screening • Consider trough whole drug cyclosporine level if non-compliance, poor absorption or drug interactions are suspected
Dapsone	CBC CMP UA G6PD level Genetic screen for HLA-B*13:01 for at-risk populations (e.g. Chinese)	CBC every 2 weeks for 2 months, then every 3–4 months; after 9–12 months of therapy, for patients on lower doses with stable normal laboratory values, consider twice-yearly testing Reticulocyte count if anemia develops CMP every 3–4 months UA every 3–4 months	• Each visit should include an assessment of peripheral motor function and an assessment for the signs and symptoms of methemoglobinemia and peripheral neuropathy (e.g. motor strength, reflexes) • Methemoglobin level if clinically indicated • Increase monitoring frequency when dose is increased

Table 130.3 Monitoring guidelines for systemic medications, as recommended by the authors.

MONITORING GUIDELINES FOR SYSTEMIC MEDICATIONS			
Drug	**Initial screening**	**Follow-up monitoring**	**Special considerations**
Methotrexate	CBC CMP Pregnancy test for women of childbearing potential Baseline panel of biochemical markers (see Fig. 130.7) Serologic tests for hepatitis A, B, and C viruses Tuberculosis screening† (should be considered depending on clinical situation) HIV testing if indicated	CBC and LFTs after initial test dose of 2.5–5 mg in higher risk patients CBC and LFTs 1–3 weeks after initiation and after each dose escalation, then monthly for 2–4 months, and then every 3–4 months, if stable BUN and serum creatinine every 6–12 months Yearly panel of biochemical markers Depending upon biochemical markers and risk factors for hepatotoxicity, yearly GI consult +/– VCTE (see Fig. 130.7)	• See Fig. 130.7[36] • Elevation of LFTs <3× upper limit of normal, repeat in 2–4 weeks • Elevation of LFTs ≥3× upper limit of normal, reduce dose or discontinue, closely monitor, repeat in 2–4 wks • Persistent elevation of LFTs during a 12-month period or a decline in serum albumin below the normal range in a patient with normal nutritional status, GI consult and consideration of liver biopsy • Consider creatinine clearance, especially in elderly patients
Mycophenolate mofetil	CBC CMP Pregnancy test for women of childbearing potential Serologic tests for hepatitis B and C virus Tuberculosis screening† HIV testing	CBC every 2 weeks for 2–3 months, then monthly for first year CMP after 1 month and then every 3–4 months	• Discontinue or decrease dose if WBC declines to <3500–4000 cells/mm^3
Thalidomide and lenalidomide	CBC CMP TSH Pregnancy test in women of childbearing potential Subjective review of sensory and motor neurologic function and neurologic examination (thalidomide > lenalidomide) Assessment of risk of arterial and venous thromboembolism (lenalidomide, thalidomide if combined with dexamethasone)	Consider CBC and LFTs every 2–3 months (recommend monthly for lenalidomide) Pregnancy test every week for 4 weeks, then monthly for women of childbearing potential with regular menses, or every 2 weeks for those with irregular menses and as clinically indicated Neurologic examination monthly for 3 months, then every 1–6 months Monitor for signs of venous or arterial thromboembolism	***Thalidomide:*** • Measurements of sensory nerve action potential amplitudes (SNAP), if indicated by history prior to therapy • Consider SNAP measurements every 6 months, or as indicated ***Lenalidomide:*** • Thromboprophylaxis may be recommended based upon underlying risk factors

*Automated visual fields and spectral domain optical coherence tomography (SD-OCT).
**Individuals with known cardiac disease including arrhythmias as well as those receiving other drugs that prolong the QT/QTc interval.
†Tuberculin skin testing (purified protein derivative [PPD]) or interferon-gamma release assay such as the QuantiFERON®-TB Gold Plus test.

Table 130.3 Monitoring guidelines for systemic medications, as recommended by the authors. Before using any of these medications, the risk–benefit profiles and adverse effects should be thoroughly discussed with each patient. More frequent monitoring is needed in high-risk patients, when results are abnormal, or when increasing doses. BUN, blood urea nitrogen; CBC, complete blood count with differential and platelet count; CMP, comprehensive metabolic panel (includes liver function tests); ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase; GFR, glomerular filtration rate; GI, gastroenterology; HDL, high-density lipoproteins; HLA, human leukocyte antigen; LFTs, liver function tests; TG, triglycerides; TPMT, thiopurine methyltransferase; UA, urinalysis; VCTE, vibration-controlled transient elastography; WBC, white blood count.

Family planning consultation and communication with the patient's obstetrician or primary care physician can prove helpful.

Several of the medications reviewed in this chapter, including mycophenolate mofetil, thalidomide, and lenalidomide, are subject to FDA-mandated Risk Evaluation and Mitigation Strategies (REMS). In addition to medication guides for patients, there are educational programs for health care providers and restrictive computerized programs to ensure compliance and safe medication use, especially as it pertains to pregnancy.

Lastly, several drugs discussed herein have parenteral formulations. Clinicians who administer parenteral medications in the ambulatory setting should be current in Advanced Cardiac Life Support (ACLS) training and keep emergency resuscitation supplies available.

ANTIMALARIALS

Quinine and its derivatives have been used since the 1600s to treat malaria. Quinine, derived from the bark of the cinchona tree in South America, was first used in dermatology by Payne in 1894 to treat discoid lesions in patients with lupus erythematosus (LE). The most common antimalarials are hydroxychloroquine (Plaquenil®), chloroquine (Aralen®), and quinacrine; currently the latter, which can lead to yellow skin discoloration, has limited availability in the US and will not be discussed in detail (see Ch. 41).

The antimalarials are absorbed extensively into tissues and slowly released, leading to a half-life of 40–50 days. A steady state is achieved slowly, and it may take 3–4 months to see adequate clinical effects. Hydroxychloroquine is catabolized into two metabolites, desethylhydroxychloroquine and desethylchloroquine. Chloroquine is only metabolized into the latter. The initial metabolites undergo further change into the primary amine form. Overall, 50% of each drug undergoes renal excretion[2].

Mechanism of Action

The mechanisms of action of antimalarials are complex and incompletely understood. Known endpoints include the following: stabilization of lysosomes within injured cells; inhibition of antigen presentation, cell-mediated immunity, and the synthesis of proinflammatory cytokines; and antithrombotic/antiplatelet effects[3]. The photoprotective effect attributed to the antimalarials may result from their anti-inflammatory properties[3].

Dosages

Most conditions will respond to dosages between 200 and 400 mg/day of hydroxychloroquine or 250 mg/day of chloroquine, with a maximum safe chronic dose (from an ocular standpoint) being 5 mg/kg/day and 2.3 mg/kg/day, respectively, utilizing *real* body weight. After a suitable therapeutic response has been achieved, the response may be maintained with hydroxychloroquine 100–200 mg daily. If available, quinacrine (100 mg/day) can be added to 200 mg twice daily of hydroxychloroquine, to maximize the clinical benefit without increasing the

risk of ocular toxicity. Lower doses of chloroquine (125 mg twice weekly) or hydroxychloroquine (100 mg three times weekly) must be used in patients with porphyria cutanea tarda, in order to minimize the risk of a toxic reaction (e.g. hepatotoxicity) in addition to a marked increase in urinary uroporphyrin output and flare of cutaneous disease (Fig. 130.1).

If no response is noted after 3–4 months, the specific antimalarial has failed and should be discontinued; however, a different antimalarial can be tried. In patients with porphyria cutanea tarda the antimalarial can be slowly increased to daily dosing if necessary and if laboratory monitoring of transaminases allows.

Monitoring guidelines are outlined in Table 130.3 and in the next section.

Major Side Effects

Antimalarials are highly concentrated in the iris and choroid, reaching levels 480 000 times that of plasma[4]. However, irreversible retinopathy rarely occurs when dosages remain within the recommended range and patients are monitored by an ophthalmologist experienced with the ocular effects of antimalarials. As noted in Table 130.4, the risk of retinopathy is much less with hydroxychloroquine than with chloroquine.

Because of the risk of dose-related ocular toxicity, referral to an ophthalmologist for evaluation is required. The American Academy of Ophthalmology (AAO) guidelines recommend that a baseline examination be performed within the first year of antimalarial use. With the exception of higher risk individuals (e.g. the elderly, history of maculopathy, renal or hepatic dysfunction) and those patients with symptoms, annual screening is performed after five years of continuous use (see Table 130.4)[5,6]. Of note, more recent data regarding long-term usage suggest a significant potential for retinopathy after 10 years of continuous therapy[7].

Up to one-third of patients who receive antimalarials for over 4 months will develop a blue–gray to black hyperpigmentation on their shins (Fig. 130.2), face, palate, and/or nail beds (Table 130.5). The discoloration fades after cessation of therapy but may take months to years to resolve completely. Reversible bleaching of the hair roots (achromotrichia) occurs in up to 10% of patients, presumably due to interference with melanosomal function. Another 10%–20% may develop an exanthem, ranging from urticaria to lichenoid reactions to exfoliative erythroderma (Fig. 130.3). Of interest, morbilliform and urticarial exanthems have been observed with greater frequency in individuals with dermatomyositis as compared to those with LE.

Fig. 130.1 Hydroxychloroquine-induced porphyria cutanea tarda (PCT). While low doses of antimalarials (e.g. 100–200 mg of hydroxychloroquine 2–3 times per week) can be used in the management of PCT, higher doses, such as those used to treat cutaneous LE, can lead to flares of PCT. This patient developed skin fragility and bullous lesions six weeks after beginning hydroxychloroquine for rheumatoid arthritis. The eruption resolved with discontinuation of the medication.

RISK FACTORS AND TYPES OF RETINOPATHY ASSOCIATED WITH ANTIMALARIAL THERAPY

	Hydroxychloroquine	Chloroquine
Risk factors		
Dosing risk		
Daily dose	>400 mg/day (>5 mg/kg/day, based upon *real* body weight)	>250 mg/d (>2.3 mg/kg/day based upon *real* body weight)
Total cumulative dose	>1000 g	>460 g
Other risk factors		
Ocular	History of retinopathy or maculopathy	History of retinopathy or maculopathy
Systemic	Renal or hepatic dysfunction Use of tamoxifen and aromatase inhibitors	Renal or hepatic dysfunction
Age	Elderly	Elderly
Types of retinopathy		
Reversible ocular toxicity: • Corneal deposits leading to blurred vision, halos of colors around lights • Loss of accommodation/diplopia • Premaculopathy: no visual symptoms or loss of visual acuity, central and paracentral scotomata	Observed in 5% of patients Often reversible with discontinuation of therapy	Observed in 90% of patients Often reversible with discontinuation of therapy
Irreversible ocular toxicity (true retinopathy): • "Bull's eye" pigment deposition • Central scotomata • Changes in visual acuity	Incidence of 0.5% after 6 years of treatment If develops, suspend treatment	Incidence can reach 1% after 5 years of treatment If develops, suspend treatment

Table 130.4 Risk factors and types of retinopathy associated with antimalarial therapy. The ocular examination should include white 10-2 threshold testing (automated visual field testing) plus one or more of the following, if available: spectral domain optical coherence tomography to detect early thinning of photoreceptors in retina, multifocal electroretinogram, or fundus autofluorescence. Adapted from references 2, 5, 6, and 49.

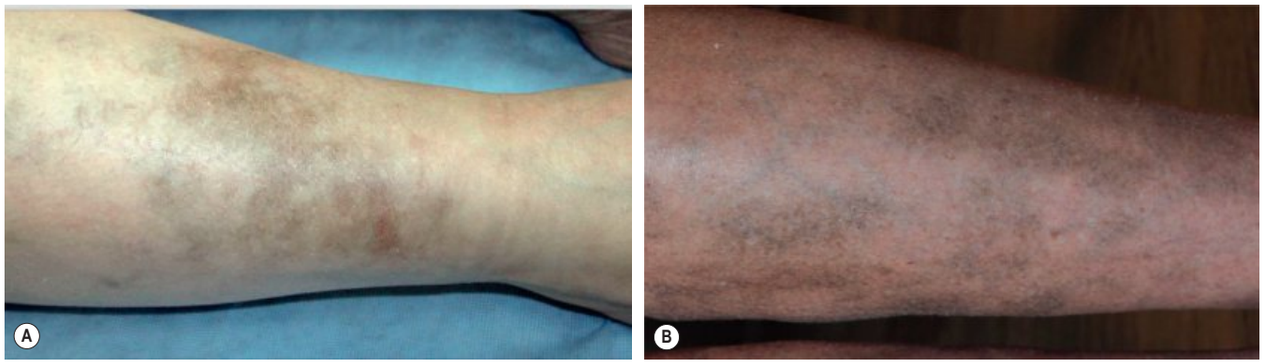

Fig. 130.2 Discoloration of the shins due to antimalarial drugs. A Areas of blue-gray to brown discoloration due to chloroquine. **B** Scattered brown to brown-gray patches due to hydroxychloroquine. *B, Courtesy Kalman Watsky, MD.*

SIDE EFFECTS OF SYSTEMIC DRUGS USED IN DERMATOLOGY			
Drug	**Common**	**Uncommon**	**Rare**
Antimalarials	***Derm***: blue–gray to black discoloration; yellowing from quinacrine	***Derm***: bleaching of hair roots, exanthem (e.g. urticarial, lichenoid) ***GI***: nausea, vomiting, elevated liver enzymes ***Neuro***: irritability, nervousness	***Heme***: pancytopenia, hemolysis (G6PD-deficient, primarily with non-dermatologic antimalarials) ***Ophtho***: reversible (early) and irreversible retinopathy, vision changes (see Table 130.4)
Apremilast	***GI:*** nausea, diarrhea ***ENT:*** nasopharyngitis ***Metabolic:*** weight loss	***Neuro:*** headaches	***Psych:*** depression and suicidal ideation
Azathioprine	***Derm***: keratinocyte carcinomas ***Heme***: leukopenia, thrombocytopenia, immunosuppression	***GI***: nausea, vomiting ***ID***: opportunistic infections	***Heme***: pancytopenia ***GI***: pancreatitis, hepatitis ***Malignancy***: lymphoma, cutaneous and gynecologic SCC Hypersensitivity syndrome
Cyclophosphamide	***GI***: nausea, vomiting ***GU***: sterility (higher doses or long-term administration) ***Heme***: leukopenia	***Derm***: diffuse hyperpigmentation, nail pigmentation, alopecia ***GU***: dysuria, hemorrhagic cystitis, amenorrhea, azoospermia, sterility (with lower doses) ***Heme***: anemia, thrombocytopenia ***ID***: opportunistic infections	***GI***: hemorrhagic colitis, hepatotoxicity ***Heme***: aplastic anemia ***Malignancy***: bladder (esp. chronic oral administration), lymphoma, acute leukemia ***Pulmonary***: pneumonitis, interstitial fibrosis Anaphylaxis
Cyclosporine	***Cardiac***: hypertension ***Derm***: keratinocyte carcinomas ***GU***: renal dysfunction* ***Metabolic***: hyperlipidemia ***Neuro***: headache, tremor	***Derm***: hypertrichosis, gingival hyperplasia, sebaceous hyperplasia, acneiform eruption, epidermoid cysts ***GI***: nausea, diarrhea ***Neuro***: paresthesia, hyperesthesia ***Metabolic***: hyperkalemia†, hypomagnesemia, hyperuricemia	***Derm***: trichodysplasia spinulosa/viral-associated trichodysplasia (see Ch. 81) ***ID***: infections (unless combined with other immunosuppressives) ***Musculoskeletal***: myalgias, myositis ***GI***: hepatotoxicity ***Malignancy***: lymphoma ***Pulmonary***: dyspnea, bronchospasm
Dapsone	***Heme***: hemolysis, methemoglobinemia	***GI***: dyspepsia, anorexia	***Heme***: agranulocytosis ***Neuro***: peripheral neuropathy Dapsone hypersensitivity syndrome
Hydroxyurea	***Heme***: anemia, megaloblastic changes	***Derm***: leg ulcers, alopecia ***Heme***: leukopenia	***Derm***: hyperpigmentation, dermatomyositis-like lesions, keratinocyte carcinomas ***GI***: hepatitis ***GU***: renal dysfunction ***Heme***: thrombocytopenia ***Malignancies***: acute leukemia
Methotrexate	***Heme***: leukopenia	***Derm***: photosensitivity, alopecia, oral ulcers ***GI***: elevated liver enzymes, nausea, vomiting, anorexia, cirrhosis ***Heme***: thrombocytopenia	***Derm***: necrosis of psoriatic plaques, accelerated rheumatoid (cutaneous) nodulosis ***Heme***: pancytopenia, lymphoproliferative disorder (primarily in patients with RA) ***ID***: infections ***Pulmonary***: pneumonitis, fibrosis
Mycophenolate mofetil	***GI***: diarrhea, cramps, nausea, vomiting	***Heme***: anemia, leukopenia, thrombocytopenia ***ID***: opportunistic infections	***Derm***: oral aphthae (especially in organ transplant patients) ***GU***: dysuria, sterile pyuria ***Neuro***: insomnia, dizziness, tinnitus
Saturated solution of potassium iodide (SSKI)	***Derm***: acneiform eruption ***GI***: nausea, vomiting, diarrhea, abdominal pain ***Metabolic***: reversible hypothyroidism	***Derm***: iododerma ***Metabolic***: hyperkalemia	***Cardiac***: CHF, pulmonary edema ***Derm***: flare of dermatitis herpetiformis ***GI***: salivary gland enlargement ***Metabolic***: irreversible hyperthyroidism, goiter, "iodism" Hypersensitivity reactions
Tacrolimus	***Cardiac***: hypertension ***Derm***: keratinocyte carcinomas ***GU***: renal dysfunction* ***Neuro***: paresthesias	***Derm:*** alopecia ***ID***: infections ***Metabolic***: hyperkalemia†, hypomagnesemia	***Derm:*** trichodysplasia spinulosa/viral-associated trichodysplasia (see Ch. 81) ***Metabolic***: diabetes mellitus, hyperuricemia ***Malignancy***: lymphoma
Thalidomide and lenalidomide	***Derm***: xerosis, pruritus ***GI***: constipation ***Neuro***: peripheral neuropathy (thalidomide > lenalidomide), sedation ***Ob/Gyn***: fetal abnormalities, amenorrhea ***Heme***: neutropenia and thrombocytopenia (more common with lenalidomide)	***Cardiac***: peripheral edema ***Endo***: hyper- and hypothyroidism ***GI***: xerostomia, increased appetite ***Gyn***: primary ovarian failure ***Heme***: thromboses (esp. in combination with corticosteroids) ***Psych***: headache, mood changes	***Derm***: exfoliative erythroderma, TEN ***Heme***: leukopenia Hypersensitivity reaction (in HIV+ patients receiving thalidomide)

*Not permanent during short-term treatment if guidelines are followed.
†Especially when used in conjunction with angiotensin converting enzyme (ACE) inhibitors.

Table 130.5 Side effects of systemic drugs used in dermatology. CHF, congestive heart failure; Derm, dermatologic; G6PD, glucose-6-phosphate dehydrogenase; Endo, endocrine; ENT, ear, nose and throat; esp., especially; GI, gastrointestinal; GU, genitourinary; Gyn, gynecologic; Heme, hematologic; ID, infectious diseases; Neuro, neurologic; Ob/Gyn, obstetrical/gynecologic; Ophtho, ophthalmologic; Psych, psychiatric; RA, rheumatoid arthritis; SCC, squamous cell carcinoma; TEN, toxic epidermal necrolysis.

Fig. 130.3 Drug reaction with eosinophilia and systemic symptoms (DRESS) secondary to hydroxychloroquine. The individual lesions were edematous and became confluent. *Courtesy Jean L. Bolognia, MD.*

Antimalarials have been reported to worsen psoriasis in some patients, even though in the past they were commonly used to treat psoriatic arthritis. Psoriatic patients traveling to malaria-endemic areas may take these drugs prophylactically.

Laboratory abnormalities do not commonly occur, but it is the practice of the authors to monitor patients as outlined in Table 130.3. An overdose of antimalarials can be fatal, and although pediatric usage is safe and effective, patients should be warned to keep the drug out of the reach of small children.

Indications

The most common dermatologic use for antimalarials is as first-line systemic therapy for cutaneous LE, after topical or intralesional corticosteroids. Antimalarials are especially useful in patients with widespread discoid lesions and in those with the annular or papulosquamous lesions of subacute cutaneous LE (SCLE). Antimalarial use has also been credited with fewer thromboembolic events in patients with systemic LE (SLE)[3]. Additional cutaneous disorders that may respond to antimalarial therapy include lichen planus, dermatomyositis, and polymorphous light eruption[8].

Contraindications

The only true contraindication is hypersensitivity to the drug. Caution should be used in patients with severe blood dyscrasias or hepatic disorders because bone marrow suppression and hepatitis can occasionally occur. Should ophthalmologic changes of pre-maculopathy develop, an alternative medication should be considered. Ocular changes at this stage are potentially reversible but could progress if the drug were continued. With the exception of halofantrine, antimalarial medications that prolong the QT/QTc interval have a low risk of cardiotoxicity. In patients with known cardiac disease including arrhythmias as well as those receiving other drugs that prolong the QT/QTc interval, consultation with a cardiologist is recommended.

Use in Pregnancy and Lactation

Chloroquine is thought to be safe for treatment and prophylaxis of malaria during pregnancy; however, there have been anecdotal reports of an increase in birth defects in pregnant women being treated for SLE. Hydroxychloroquine is thought to be safer during pregnancy. Although excreted into breast milk, standard doses of either drug are not harmful to breastfed infants and are approved by the American Academy of Pediatrics for use during lactation[9].

Drug Interactions

Cimetidine may increase circulating levels of antimalarials, and antimalarials may increase digoxin levels. Kaolin and magnesium trisilicate, over-the-counter gastrointestinal drugs, decrease absorption of antimalarials. The most significant potential interaction is the additive risk of retinal toxicity when chloroquine and hydroxychloroquine are used concomitantly. Combined therapy consisting of chloroquine or hydroxychloroquine plus quinacrine is acceptable. As noted previously, assessment is required when antimalarials are coadministered with other medications that prolong the QT/QTc interval (e.g. azithromycin).

In patients with LE, cigarette smoking has been associated with decreased efficacy of antimalarials. It is unknown whether this represents a "drug–drug" interaction, decreased compliance (as a manifestation of high-risk behavior), or an unrecognized interplay. Suspected noncompliance can be confirmed by measuring serum levels of hydroxychloroquine.

APREMILAST

A novel, small-molecule inhibitor of phosphodiesterase 4, apremilast (Otezla®) works intracellularly to reduce the production of proinflammatory mediators and increase those that are anti-inflammatory (see below). When administered orally, apremilast is 70%–75% bioavailable, with peak plasma concentrations observed at ~2.5 hours. Nearly 70% of the drug is bound to plasma proteins, and it is metabolized by cytochrome P450 (CYP) enzymes, predominately CYP3A4 (see Ch. 131); this is followed by glucuronidation and non-CYP-mediated hydrolysis. Apremilast has a terminal elimination half-life of 6–9 hours and is excreted in the urine and feces.

Mechanism of Action

Apremilast inhibits phosphodiesterase 4, which is an intracellular enzyme that degrades cAMP and represents the predominant phosphodiesterase in keratinocytes, dendritic cells, monocytes, and neutrophils. Increasing intracellular cAMP levels activates protein kinase A, leading to enhanced expression of several transcription factors including *c*AMP-*r*esponse *e*lement *b*inding protein (CREB), while inhibiting others such as nuclear factor kappa B (NF-κB). By inhibiting phosphodiesterase 4 and increasing intracellular cAMP levels, apremilast has multiple downstream effects: it decreases the production of inflammatory mediators such as TNF, IFN-γ, and interleukins (IL)-2, -12, and -23; it increases the production of anti-inflammatory mediators including IL-10; and it inhibits natural killer responses (Fig. 130.4)[10].

Dosages

The recommended dosage for psoriatic arthritis and psoriasis is 30 mg twice daily. In order to reduce gastrointestinal symptoms, an upward titration of the dose by 10 mg/day is recommended, starting with an initial dose of 10 mg/day. Apremilast is available in 10, 20, and 30 mg tablets. For individuals with severe renal impairment, the recommended maximum daily dose is 30 mg; there is no dosing adjustment for hepatic impairment.

Major Side Effects

The most common side effects are gastrointestinal, especially nausea and diarrhea, which are most evident during the first 15 days of administration and gradually resolve over several weeks. Headache and nasopharyngitis are additional potential side effects. Because depression, including suicidal ideation, can be observed in up to 1% of patients, patients with a history of depression should be monitored closely. Loss of ~5%–10% of body weight occurs in ~10% of patients. No laboratory monitoring is recommended, but serial measurements of weight can be considered.

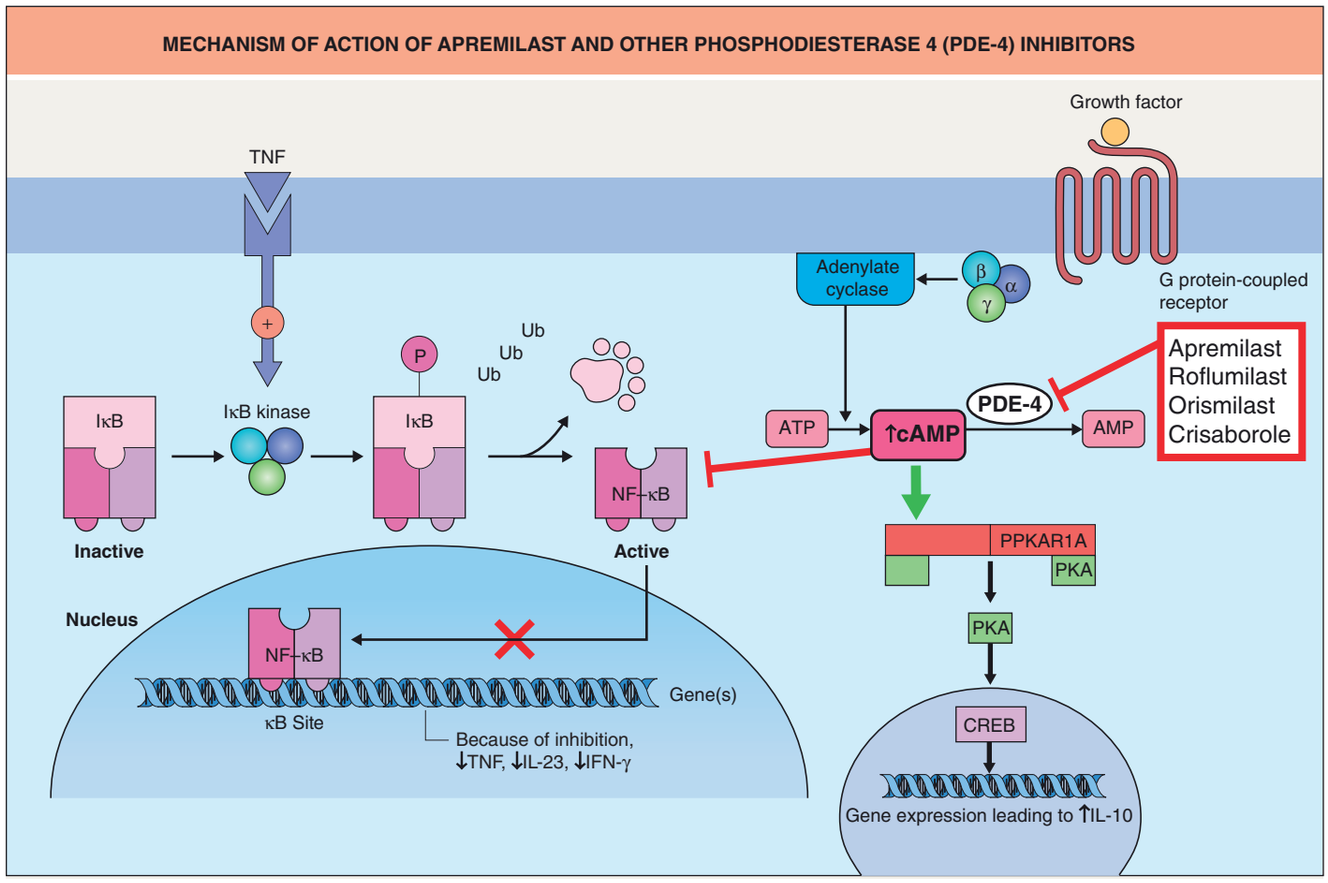

Fig. 130.4 Mechanism of action of apremilast and other phosphodiesterase 4 (PDE-4) inhibitors. Inhibition of phosphodiesterase 4 (PDE-4) results in increased intracellular cAMP levels. This leads to activation of protein kinase A (PKA), which in turn phosphorylates the transcription factor *c*AMP *r*esponse element *b*inding protein (CREB). Binding of CREB acts to increase the expression of anti-inflammatory mediators, e.g. interleukin (IL)-10. Increased intracellular cAMP levels also inhibit nuclear factor kappa B (NF-κB) leading to decreased expression of inflammatory mediators, e.g. tumor necrosis factor-alpha (TNF-α), IL-23, interferon-γ (IFN-γ). NEMO is another name for the gamma subunit of IκB kinase. ATP, adenosine triphosphate; α, α subunit of the stimulatory G protein; Ub, ubiquitin. *Adapted from Schafer P. Apremilast – mechanism of action and application to psoriasis and psoriatic arthritis. Biochem Pharmacol 2012;83:1583–90.*

Indications

Apremilast is FDA-approved for adult patients with active psoriatic arthritis and moderate to severe plaque psoriasis. The ESTEEM trial reported that a significantly greater proportion of patients receiving apremilast (30 mg BID) achieved Psoriasis Area and Severity Index (PASI)-75 (33.1%) and PASI-50 (58.7%) at week 16 compared with placebo (5.3% and 17.0%); quality of life measures and nail and scalp psoriasis were similarly improved[11,12]. It is also approved for the treatment of oral ulcers associated with Behçet disease and is currently being investigated for other inflammatory skin diseases including lichen planus, hidradenitis suppurativa, granulomatous dermatoses, discoid LE, and atopic dermatitis.

Contraindications

Apremilast is contraindicated in patients with known hypersensitivity to the drug or its components. Dosing should be adjusted for renal failure (see above). Relative contraindications include a history of depression or suicidal ideation.

Use in Pregnancy and Lactation

Because well-controlled studies of pregnant women receiving apremilast have not been conducted, incidences of malformations and fetal loss are currently not known. In studies in monkeys, administration of apremilast during organogenesis resulted in dose-related increases in abortion/embryo-fetal death at dose exposures of 2.1× MRHD (maximum recommended human therapeutic dose) and no adverse effects at exposure of 1.4×. Although it is not known whether apremilast or its metabolites are present in human milk, the drug was detected in the milk of lactating mice[1]. Fertility studies in male mice detected no adverse effects; in female mice, estrous cycles were prolonged (at higher doses) and those mice that became pregnant had an increased incidence of early postimplantation loss[1].

Drug Interactions

Coadministration of apremilast with potent CYP450 inducers including rifampin, phenobarbital, carbamazepine, and phenytoin may significantly diminish apremilast levels and should be avoided (see Ch. 131).

AZATHIOPRINE

Azathioprine was developed in 1959 from its parent drug 6-mercaptopurine (6-MP). After its anti-inflammatory and immunosuppressive effects were noted, dermatologists began to utilize azathioprine for the treatment of inflammatory diseases. With its moderately potent immunosuppressive and anti-inflammatory effects, azathioprine has a reasonable risk–benefit profile. However, it should be reserved for serious, life-threatening or recalcitrant dermatoses after other therapies have failed.

Azathioprine (Imuran®, Azasan®, Azamun™) has an 88% bioavailability. Immediately after absorption, it is converted to 6-MP and subsequently processed through three different, competing pathways (Fig. 130.5). When 6-MP is catabolized via two of these metabolic pathways, by either xanthine oxidase or thiopurine methyltransferase (TPMT), inactive metabolites result. Active metabolites, such as the purine analogue thioguanine monophosphate and others, are produced from the third and only anabolic pathway via hypoxanthine-guanine phosphoribosyl transferase (HGPRT)[13]. Should either the xanthine oxidase or TPMT catabolic pathway be blocked, more 6-MP will be shunted through the anabolic HGPRT pathway, leading to more active metabolites; excessive immunosuppression and pancytopenia may result[13].

The TPMT pathway is important because enzyme activity varies based upon genetic polymorphisms[14], and evaluating enzyme activity helps to guide dosing parameters. When TPMT activity within red blood cells (RBCs) is measured, which mirrors systemic activity, three subsets are identified – high, intermediate, and low activity (Table 130.6). Azathioprine should be avoided in patients with *low* activity because of the risk of accumulating metabolites which could increase the risk of severe myelosuppression. Underdosing is possible in those with *high* enzyme levels and the dosage may need to be titrated upwards. Although TPMT activity may vary somewhat between different laboratories and within different batches of the same test kit, knowledge of baseline TPMT activity is clinically useful in most patients.

Ethnic variations at the *TPMT* locus have also been described, with certain mutations unique to particular ethnic groups[14]. However, given the diversity of ethnicities, one should not profile a specific group as a means of predicting TPMT activity. Rather, the functional enzyme assay should be utilized prior to initiating azathioprine.

Although decreased xanthine oxidase activity is rarely due to genetic polymorphisms, this enzyme is inhibited by the medications allopurinol and febuxostat (see Fig. 130.5). Azathioprine dosage should be decreased by 75% in patients receiving allopurinol or febuxostat.

Mechanism of Action

6-Thioguanine, the active metabolite of azathioprine, is a purine analogue similar in structure to both adenine and guanine. Instead of an amino or hydroxyl group, it contains a thiol moiety. Incorporation of 6-thioguanine into DNA and RNA inhibits purine metabolism and cell division. 6-Thioguanine has other activities which are not well understood, such as suppression of T cell function and B cell antibody production[15]. It also decreases the number of Langerhans cells in the skin and inhibits their ability to present antigens[16].

Dosages

Available in 25, 50, 75, and 100 mg tablets, *empiric* dosing is generally started at 50 mg/day and increased to a maximum of 2.5 mg/kg/day according to clinical efficacy and careful monitoring. Maximum doses based on baseline TPMT determination are outlined in Table 130.6. In either case, renal insufficiency dictates dose reduction (see Table 130.3). Baseline evaluation should include a complete medication history because of adverse effects when azathioprine is used concomitantly with allopurinol, febuxostat, captopril, or warfarin (see below). Monitoring guidelines are outlined in Table 130.3.

Major Side Effects

Major side effects are related to the immunosuppressive effects of azathioprine (see Table 130.5). Pancytopenia occurs rarely, particularly when doses are based on TPMT activity. Patients may be at increased risk for malignancies, especially lymphoproliferative disorders and squamous cell carcinomas of the skin and female genitourinary tract, and should be monitored accordingly. Factors influencing a patient's malignancy risk include degree and duration of immunosuppression, skin phototype, and existing comorbidities.

Azathioprine may rarely cause a life-threatening hypersensitivity reaction. It most commonly develops during the first month of therapy and when there is concurrent use of either cyclosporine or methotrexate. The cutaneous eruption is typically morbilliform with areas of confluence. Other components of the syndrome include fever, respiratory and gastrointestinal distress, hepatotoxicity, and possible cardiovascular collapse. This hypersensitivity reaction represents an absolute contraindication as re-exposure may lead to cardiovascular collapse. Azathioprine can also induce the triad of pancreatitis, polyarthritis, and panniculitis, referred to as PPP syndrome.

Indications

Although azathioprine has FDA approval for non-dermatologic uses only, dermatologists have been using this drug for decades to treat severe dermatologic conditions, most often as a corticosteroid-sparing agent in the treatment of immunobullous diseases, chronic actinic dermatitis, and various subtypes of cutaneous vasculitis[15,17]. It is inexpensive and has moderate immunosuppressive and anti-inflammatory effects. Clinical benefit of the drug may not be apparent until it has been administered for at least 4 to 6 weeks.

DOSING OF AZATHIOPRINE AS DETERMINED BY BASELINE THIOPURINE METHYLTRANSFERASE (TPMT) ACTIVITY	
TPMT activity (U/ml)	**Maximum dose of azathioprine (AZA)**
Low: <6.3	AZA contraindicated
Intermediate: 6.3–15	Up to 1 mg/kg/day
High: 15.1–26.4	Up to 2–2.5 mg/kg/day

Table 130.6 Dosing of azathioprine as determined by baseline thiopurine methyltransferase (TPMT) activity. Doses are based upon *actual* weight. U, units. Adapted from reference 13.

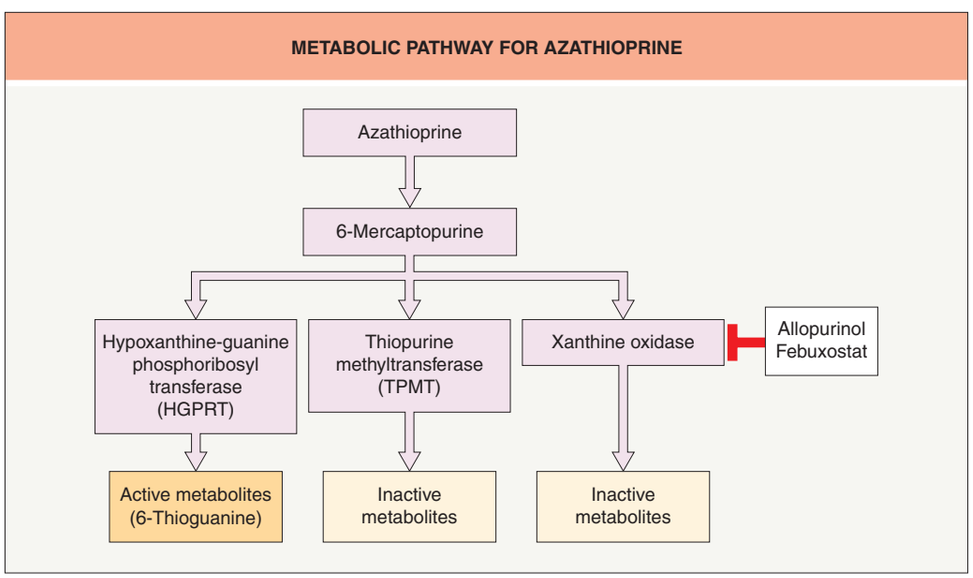

Fig. 130.5 Metabolic pathway for azathioprine. Either decreased activity of TPMT or inhibition of xanthine oxidase by allopurinol or febuxostat can lead to shunting of 6-mercaptopurine to the HGPRT pathway. As a result of this shunting, there is an increase in active metabolites and an increased risk of toxicity. Azathioprine dosage should be decreased by 75% in patients receiving allopurinol or febuxostat. *Adapted from Wolverton SE. Comprehensive Dermatologic Drug Therapy, 4th edn. Philadelphia: Saunders, 2020.*

Contraindications

Absolute contraindications to azathioprine therapy include history of a hypersensitivity reaction, as re-challenge may prove fatal. Active serious infections and pregnancy are relative contraindications. Concomitant use of allopurinol or febuxostat requires dose reduction of azathioprine (see above) or selection of an alternative medication.

Use in Pregnancy and Lactation

Azathioprine may be associated with preterm delivery, low-birth-weight infants, sporadic anomalies, and hematologic toxicities. Even though it is considered relatively safe for use in transplant patients who become pregnant, for dermatologic purposes it should not be prescribed during pregnancy. Azathioprine may be compatible with breastfeeding, but it is recommended that patients wait for four hours after medication ingestion to initiate breastfeeding and to monitor complete blood counts in breastfed infants. There is no recommendation for male patients to discontinue azathioprine when trying to conceive with their partner; data regarding effects on female fertility are limited[1].

Drug Interactions

Inhibition of xanthine oxidase by allopurinol or febuxostat (see Fig. 130.5) increases the risk of pancytopenia in azathioprine-treated patients. Captopril may increase the risk of leukopenia. Azathioprine can decrease the effectiveness of warfarin and pancuronium, necessitating larger doses of these drugs. Since azathioprine may decrease the effectiveness of intrauterine contraceptive devices, alternative birth control methods should be employed.

BLEOMYCIN

The dosage, uses, and side effects are outlined in Table 130.7.

CLOFAZIMINE

The dosage, uses, and side effects are outlined in Table 130.8.

COLCHICINE

The dosage, uses, and side effects are outlined in Table 130.9.

CYCLOPHOSPHAMIDE

Cyclophosphamide (Cytoxan®) was derived from mechlorethamine (nitrogen mustard) in 1958; the latter was combined with phosphoric acid in an effort to make an inert drug capable of entering and releasing active mechlorethamine within target cells[18]. It has ~75% oral bioavailability, peaks in the plasma at about 1 hour, and crosses the blood–brain barrier. Cyclophosphamide itself is inactive, but it is metabolized by CYP enzymes into the active metabolite 4-hydroxy-cyclophosphamide (nornitrogen mustard; $t_{1/2}$ = 3.3 hours), which may then be converted into the other active metabolite phosphoramide mustard ($t_{1/2}$ = 9 hours). Metabolites are excreted primarily via the kidney (50%). The inactive metabolite acrolein is believed to cause hemorrhagic cystitis and associated transitional cell carcinoma of the bladder[19].

BLEOMYCIN
Source: *Streptomyces verticillus* **Mechanism of action**: inhibits DNA synthesis in infected keratinocytes, but no direct effect on the human papillomavirus **Dermatologic use**: intralesional treatment of therapy-resistant verrucae vulgaris; 65%–80% of lesions clear after 1 to 2 injections **Dosage**: 0.1 to 0.3 ml of 1 U/ml (of saline) injected into targeted lesions, with maximum total dose per treatment = 2 ml; repeated every 3 to 6 weeks until resolution; given its rapid degradation and expense, newly constituted solution should be divided into glass vials and can be stored at 2–8°C for ~3 months **Side effects of intralesional administration**: injection is extremely painful (local or regional anesthesia may be required); pain and burning postinjection for 2–3 days; Raynaud phenomenon occasionally; nail dystrophy; flagellate dermatitis (above recommended total dose); no systemic toxicity with recommended total dose **Contraindications:** pregnancy, immunosuppression, vascular compromise **Pregnancy and lactation**: not recommended; formerly pregnancy prescribing category D

Table 130.7 Bleomycin. Case reports of its use for keloids, hypertrophic scars, keratinocyte carcinomas, and vascular tumors (e.g. hemangiomas).

Mechanism of Action

Cyclophosphamide is an alkylating agent that functions in a cell cycle-independent fashion. Although its major effect is suppression of B cell function, it also suppresses T cell function (especially of regulatory

CLOFAZIMINE
Drug properties: riminophenazine dye (red color) **Mechanism of action**: disrupts cell membranes (activation of phospholipase A_2 leads to generation of membrane-destabilizing lysophospholipids); enhances superoxide production; inhibits neutrophil motility and lymphocyte proliferation **Dermatologic use**: treatment of multibacillary Hansen disease (leprosy), other infections (mycobacterial, malacoplakia, rhinoscleroma), and inflammatory skin diseases including neutrophilic dermatoses (pyoderma gangrenosum, Sweet syndrome), granuloma faciale, orofacial granulomatosis, erythema dyschromicum perstans, and discoid LE **Dosage**: 50–400 mg orally daily*; avoid long-term administration of >200 mg daily; see Table 75.5 for leprosy regimens **Side effects**: discoloration of skin† (red to red–brown diffusely, bluish to violet–brown in lesional sites), cornea/conjunctiva, and body fluids (urine, sweat, tears); xerosis/ichthyosis; gastrointestinal symptoms (abdominal pain, nausea, vomiting, diarrhea); ocular irritation; elevated hepatic enzymes; crystal deposition-related enteropathy (rarely); cardiac arrhythmias (rarely; associated with electrolyte disturbances) **Monitoring guidelines**: baseline electrolyte panel; periodic LFTs if daily doses >100 mg; periodic evaluation for GI side effects and skin discoloration **Contraindications**: prior hypersensitivity reaction **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy and lactation (concentrated in breast milk) *Larger doses are usually divided into two to four times daily. †Due to deposits of drug within fat and macrophages.

Table 130.8 Clofazimine. LE, lupus erythematosus; LFTs, liver function tests.

COLCHICINE
Source: alkaloid from *Colchicum autumnale* (autumn crocus) **Mechanism of action**: prevents microtubule assembly, resulting in mitotic arrest at metaphase and inhibition of cellular motility; decreases neutrophil chemotaxis, adhesion, and degranulation **Dermatologic use**: treatment of neutrophilic dermatoses (Behçet disease, Sweet syndrome), cutaneous small vessel vasculitis, neutrophil-rich autoimmune bullous diseases (EBA, linear IgA bullous dermatosis), and aphthous stomatitis **Dosage**: 0.5 or 0.6 mg orally two to three times daily; drug must be shielded from light (degraded by UVR) **Side effects**: commonly, gastrointestinal symptoms (diarrhea, abdominal pain, nausea, vomiting; dose-related); occasionally, alopecia, peripheral neuropathy, myopathy, and bone marrow suppression (with prolonged therapy*); multiorgan failure with acute overdose† **Monitoring guidelines**: baseline CBC, CMP, and UA; repeat CBC monthly for first several months then every 3–6 months **Contraindications**: prior hypersensitivity reaction; severe renal, hepatic, gastrointestinal, or cardiac disease; blood dyscrasias **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy; excreted in breast milk, but use during lactation allowed per AAP recommendations *Particularly in patients with renal insufficiency. †A toxic epidermal necrolysis-like reaction has been described.

Table 130.9 Colchicine. In patients with renal or hepatic impairment on colchicine, P-glycoprotein and strong CYP3A4 inhibitors should be avoided. AAP, American Academy of Pediatrics; CBC, complete blood count with differential and platelet count; CMP, comprehensive metabolic panel (includes liver function tests); EBA, epidermolysis bullosa acquisita; UA, urinalysis; UVR, ultraviolet radiation.

T cells). Clearly, the T cell effects are greatest if the drug is given prior to antigen presentation. Cyclophosphamide crosses the nuclear membrane, covalently binds with DNA, and inhibits the synthesis of guanine, cytosine, and adenine. Cytotoxicity occurs by several mechanisms: (1) DNA cross-linking with various proteins or other DNA strands; (2) G-C → A-T substitution; and (3) depurination resulting in chain scission. These mechanisms can overwhelm the DNA repair mechanisms, inducing cell death[18].

Dosages

Cyclophosphamide is available in 25 and 50 mg tablets. Doses range from 1 to 3 mg/kg/day, either as a single morning dose or in equally divided doses. Dermatologic diseases seldom require more than 2 to 2.5 mg/kg/day of cyclophosphamide. Dose reduction is necessary in patients with hepatic or renal dysfunction. Because of the risk of hemorrhagic cystitis, patients should be advised to always consume plenty of fluids. A monthly intravenous infusion (pulse) of 500 to 1000 mg has been used to treat a number of rheumatologic disorders, including severe SLE. Nowadays, monthly IV administration is favored over chronic daily use because of a reduced risk of side effects including bladder toxicity.

Prior to prescribing cyclophosphamide, patients should have a documented white blood count (WBC) of >4500/mm^3 and a granulocyte count of >1500/mm^3. If the counts are lower and there is no alternative drug, then consultation with a hematologist is recommended. Laboratory monitoring guidelines are outlined in Table 130.3. Of note, it is not necessary to induce significant myelosuppression in order to achieve immunosuppression[19].

Major Side Effects

The most common side effects from cyclophosphamide treatment are hematologic and gastrointestinal (see Table 130.5). Dermatologic side effects include anagen effluvium (5%–30%, typically reversible), pigmented bands of the teeth (irreversible), diffuse cutaneous hyperpigmentation, transverse ridging and hyperpigmentation of nails, acral erythema, and, rarely, Stevens–Johnson syndrome. Up to 40% of patients have hemorrhagic cystitis, presumably from the acrolein metabolite, which is associated with a 10-fold increase in the risk for transitional cell carcinoma of the bladder. This risk is greater in patients who receive chronic "low-dose" cyclophosphamide (as traditionally given for dermatologic diseases) than in those exposed to brief courses of high-dose pulse therapy (as given for systemic lymphomas and SLE). Immunosuppression is significant, especially in patients concomitantly receiving systemic corticosteroid therapy. Infection and malignancy risks are real with appropriate monitoring recommended. Long-term or high-dose therapy may be associated with infertility in either sex[15].

Indications

Although cyclophosphamide is only FDA-approved for use in advanced mycosis fungoides and hematopoietic malignancies, it can be useful in treating a variety of severe cutaneous diseases. Cyclophosphamide has been regularly used to treat systemic vasculitides, in particular granulomatosis with polyangiitis and severe eosinophilic granulomatosis with polyangiitis, while it represents second-line therapy for polyarteritis nodosa and microscopic polyangiitis[19]. In the future, administration of rituximab or avacopan may lead to a reduction in its use for ANCA-related vasculitides. Cyclophosphamide can also be employed as a corticosteroid-sparing agent in a variety of severe mucocutaneous diseases or as monotherapy after corticosteroids are discontinued. In particular, cyclophosphamide plus corticosteroids can be used to treat mucous membrane (cicatricial) pemphigoid, especially when there is rapidly progressive or severe ocular involvement.

Contraindications

Absolute contraindications are pregnancy, lactation, depressed bone marrow function, and hypersensitivity to the drug. Cyclophosphamide-allergic patients may have cross-reactions with chlorambucil or mechlorethamine. Relative contraindications include active infections and significantly impaired hepatic or renal function.

Use in Pregnancy and Lactation

Cyclophosphamide is a first-trimester teratogen and is immunosuppressive in breastfed infants. It should not be used during pregnancy or lactation[9]. There is a high rate of permanent azoospermia; therefore cryopreservation of sperm may be necessary before treatment[1]. The risk of infertility in females is related to cumulative dose and patient age[1]; consultation with a reproductive endocrinologist prior to initiating therapy is recommended to discuss oocyte, embryo, and ovarian tissue cryopreservation.

Drug Interactions

Allopurinol, cimetidine, and chloramphenicol may elevate cyclophosphamide drug levels and produce toxicity (via CYP450 interactions), whereas barbiturates may enhance conversion to inactive metabolites. Digoxin absorption may be decreased. Cyclophosphamide may enhance the effect of succinylcholine, increase the cardiotoxicity of doxorubicin, and cause additive immunosuppressive and carcinogenic effects with other immunosuppressive drugs. Unpredictable effects can be seen when used with the inhalation anesthetics halothane and nitrous oxide.

CYCLOSPORINE

Cyclosporine, a cyclic peptide of 11 amino acids, was isolated from the soil fungus *Tolypocladium inflatum* in 1970 and was found to have clinical immunosuppressive effects in 1976. In 1979, during a rheumatoid arthritis trial, it was discovered that cyclosporine improved cutaneous psoriasis in patients with psoriatic arthritis. Two forms are available, the original preparation (Sandimmune®) and a predigested microemulsion (Neoral®) that is more completely and consistently absorbed. The latter is available as capsules (25 and 100 mg) or as an oral solution (100 mg/ml)[20]. The solution can be mixed in orange juice or apple juice, but grapefruit juice should be avoided because it alters cyclosporine's metabolism (see Fig. 131.4).

Bioavailability of the microemulsion is not known, but it yields 40%–106% higher peak blood levels than the original formulation. Cyclosporine is both metabolized by the CYP3A4 pathway and is a CYP3A4 inhibitor; primary excretion is via bile and feces. Only 6% of cyclosporine is excreted unchanged in the urine. Drug levels (11-hour trough level) can be measured but the therapeutic range is relatively wide; determinations are helpful when drug–drug interactions or non-compliance are a concern.

Mechanism of Action

T cell receptor activation causes release of intracellular calcium that in turn binds calmodulin and activates calcineurin (see Ch. 129). This calcineurin complex dephosphorylates the nuclear factor of activated T cells ($NFAT_c$) which is present within the cytoplasm, allowing it to migrate into the nucleus and bind with its intranuclear counterpart $NFAT_n$. This complex is a transcription factor for inflammatory cytokines such as IL-2. IL-2 receptors are also upregulated as a result of this process.

Cyclosporine binds to cyclophilin, a member of the family of intracytoplasmic proteins called immunophilins. This complex blocks the dephosphorylation of $NFAT_c$ and the subsequent upregulation of IL-2 and IL-2 receptors, resulting in a reduction of $CD4^+$ and $CD8^+$ (cytotoxic) T cells in the epidermis[15,20].

Dosages

Cyclosporine is best used on a short-term basis (<6–12 months) to control flares of psoriasis relatively quickly and to provide an alternative to the patient's current regimen (see Ch. 8). However, safety has been documented in psoriasis patients receiving therapy for up to 2 years[21]. It is reasonable to use cyclosporine as sequential therapy with acitretin, methotrexate, or other systemic agents such as systemic immunomodulators ("biologics"). After psoriasis clearance has been initiated by cyclosporine, the alternative medicine may be started and advanced to the therapeutic dose. At the same time, cyclosporine may be weaned by 1 mg/kg/day each month until the patient is maintained on the

alternate systemic agent. Historically, the maximum dermatologic dose for cyclosporine is 5 mg/kg/day, although a maximum dose of 4 mg/kg/day of the microemulsion formulation should be considered, given its greater bioavailability. The dose for obese patients is based on ideal body weight.

For psoriasis patients with a severe flare or recalcitrant disease, cyclosporine may be initiated at the maximum dosage until significant disease resolution occurs. The dose is then tapered by 1 mg/kg/day every 2 weeks until the minimum effective maintenance dose is determined. For most patients with more moderate disease, therapy should be initiated at 2.5 mg/kg/day and increased by 0.5 to 1 mg/kg/day every other week until clinical improvement is seen or a maximum dose of 4–5 mg/kg/day (depending upon the formulation) is reached. If no improvement is observed after 3 months at maximum dose, therapy has failed and should be discontinued[22,23].

Patients must be adequately monitored for the development of hypertension and laboratory abnormalities as outlined in Table 130.3. If the serum creatinine rises by >25% over baseline, the value should be rechecked within 2 weeks. If it returns to <25% over baseline, therapy can be continued at the current dose. However, if the elevation persists at that level, the dose should be decreased by 25%–50% for 1 month and then the serum creatinine rechecked. If it is still >25% above baseline, therapy should be discontinued until the serum creatinine is within 10% of the baseline value. At that time, restarting therapy may be considered, but at a significantly lower dose.

Major Side Effects

Cyclosporine is associated with a wide variety of adverse effects, including hypertension, renal dysfunction, hyperlipidemia, hyperkalemia, hyperuricemia, hypomagnesemia, hypertrichosis, and gingival hyperplasia (see Table 130.5). Most of the side effects associated with short-term therapy are reversible upon discontinuation of the drug. A quarter of all psoriasis patients on cyclosporine will develop hypertension, which is usually mild and manageable; calcium channel blockers of the dihydropyridine class are the recommended first-line antihypertensive agents. A direct vasoconstrictive effect of cyclosporine on the kidney vasculature is responsible for the development of hypertension short-term[24]. Hypertension due to cyclosporine is both time- and dose-related.

Modern, conservative dosing guidelines have prevented significant kidney damage in the vast majority of patients on short-term therapy. However, renal interstitial fibrosis has been demonstrated histologically even in the absence of abnormal laboratory tests in patients on appropriate dosing and monitoring regimens. Renal biopsy specimens from patients on long-term treatment demonstrate irreversible changes including renal tubular atrophy, arteriolar hyalinosis, glomerular obsolescence, and interstitial fibrosis[25,26]. In fact, all patients on cyclosporine for >2 years were shown to have some of these abnormalities.

Although transplant recipients on high doses and prolonged courses of cyclosporine have an increased risk of certain malignancies (e.g. lymphoma, cutaneous squamous cell carcinoma), patients with skin diseases on cyclosporine for less than 2 years and on lower "dermatologic" doses have not been observed to have a similar risk.

Indications

Cyclosporine can be beneficial for patients with psoriasis who have failed or cannot tolerate other therapies and for those with widespread, inflammatory disease. In fact, cyclosporine has FDA approval for three "types" of psoriasis: (1) severe; (2) recalcitrant; and (3) disabling. Patients with plaque-type psoriasis may also benefit from cyclosporine in rotating or sequential regimens with other modalities.

The use of cyclosporine in atopic dermatitis has been examined, and a high percentage of patients improve with therapy; unfortunately, most relapse within 4 weeks of discontinuation. Cyclosporine efficacy has been established in patients with severe pyoderma gangrenosum; however, some clinicians prefer cyclosporine for idiopathic pyoderma gangrenosum only, arguing that when there is a known underlying cause, therapy is best aimed at the latter (e.g. inflammatory bowel disease, myelodysplasia). Very short-term cyclosporine has been used for Stevens–Johnson syndrome and toxic epidermal necrolysis as well as other severe cutaneous adverse reactions such as DRESS (drug reaction with eosinophilia and systemic symptoms) and AGEP (acute generalized exanthematous pustulosis) with promising results[27]. Most other uses of cyclosporine are based upon anecdotal evidence[28].

Contraindications

Absolute contraindications include significant renal impairment, uncontrolled hypertension, and hypersensitivity to cyclosporine. Relative contraindications include age <18 years or >64 years, controlled hypertension, and medication usage that may interfere with cyclosporine metabolism or worsen renal function. Caution is necessary if used in patients with significant infections, recent live-virus vaccinations (see Table 128.9) or immunodeficiency syndromes, or in combination with methotrexate, phototherapy, or other immunosuppressive drugs.

Use in Pregnancy and Lactation

Cyclosporine is not associated with an increased risk of major fetal malformations when compared to the general population[1]. Use during pregnancy should be considered only in exceptional patients for whom the potential benefits dramatically outweigh the risks, with close monitoring of maternal blood pressure and renal function[1]. Cyclosporine is excreted into breast milk and should not be used during lactation, due to risks of immunosuppression and possible carcinogenesis in the breastfed infant[9]. There is no recommendation for male patients to discontinue cyclosporine while trying to conceive with their partner and limited data are available regarding impact on female fertility[1].

Drug Interactions

Drugs that interact with cyclosporine are discussed in Chapter 131. The clinician should review the patient's medication list for potential interactions using the following guidelines. In general, drugs that inhibit the CYP3A4 pathway will increase cyclosporine levels, while inducers of the 3A4 pathway will decrease the effectiveness of cyclosporine, due to lower serum levels. Some drugs will potentiate renal toxicity, such as nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, amphotericin B, and miscellaneous antibiotics (vancomycin, trimethoprim–sulfamethoxazole). Cyclosporine will reduce the renal clearance of digoxin, lovastatin, and prednisolone. Increased risk of hyperkalemia occurs with concurrent use of angiotensin-converting enzyme (ACE) inhibitors, potassium supplements, and potassium-sparing diuretics.

DAPSONE

Dapsone is a sulfone drug, and sulfones are related to the sulfonamide family. Sulfonamides were initially derived from coal tar in the early 1900s for use as fabric dyes. Medically, they were first demonstrated to be effective against streptococcal infections. Synthesized in 1908, dapsone was shown to be effective against tuberculosis and Hansen disease (leprosy). During the first half of the twentieth century, the related drugs sulfapyridine and sulfoxone were used to treat dermatitis herpetiformis (DH). However, since 1953, dapsone (the parent compound of sulfoxone) has been the mainstay of treatment for DH. Due to its activity in neutrophil-mediated dermatoses, dapsone has also proven useful in the treatment of several forms of autoimmune bullous diseases and vasculitis syndromes.

Dapsone is 80% orally bioavailable, peaks in the serum between 2 and 6 hours post-administration and has a half-life of 24–30 hours. Being highly lipophilic, it has excellent cell penetration. Dapsone and its major metabolite monoacetyldapsone are strongly protein-bound and undergo enterohepatic recirculation. Thus, dapsone may be found in the bloodstream up to 1 month following a single dose[29].

Dapsone is metabolized by *N*-acetylation and *N*-hydroxylation in the liver[29,30]. Acetylation yields monoacetyldapsone, which is then de-acetylated to dapsone, yielding an equilibrium between dapsone and monoacetyldapsone. Hydroxylation via CYP enzymes produces *N*-hydroxy-dapsone, the metabolite which is believed to be responsible for the majority of dapsone side effects. Both dapsone and *N*-hydroxy-dapsone undergo glucuronidation in the liver, which results in more water-soluble compounds that are rapidly excreted in the urine[29].

Mechanism of Action

Dapsone is clinically most useful in the treatment of dermatologic diseases involving neutrophilic infiltrates. Researchers have demonstrated that dapsone inhibits neutrophil myeloperoxidase, thus reducing damage from the neutrophil respiratory burst mediated by this enzyme. Furthermore, dapsone has been shown to inhibit neutrophil chemotaxis to *N*-formyl-methionyl-leucyl-phenylalanine (fMLP) and to interfere with the CD11b/CD18-mediated neutrophil binding that induces chemoattractant signal transduction. IgA adherence is also inhibited. It is of clinical interest that dapsone also inhibits eosinophil myeloperoxidase activity, and thus may be efficacious in diseases in which eosinophils have a central role in pathogenesis, such as eosinophilic cellulitis[30].

Dosages

Dapsone is available in 25 and 100 mg tablets. The initial dose is often 50 mg/day in a single dose. Most conditions require 50–200 mg/day for adequate control of symptoms; rarely are dosages up to 300 mg/day required. In those with DH who respond to dapsone, rapid resolution of symptoms (within 48 hours) is usually noted; conversely, symptoms flare relatively rapidly after discontinuing therapy. Patients must be strictly warned against self-adjustment of the dosage, due to dose-dependent side effects.

Because of potential adverse effects, any cardiopulmonary or neurologic symptoms should be assessed prior to therapy. Documentation of peripheral motor nerve function may occasionally be necessary before or during therapy. Table 130.3 outlines monitoring guidelines for therapy. The clinician must be aware of all signs and symptoms associated with methemoglobinemia and peripheral neuropathy to ensure proper monitoring.

Major Side Effects

Serious systemic side effects of dapsone may be idiosyncratic or pharmacologic. The pharmacologic and dose-dependent adverse effects include methemoglobinemia and hemolytic anemia (see Table 130.5). Agranulocytosis, peripheral motor neuropathy, and dapsone hypersensitivity are idiosyncratic reactions; however, patients on higher daily doses or long-term therapy may be more likely to develop a peripheral motor neuropathy. Although rare, dapsone hypersensitivity syndrome may be fatal. Patients present with fever, hepatitis, and a generalized cutaneous eruption. Cutaneous reactions range from an exanthematous eruption to toxic epidermal necrolysis (TEN). Liver failure has occurred in patients with the dapsone hypersensitivity syndrome[31], and hypothyroidism may develop following resolution of the acute eruption. Thus, there is significant overlap with DRESS/DIHS (drug reaction with eosinophilia and systemic symptoms/drug-induced hypersensitivity syndrome). In particular, HLA-B*13:01 has been associated with dapsone-related DRESS in Chinese populations and its incidence can be reduced via screening prior to therapy[32].

Indications

Dapsone works well in a number of neutrophilic dermatoses and immunobullous diseases. Although only FDA-approved for DH, dapsone is very useful in linear IgA bullous dermatosis, bullous eruption of SLE, erythema elevatum diutinum, mucous membrane (cicatricial) pemphigoid, and perhaps cutaneous small vessel vasculitis[29,30]. It is also a key component of combination therapy for Hansen disease.

Contraindications

The absolute contraindication to dapsone therapy is prior hypersensitivity to dapsone. Relative contraindications include a low glucose-6-phosphate dehydrogenase (G6PD) level, significant cardiopulmonary disease, and allergy to sulfonamide antibiotics (because of possible cross-reactivity). In patients with low G6PD levels, there is an increased risk for oxidative stress of the dapsone metabolites on RBCs. Those with significant cardiopulmonary disease may not tolerate the methemoglobinemia and hemolysis induced by dapsone.

Use in Pregnancy and Lactation

Dapsone does not appear to present a major risk to the fetus; however, it should only be used during pregnancy if the benefits clearly outweigh the risks. There have been publications reporting its use in pregnant patients with Hansen disease. Dapsone is found in breast milk and can cause hemolytic anemia in breastfed infants; however, it is approved by the American Academy of Pediatrics for use during lactation when required, as in patients with Hansen disease[9].

Drug Interactions

Drugs that may increase dapsone levels (and side effects) are probenecid (via decreased renal clearance), trimethoprim, and other folate antagonists such as methotrexate. Sulfonamides and hydroxychloroquine increase the oxidative stress on RBCs and may worsen hemolysis. Dapsone levels may be reduced by activated charcoal, para-aminobenzoic acid (PABA), and rifampin. Although cimetidine can increase absolute levels of dapsone, the former leads to a reduction in the more toxic hydroxylamine metabolite, and thus the end result is a lower level of methemoglobin.

HYDROXYUREA

The dosage, uses, and side effects are outlined in Table 130.10.

LEUKOTRIENE (LT) INHIBITORS

Initially identified as the slow-reacting substance of anaphylaxis, leukotrienes play a key role in systemic and cutaneous inflammatory reactions[33]. Primarily used for the treatment of asthma, leukotriene inhibitors have been explored in a myriad of dermatologic conditions, including atopic dermatitis, urticaria, autoimmune bullous diseases, and Sjögren–Larsson syndrome[33]. These inhibitors include montelukast

HYDROXYUREA
Formulation: Hydrea®; 100% bioavailable; renal excretion: 80%; accumulates preferentially in leukocytes > erythrocytes; can cross blood–brain barrier
Mechanism of action: inhibits M_2 subunit of ribonucleotide reductase thereby blocking DNA synthesis; cells are arrested in G_2 phase and unable to repair UV- and ionizing radiation-induced damage; also causes gene hypomethylation, inducing differentiation and normalization of psoriatic skin; resistance may arise via increased levels of ribonucleotide reductase or alteration of the enzyme
Dermatologic use: maintenance therapy of psoriasis after control with another drug or phototherapy, but ineffective in psoriatic arthritis; lymphocytic hypereosinophilic syndrome unresponsive to corticosteroids
Dosage: 20–30 mg/kg/day in divided doses, with a maximum of 2 g/day; average dose: 1–2 g/day
Side effects: megaloblastosis (all patients), with 10%–35% developing anemia (see Table 130.5); rarely, leukopenia, thrombocytopenia, or transient reversible hepatitis with an acute "flu-like" syndrome; ulcers of the distal lower extremity (Fig. 130.6A); diffuse cutaneous hyperpigmentation and mucosal pigmentation (Fig. 130.6B); dermatomyositis-like eruption on dorsal hands, keratinocyte carcinomas
Monitoring guidelines: baseline CBC, CMP, UA, and pregnancy test for women of childbearing potential then CBC weekly until stable and then monthly; CMP and UA monthly until stable then every 3–6 months; a drop in HGB of 1–2 g should be expected; discontinue hydroxyurea if: HGB declines by more than 3 g, WBC drops to <3500–4000 cell/mm^3, or PLT to <100 000/mm^3
Contraindications: *absolute* – hypersensitivity to drug; *relative* – blood dyscrasias; infections; cardiac, renal, or pulmonary disease; unstable/fulminant psoriasis; concomitant use of cytarabine
Pregnancy and lactation: known teratogen; not to be used during pregnancy or lactation. Potentially irreversible decreased sperm motility and spermatogenesis in male fertility studies; limited data on impact on female fertility[1]

Table 130.10 Hydroxyurea. CBC, complete blood count with differential and platelet count; CMP, comprehensive metabolic panel (includes liver function tests); HGB, hemoglobin; UA, urinalysis; WBC, white blood count.

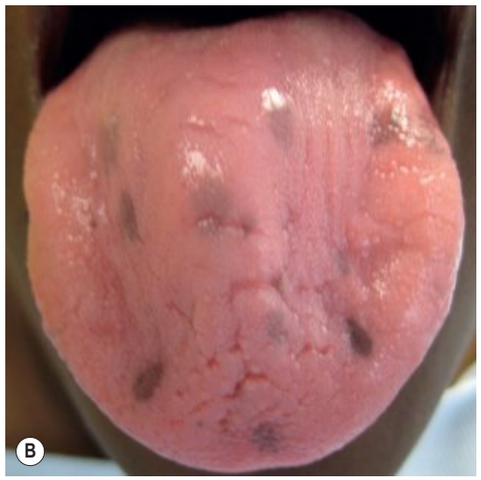

Fig. 130.6 Hydroxyurea-induced mucocutaneous changes. A Lower extremity ulcerations. **B** Hyperpigmentation of the oral mucosa. *B, Courtesy Brian Horvath, MD.*

(Singulair®), zafirlukast (Accolate®), and pranlukast (Ultair®), which block LTC_4, LTD_4 and LTE_4, as well as zileuton (Zyflo CR®) which inhibits 5-lipoxygenase (Table 130.11)[33].

LEUKOTRIENE INHIBITORS
Mechanisms of action: antagonists of cysteinyl leukotriene receptors (block LTC_4, LTD_4 & LTE_4 binding) – montelukast (Singulair®), pranlukast (Ultair®), zafirlukast (Accolate®); inhibitor of 5-lipoxygenase – zileuton (Zyflo CR®)
Dermatologic uses: limited evidence for atopic dermatitis, autoimmune bullous diseases, urticaria, Sjögren–Larsson syndrome; primary use is asthma
Dosages*: montelukast – 10 mg [adults], 5 mg [children 6–14 years]; pranlukast – 225 mg BID [adults], 7 mg/kg/day [children]; zafirlukast – 20 mg BID [adults & adolescents], 10 mg BID [5–12 years] on empty stomach; zileuton – 1200 mg BID [adults & adolescents] with meals
Side effects: indigestion, nausea, myalgias, headaches, hepatitis; montelukast, pranlukast, and zafirlukast have been associated with the development of eosinophilia and eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome), usually in the setting of a taper of corticosteroids
Contraindications: prior hypersensitivity reaction to drug; significant liver disease
Monitoring guidelines: zafirlukast – LFTs every 2–3 months; zileuton – baseline LFTs, monthly LFTs for 2–3 months and then every 2–3 months
Pregnancy and lactation: montelukast and zafirlukast most likely compatible; zileuton limited data so harm cannot be assessed
Drug interactions: zileuton may increase circulating levels of propranolol, theophylline, terfenadine, or warfarin; zafirlukast may increase circulating levels of warfarin; aspirin or erythromycin may decrease plasma level of zafirlukast; phenobarbital may reduce levels of montelukast
*Oral.

METHOTREXATE

The effectiveness of the folic acid analogue methotrexate (MTX) in psoriasis was noted in the early 1950s, but remained without FDA approval until the 1960s. MTX is not difficult to use and oral administration achieves reliable blood levels unaffected by food intake. MTX is widely distributed throughout the body but penetrates the blood–brain barrier poorly.

Within 1 hour of ingestion, distribution and active cellular uptake is complete. Plasma MTX is 50% protein-bound, and irreversibly bound to dihydrofolate reductase, the enzyme it inhibits. By 4 hours, the kidneys have excreted the plasma portion of the drug[34]. Over the next 10–27 hours, the drug is slowly released from body tissues.

Mechanism of Action

Dihydrofolate reductase (DHFR) converts dihydrofolate to tetrahydrofolate (fully reduced folic acid; see Fig. 127.6), which is a necessary cofactor in the synthesis of thymidylate and purine nucleotides, which, in turn, are required for DNA/RNA synthesis. MTX competitively inhibits DHFR, although this inhibition can be at least partially reduced by concomitant folic acid administration. MTX also exerts partially reversible inhibition downstream on thymidylate synthetase, inhibiting cell division during the S phase[15].

Although originally believed to suppress keratinocyte proliferation, it is more likely that MTX inhibits DNA synthesis in immunologically active cells. MTX decreases inflammation through other mechanisms as well. For example, by inhibiting aminoimidocarboxyamido-ribonucleotide transformylase, MTX increases local tissue concentrations of the potent anti-inflammatory mediator adenosine. By inhibiting methionine synthase, MTX reduces production of the proinflammatory mediator S-adenyl methionine[35].

Dosages

MTX is administered as a once-weekly dose of up to 30 mg for dermatologic and rheumatologic diseases. Oncologists may prescribe 20–40 mg/m^2 every 1 to 4 weeks with folinic acid rescue. Historically, MTX was administered in three doses over 24 hours (8 a.m. and 8 p.m. day 1, and 8 a.m. day 2). There were theoretical advantages for the divided dosing regimen from a cell cycle kinetics standpoint. However, since the clinical result is the same, a single dose, which is easier and less confusing (for the patient and the pharmacist), is currently recommended. The patient should be admonished to adhere to the dosing schedule religiously, as more frequent dosing is much more likely to produce major hematologic complications and potentially an increased risk of liver fibrosis. Because absorption of oral MTX in doses >15 mg may be impaired, the weekly dose can be split into two administrations in patients requiring higher doses. Parenteral administration (intramuscular or subcutaneous) is available for patients who cannot tolerate oral MTX and has also been advocated by some clinicians for use in erythrodermic patients who may have decreased gastrointestinal absorption or when compliance is an issue. Also, in addition to a lower incidence of gastrointestinal side effects, subcutaneous MTX may be more efficacious. Use of intralesional MTX is reviewed in Chapter 108.

Available in 2.5 mg tablets, therapy may begin with a test dose of 2.5–5 mg followed one week later by a CBC with platelet count and hepatic profile. This test dose may be considered in higher risk patients (e.g. reduced renal function, hyperlipidemia, potential drug–drug interactions)[36]. In low-risk patients, treatment may be started at 10 to 15 mg weekly and gradually increased by 2.5 to 5 mg every 2–4 weeks until satisfactory results are obtained with minimal toxicity. For parenteral administration, both prefilled syringes (7.5, 10, 15, 20, 25 mg) and a 2 ml vial (25 mg/ml) are available.

Laboratory monitoring – CBC with platelet count and hepatic profile – can be done 1–3 weeks after initiation and following each dose escalation (see Table 130.3). Once disease control has been attained for at least 1–2 months, the MTX can be tapered by 2.5 mg every 1–2 weeks to the lowest dose that still maintains disease control. The usual weekly dose for psoriasis is 10–15 mg, although doses up to 25 mg per week are not uncommonly used, except in patients with renal insufficiency.

RISK FACTORS FOR DEVELOPING HEPATIC TOXICITY FROM METHOTREXATE
• Persistent abnormal liver function tests
• History of liver disease, including chronic hepatitis B or C viral infections
• Previous or concurrent excessive alcohol intake
• Family history of inheritable liver disease
• Diabetes mellitus
• Obesity
• Hyperlipidemia
• History of significant exposure to hepatotoxic drugs or chemicals
• Lack of folate supplementation

Table 130.12 Risk factors for developing hepatic toxicity from methotrexate. Adapted from reference 33.

Major Side Effects

The most important side effects of MTX include pancytopenia and hepatotoxicity (see Table 130.5). Pancytopenia typically develops early, compared to hepatic fibrosis and cirrhosis, which may take years to develop and are related to higher cumulative doses. Risk factors for hepatotoxicity are well established (Table 130.12). Before prescribing MTX, references discussing this issue in detail should be reviewed[34] and consultation with a hepatologist considered for patients with risk factors.

While the gold standard for detection of hepatic fibrosis remains liver biopsy, this invasive procedure harbors risks and is no longer routinely performed prior to initiating MTX (see Table 130.3). Both a panel of serum biomarkers and imaging studies can be performed to assess liver fibrosis (Table 130.13)[36,38]. Screening algorithms for assessing methotrexate hepatotoxicity have also been developed (Fig. 130.7) and take into account whether patients have risk factors for hepatotoxicity (see Table 130.12).

Photosensitivity may occur with MTX and patients should take appropriate sun precautions (see Ch. 21)[15]. Gastrointestinal intolerance is often abated with concomitant folic acid therapy (1–5 mg orally daily, based on symptoms). Other MTX-induced side effects include accelerated rheumatoid (cutaneous) nodulosis and reversible lymphoproliferative disorders. When used in very high doses, MTX may cause reversible oligospermia[34].

Drug Indications

MTX has FDA approval for use in psoriasis; however, it is used primarily for those individuals with severe, debilitating, or recalcitrant disease. Other disorders that respond to MTX include dermatomyositis and lymphomatoid papulosis. Of note, pityriasis rubra pilaris commonly requires up to twice the typical psoriasis dose, whereas PLEVA often responds to small MTX doses (2.5–5 mg/week). Methotrexate can also be used as a "steroid-sparing" agent, and in the elderly, monotherapy with weekly MTX is an option for the treatment of bullous pemphigoid.

Contraindications

Absolute contraindications to MTX are pregnancy and lactation. Relative contraindications include significant liver disease, elevated liver enzymes, and excessive alcohol intake. The presence of active infection or immunodeficiency, and the desire for imminent pregnancy are relative contraindications to MTX therapy. Caution is indicated and significant dose reduction necessary if used in patients with decreased renal function. In the elderly, serum creatinine levels may be deceptively low and not reflect true renal function.

Use in Pregnancy and Lactation

MTX is an abortifacient and teratogen and should not be used during pregnancy. The American Academy of Pediatrics considers MTX to be contraindicated in breastfeeding owing to concerns of immune suppression, growth retardation, and carcinogenesis[9]. Both female and male patients should discontinue MTX for at least three months before attempting to conceive[1].

SELECTED METHODS OF MONITORING FOR HEPATIC FIBROSIS	
Biochemical markers (+/– age, sex)	
Benefits: only requires serum sample; good inter-laboratory reproducibility	
Limitations: most panels primarily validated for hepatitis B or C viral infections, alcoholic liver disease, and/or NASH; interpretation of results may require critical analysis to avoid false positives or negatives (e.g. Gilbert disease, chronic hemolysis)	
Test	**Methodology**
FibroTest™*	Measurement of α_2-macroglobulin, haptoglobin, apolipoprotein A_1, GGT, and total bilirubin; computational formula includes age and sex
FibroSure™*	Measurement of α_2-macroglobulin, haptoglobin, apolipoprotein A_1, ALT, AST, GGT, total bilirubin, cholesterol, TTG, and glucose; formula includes age, sex, height, and weight
FibroMeter™*	Measurement of α_2-macroglobulin, ALT, AST, GGT, prothrombin index, urea, and platelet count; formula includes age and sex
Fibrosis-4 (Fib-4) index	Measurement of ALT, AST, and platelet count; formula includes age
PROMETHEUS® Fibrospect II®	Measurement of α_2-macroglobulin, hyaluronic acid, and TIMP-1
Type III procollagen peptide (PIIINP)†	Serum marker of collagen turnover, but active PSA may falsely elevate level
Imaging	
Vibration-controlled transient elastography (VCTE; FibroScan®)	• Assesses liver stiffness by measuring low-frequency elastic shear waves propagating through the liver • Validated bedside test with high sensitivity and high negative predictive value for liver fibrosis and good reproducibility • Less reliable in patients with higher BMI (≥30–40)
Magnetic resonance elastography	• Modified-contrast method to image the propagation characteristics of shear waves in the entire liver • Can be used in obese patients or patients with ascites, but more costly than VCTE
Liver biopsy	• Histopathologic assessment of degree of fibrosis, but there can be sampling error • More costly invasive procedure with risk of hemorrhage; risk percutaneous > transjugular • Considered gold standard
*Tests available in major commercial laboratories in US. †Not commercially available in US.	

Table 130.13 Methods of monitoring for hepatic fibrosis. If liver function tests, biochemical markers, or imaging assays indicate abnormalities, consultation with a gastroenterologist is recommended. ALT, alanine aminotransferase; AST, aspartate aminotransferase; BMI, body mass index; GGT, γ-glutamyl transpeptidase; NASH, nonalcoholic steatohepatitis; PIIIP N-P, amino-terminal propeptide of type III procollagen; PSA, psoriatic arthritis; TIMP-1, tissue inhibitor of metalloproteinase 1; TTG, triglycerides. Adapted from references 36 and 37.

Drug Interactions

Drugs that elevate MTX blood levels include NSAIDs, salicylates, sulfonamides, chloramphenicol, phenothiazines, phenytoin, and tetracyclines. Dipyridamole and probenecid increase intracellular accumulation of MTX. Trimethoprim, sulfonamides, and dapsone also inhibit the folate metabolic pathway (see Ch. 127) and markedly increase the risk for pancytopenia with concomitant use. However, the combination of MTX with reduced doses of trimethoprim–sulfamethoxazole used for *Pneumocystis jirovecii* pneumonia (PCP) prophylaxis was reported to be well tolerated[39]. Systemic retinoids and alcohol may cause synergistic liver damage in combination with MTX.

MYCOPHENOLATE MOFETIL AND MYCOPHENOLATE SODIUM

Mycophenolic acid (MPA) was used to treat various forms of psoriasis beginning in the 1970s. Its use declined steadily until the early 1990s, when a more bioavailable and safer formulation, mycophenolate mofetil (CellCept®), became commercially available. Initially inactivated during first-pass glucuronidation in the liver (into the phenolic glucuronide of MPA, MPAG), MPA is then reactivated in the epidermis and gastrointestinal tract by β-glucuronidase (see Fig. 131.1). Mycophenolate mofetil has greater bioavailability than MPA, undergoes complete presystemic conversion to MPA after ingestion, and then follows the same inactivation/activation cycle[40]. Mycophenolate mofetil is 94% bioavailable. MPA is 97% and MPAG 82% albumin-bound. Over 90% of the drug is excreted in the urine, mainly as MPAG. Renal insufficiency can increase plasma concentrations up to sixfold[19]. Enrollment in the REMS program for MPA preparations (see Introduction) is recommended but not yet FDA-mandated. It provides education on pregnancy planning and prevention (www.mycophenolaterems.com).

Mechanism of Action

MPA selectively and non-competitively inhibits the enzyme inosine monophosphate dehydrogenase (IMPDH), preventing conversion of inosine- and xanthine-5-phosphate to guanosine-5-phosphate. This blocks *de novo* synthesis of guanine nucleotides and their subsequent incorporation into DNA (Fig. 130.8). DNA synthesis in T and B lymphocytes is preferentially inhibited because these cells lack the purine salvage pathway and are dependent on *de novo* purine synthesis. MPA decreases immunoglobulin levels and delayed-type hypersensitivity responses by inhibiting proliferative responses to mitogenic and allospecific stimulation; MPA also suppresses antibody formation by B lymphocytes.

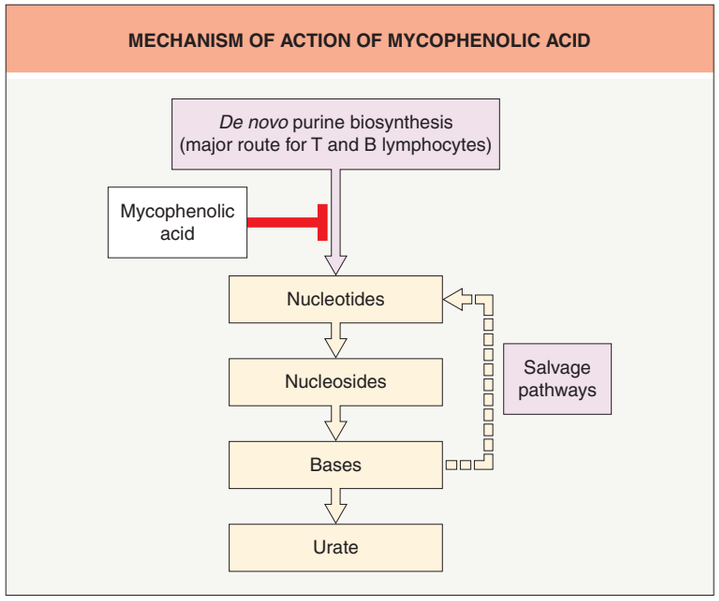

Fig. 130.8 Mechanism of action of mycophenolic acid. While most nucleated cells utilize salvage pathways, T and B lymphocytes must rely primarily on the *de novo* pathway for purine biosynthesis. Mycophenolic acid, the active drug form of the prodrug mycophenolate mofetil, inhibits inosine monophosphate dehydrogenase, an enzyme in the *de novo* pathway of purine biosynthesis. *Adapted from Wolverton SE. Comprehensive Dermatologic Drug Therapy, 4th edn. Philadelphia: Saunders, 2020.*

Dosages

Mycophenolate mofetil (CellCept®) is available in 250 mg capsules, 500 mg tablets, and a 200 mg/ml solution. For dermatologic diseases, best results are obtained with doses of 2000–3000 mg daily, in divided doses.

A newer enteric-coated formulation, mycophenolate sodium (Myfortic®), is also available in 360 mg and 720 mg tablets. Therapeutic equivalence has been documented by comparing enteric-coated mycophenolate sodium (720 mg twice daily) with mycophenolate mofetil (1000 mg twice daily).

Major Side Effects

The most common side effects of mycophenolate mofetil are gastrointestinal, including nausea, vomiting, diarrhea, abdominal cramps, and tenderness (see Table 130.5). Cutaneous side effects are rare. Significant hematologic and hepatic toxicity occur uncommonly. In 2008, the FDA released a safety report regarding a potential association (in transplant patients) between mycophenolate mofetil and the development of progressive multifocal leukoencephalopathy. Although rare, and cause-and-effect remains speculative, patients should be monitored accordingly[41]. Monitoring guidelines are outlined in Table 130.3. For a WBC <3500–4000 cells/mm^3, the dosage should be reduced or therapy discontinued[40].

Indications

Mycophenolate mofetil is currently FDA-approved for renal allograft rejection only. However, it is quite useful in the treatment of autoimmune bullous diseases, severe forms of atopic dermatitis, cutaneous LE, dermatomyositis, and refractory pyoderma gangrenosum. Mycophenolate mofetil is generally used in conjunction with other immunosuppressive drugs, most commonly as a "steroid-sparing" agent.

Contraindications

Absolute contraindications to mycophenolate mofetil use are pregnancy and allergy to MPA. Relative contraindications include lactation, as MPA is partially excreted in breast milk. Peptic ulcer disease and hepatic, renal, or cardiopulmonary disease are also relative contraindications. As noted previously, renal insufficiency can increase plasma concentrations up to sixfold[19].

Use in Pregnancy and Lactation

Human data suggest that mycophenolate mofetil may cause birth defects, with a characteristic phenotype of cleft lip and palate, microtia with atresia of the external auditory canal, micrognathia, and hypertelorism[42]. Additional data suggest that defect severity may be dependent on dose and duration of therapy as well as timing during pregnancy[43]. Based on the MPA REMS, a pregnancy test must be done immediately before starting an MPA preparation as well as 8–10 days later and at routine follow-up visits. Mycophenolate mofetil is contraindicated during lactation, due to potential immunosuppression. Due to the risk of teratogenicity, male and female patients are advised to discontinue the medication for three months and six weeks, respectively, before attempting to conceive. There are limited data regarding its impact on female fertility[1].

Drug Interactions

Drugs that alter the enterohepatic recirculation or gastrointestinal absorption of mycophenolate mofetil, such as cholestyramine, iron, or aluminum and magnesium hydroxides, may decrease the effectiveness of mycophenolate mofetil (see Ch. 131). Plasma levels of both acyclovir and mycophenolate mofetil are elevated when used concomitantly.

SATURATED SOLUTION OF POTASSIUM IODIDE (SSKI)

The dosage, uses, and side effects are outlined in Table 130.14.

SATURATED SOLUTION OF POTASSIUM IODIDE (SSKI)
Formulation: saturated solution; rapid absorption and wide distribution in thyroid and salivary glands, choroid plexus, and placenta; primarily renal excretion
Mechanism of action: speculative; possible immune modulator; suppresses neutrophil migration and toxicity
Dermatologic use: erythema nodosum; cutaneous and lymphocutaneous sporotrichosis (not systemic); neutrophilic dermatoses; other granulomatous diseases
Dosage: concentration = 1000 mg/ml of saturated solution*; inflammatory diseases: initial dose = 150–300 mg three times per day, then increased weekly until clinical response; sporotrichosis: initial dose = 600 mg three times per day, then increased (maximum = 6 g/day if tolerated) for a total of 6–10 weeks
Side effects: short-term – GI (see Table 130.5), acneiform eruption, reversible hypothyroidism > iododerma, hyperkalemia; long-term – "iodism" with burning mouth, metallic taste, sore teeth and gums, severe headache
Monitoring guidelines: baseline TFTs, including TSH and T_4; pregnancy test in women of childbearing potential; repeat TSH one month after therapy or if symptoms of hypothyroidism develop
Contraindications: hypersensitivity reaction to iodides; thyroid, renal, or cardiac disease; Addison disease (risk of hyperkalemia)
Pregnancy and lactation: avoid during pregnancy; fetal goiter and hypothyroidism known risks; compatible with breastfeeding per AAP
Drug interactions: risk of hyperkalemia with ACE inhibitors, potassium-sparing diuretics, and potassium-containing medications; increased risk of hypothyroidism with concomitant use of amiodarone, lithium, phenazone, and possibly sulfones
*See Table 100.6 for drops (gtt) to mg conversion.

Table 130.14 Saturated solution of potassium iodide (SSKI). AAP, American Academy of Pediatrics; GI, gastrointestinal; TFTs, thyroid function tests; TSH, thyroid stimulating hormone.

SIROLIMUS (RAPAMYCIN) AND TACROLIMUS

The dosage, uses, and side effects are outlined in Table 130.15.

THALIDOMIDE AND LENALIDOMIDE

Few drugs have garnered such notoriety as has thalidomide. Originally introduced in Europe during the 1950s as a sedative/hypnotic, it was commonly used to control morning sickness during pregnancy and thus was prescribed to thousands of pregnant women with tragic results. By 1961, thalidomide was withdrawn worldwide after being linked to thousands of babies born with phocomelia (severe underdevelopment of the extremities)[44]. At the time of withdrawal, thalidomide had never received FDA approval for use in the US. Renewed interest in the drug ensued in the mid-1960s with reports that thalidomide provided significant relief from symptoms of erythema nodosum leprosum (ENL). Thalidomide (Thalomid®) received FDA approval for treatment of ENL in 1997 and has since been successfully employed for various inflammatory skin conditions. Lenalidomide (Revlimid®), a second-generation thalidomide analogue, has been used to treat skin disorders such as refractory cutaneous LE since its release in 2006.

In the US, both the prescribing physician and the dispensing pharmacist must be enrolled in the FDA-mandated THALOMID REMS® program (www.thalomidrems.com) or REVLIMID REMS® program (www.revlimidrems.com). Standardized informed consent forms, patient education packets, and monitoring requirements are included in these programs.

Thalidomide is a lipophilic, non-polar piperidine-dione that is poorly absorbed and highly protein-bound. Peak plasma levels are attained 2–6 hours after ingestion and absorption is not affected by food intake. The half-life of thalidomide is 9 hours. Although the major degradative pathway is non-enzymatic hydrolysis, the drug is also metabolized by CYP enzymes. The precise method of excretion is unknown but non-renal[45].

Both thalidomide and lenalidomide possess immunomodulatory, antiangiogenic, and antitumor properties. Lenalidomide produces a greater effect on T cells as well as IL-2 and IFN-γ production compared to thalidomide. There is a minimal risk of neuropathy with lenalidomide, and sedation and constipation are much less common[46].

SIROLIMUS (RAPAMYCIN) AND TACROLIMUS
Sirolimus (rapamycin)
Drug properties: macrocyclic lactone antibiotic **Mechanism of action**: mTOR (*m*echanistic [or *m*ammalian] *t*arget *o*f *r*apamycin) inhibitor; first binds FK-binding protein 12 (FKBP12) then protein pair binds mTOR complex 1 (mTORC1); blocks T lymphocyte proliferation; inhibits cell proliferation and angiogenesis (Akt pathway) **Dermatologic use**: Kaposiform hemangioendothelioma or tufted angioma with Kasabach–Merritt phenomenon, lymphatic malformations; GVHD – prophylaxis, acute, and chronic; post-transplant Kaposi sarcoma, keratinocyte carcinomas, and lymphoproliferative disorder (substitute immunosuppressant); topical formulations – facial angiofibromas and ungual fibromas in tuberous sclerosis complex, lymphatic and vascular malformations, perhaps hyperkeratotic disorders (e.g. epidermal nevi, acanthosis nigricans) **Dosage**: in children, initially, 0.8 mg/m^2 twice daily, then titrated to obtain trough level of 5–15 ng/ml in children; in adults, loading dose of 6 mg followed by maintenance dose of 2 mg daily, with dose adjusted based upon trough levels; compounded topical formulations usually 1% cream or ointment, but varies from 0.1%–1%; 0.1% oral solution used topically
Tacrolimus
Drug properties: macrolide lactone antibiotic **Mechanism of action**: calcineurin inhibitor (see Ch. 128); inhibits production of cytokines such as IL-8 **Dermatologic use**: GVHD – prophylaxis, acute, and chronic; pyoderma gangrenosum; sarcoidosis; recalcitrant psoriasis **Dosage**: 1–2 mg orally twice daily (blood level 5–10 ng/ml)
Sirolimus and tacrolimus
Side effects: immunosuppression, hypertension, diabetes mellitus (tacro > CSA), renal dysfunction (tacro > siro), hyperlipidemia, posterior reversible encephalopathy syndrome (PRES; tacro > CSA or siro); *tacrolimus:* hyperkalemia (esp. in conjunction with ACE inhibitors). For mucocutaneous side effects, see Table 21.17. **Monitoring guidelines**: see those for CSA (see Table 130.3); lower dose or discontinue treatment if serum creatinine rises by >30% of baseline **Contraindications**: uncontrolled hypertension, significant renal impairment, prior hypersensitivity reaction to drug; see contraindications for cyclosporine; *tacrolimus*: for parenteral administration, allergy to HCO-60 (polyoxyl 60 hydrogenated castor oil that is used as a surfactant) **Pregnancy and lactation**: for dermatologic disorders, should be avoided during pregnancy and lactation (concentrated in breast milk) **Drug interactions**: other renal-toxic drugs

Table 130.15 Sirolimus (rapamycin; Rapamune®) and tacrolimus (Prograf®). There is significantly less hypertrichosis as compared to cyclosporine. Everolimus is an immunosuppressant with a mechanism of action similar to sirolimus that also has anti-tumor effects (e.g. tuberous sclerosis complex-associated tumors, Kaposi sarcoma); additional side effects include mucositis, diarrhea, and pulmonary toxicity. ACE, angiotensin converting enzyme; CSA, cyclosporine; siro, sirolimus; tacro, tacrolimus.

Mechanism of Action

The precise mechanism of actions of thalidomide and lenalidomide are unknown. However, the anti-inflammatory and immunomodulatory effects on dermatologic diseases are thought to be largely through inhibition of TNF release and activity.

Dosages

A major emphasis of the THALOMID REMS® and REVLAMID REMS® programs is pregnancy prevention. Prior to therapy, women of childbearing potential must be on birth control for 1 month and have a negative serum pregnancy test within 24 hours of the first dose. If initial history or physical examination indicates peripheral nervous system disease, neurologic consultation should be sought. Monitoring guidelines are listed in Table 130.3.

Thalidomide is available in 50, 100, 150 and 200 mg capsules. Dosing regimens will vary according to the particular disease and severity. Used in combination with anti-leprosy chemotherapy, the dose for ENL ranges from 100 to 400 mg/day (see package insert for details). Dosages for HIV-associated oral aphthae and neutrophilic dermatoses are generally 100 mg/day. Sedation is the most common dose-limiting side effect, being fairly common at even 50 mg/day. Lenalidomide is available in 2.5, 5, 10, 15, 20, and 25 mg capsules. Dosages to treat skin diseases typically range from 5 to 10 mg daily.

Patients with recalcitrant discoid or SCLE lesions experience 75%–90% clearance rates with thalidomide (Fig. 130.9). The initial dose of 50–100 mg/day is subsequently tapered to 25–50 mg/day after a clinical effect is seen, usually within 2 weeks. Acute cutaneous lesions of SLE have up to a 90% resolution rate, but require higher doses and longer treatment periods before results are noted. For some patients, intermittent courses of thalidomide (for 2–3 months) can be used to clear lesions, with antimalarials given concomitantly and as maintenance therapy.

Major Side Effects

A single dose of *thalidomide* during the first 21–36 days of gestation yields a 100% incidence of birth defects (see Table 130.5). Sedation is by far the most common adverse side effect and may necessitate night-time dosing and gradual titration of the dose. Constipation is also common. Permanent nerve damage (primarily sensory neuropathy) can develop and is more common with long-term therapy. Measurements of sensory nerve action potential amplitudes (SNAP) may be indicated before and/or during therapy. Amenorrhea and primary ovarian failure may occur.

Severe leukopenia, exfoliative erythroderma, and TEN are rare consequences of thalidomide treatment. A hypersensitivity reaction specific to HIV-positive patients has been described. Common dermatologic side effects include brittle fingernails, xerosis, pruritus, and red palms. Peripheral edema can develop occasionally. Vascular thromboses are unusual unless the patient is receiving concomitant corticosteroids.

Fig. 130.9 Improvement of discoid lupus erythematosus with thalidomide. A Baseline. **B** Following therapy with a marked reduction in erythema and scale-crust. *Courtesy Jeffrey Callen, MD.*

In addition to teratogenicity, *lenalidomide* can cause significant neutropenia and thrombocytopenia, requiring close monitoring as outlined in Table 130.3. Hepatotoxicity has also been observed. While neuropathy is typically not seen with lenalidomide, venous and arterial thromboembolism can occur, consisting predominately of deep venous thrombosis and pulmonary embolus. Thromboprophylaxis is recommended with the choice (e.g. low-dose ASA, directly acting oral anticoagulant) based upon the patient's risk factors. Severe drug eruptions including Stevens–Johnson syndrome have also been reported.

Indications

Thalidomide is FDA-approved and 99% effective for ENL (type II leprosy reaction) although it has no effect on type I leprosy reactions. A variety of off-label uses of thalidomide have emerged over the years including cutaneous LE (see above), prurigo nodularis, actinic prurigo, and aphthous stomatitis[47,48]. Although HIV-associated mucosal ulceration, as well as aphthae associated with neutrophilic dermatoses (including Behçet disease), respond rapidly to thalidomide, ulcerations relapse quickly when the drug is discontinued. Curiously, the highest rate of peripheral neuropathy has been observed in prurigo nodularis patients[47].

Lenalidomide is currently FDA approved for follicular or mantle cell lymphoma, multiple myeloma, and deletion 5q myelodysplastic syndrome. Taking advantage of the reduced risk of neuropathy, lenalidomide has been used to treat a similar group of skin diseases as thalidomide including severe refractory cutaneous LE, chronic actinic dermatitis, and prurigo nodularis[48]. Because of its association with a monoclonal gammopathy, lenalidomide has also been used to treat scleromyxedema.

Contraindications

Absolute contraindications to thalidomide and lenalidomide therapy include sensitivity to the drug, pregnancy and, for thalidomide, a pre-existing peripheral neuropathy. Women of childbearing potential must agree to use highly effective methods of birth control with both thalidomide and lenalidomide (e.g. two reliable forms of contraception simultaneously). Men taking these medications who have female partners of childbearing potential must wear condoms (even if they have had a vasectomy) while their partners use an additional form of birth control (either oral or barrier). Relative contraindications for both medications include significant hepatic or renal disease, a history of neurologic disease, congestive heart failure, hypertension, constipation, and hypothyroidism. In patients with a predisposing condition (e.g. antiphospholipid antibodies, myeloma), there can be an increased risk of thromboses, especially with lenalidomide. Individuals receiving antimalarials should continue to do so, because these drugs have been reported to inhibit platelet aggregation and adhesion.

Use in Pregnancy and Lactation

Thalidomide and lenalidomide should not be used in pregnant women[9]. It is also wise to avoid both drugs in nursing mothers. There are limited data regarding male fertility, but animal studies have reported testicular degeneration. To date, no adverse effects have been observed in animal studies of female fertility[1].

Drug Interactions

Thalidomide may amplify the sedative effects of alcohol, barbiturates, chlorpromazine, and reserpine. Any drug that significantly induces the CYP3A4 enzymes may decrease the effectiveness of hormonal contraception, increasing the potential of pregnancy and, thus, teratogenicity. Lenalidomide may increase the level of digoxin, thus monitoring of plasma levels is recommended. Patients receiving concomitant prothrombotic agents, e.g. estrogen, IVIg, erythropoietin, along with lenalidomide may have an increased risk of thromboembolism.

Additional figures and tables on Select cutaneous disorders that can be treated with specific systemic drugs, and Methotrexate – counseling for patients of childbearing potential, available in our eBook (see inside front cover for access code).

INTRODUCTION

There are two concerns in drug safety: drug reactions and drug interactions. When multiple medications are prescribed, drug interactions become an important safety and efficacy consideration for patients and physicians alike. Non-prescription drugs, in addition to herbal supplements and alternative medicines as well as foods (such as grapefruit juice), may also be implicated in interactions with drug therapy.[1]

It is difficult to obtain precise rates of incidence and prevalence, as specific diagnostic codes for drug interactions are lacking[1a]. This may be due to the fact that interactions can affect multiple processes by which drugs are absorbed, distributed, bound by plasma proteins, metabolized, and excreted, i.e. pharmacokinetic drug interactions. The drug interaction prevalence rate for hospitalized patients is about 1.1%[2], but differs considerably amongst medical disciplines[3]. Every second dermatologic inpatient has a potential risk for relevant drug interactions[4], but one has to keep in mind that *potential* drug interactions far outnumber *actual* drug interactions[3].

Although it is impossible to remember all potential drug interactions, knowledge of the interactive properties of drugs can help reduce the risk of serious adverse outcomes. Moreover, it is the responsibility of physicians to counsel patients regarding drug interactions[5]. Unfortunately, even when serious new drug interactions are recognized and reported, physicians, pharmacists, and patients are often unaware that there is a risk[6].

PUTTING INTERACTIONS INTO PERSPECTIVE

While most drugs are associated with interactions, many do not produce significant outcomes[7]. In fact, not all listed or reported drug interactions are actually clinically significant. Whereas some have little clinical relevance, others are clearly defined as contraindications on the basis of substantiation of risk, potential severity, and frequency of occurrence. Still others can be successfully managed by dosage adjustment and monitoring. In other words, prescribing drugs with the potential for a deleterious interaction increases the risk of, but need not lead to, an adverse outcome.

In one study that examined the occurrence of drug interactions, based upon adverse events reported during large clinical trials[8], the authors concluded that serious adverse drug reactions (ADRs) secondary to drug–drug interactions were infrequent; however, drug–drug interactions that involved selected drugs with a narrow therapeutic index (which elicited life-threatening undesired effects) did occur. Drug–drug interactions are the most common cause of medication errors in high-income countries, with a prevalence of 20%–40%, especially due to polypharmacy in the elderly[9]. Thus, for most drug interactions, it is necessary to assess each patient situation individually.

ASSESSMENT OF RISK IN THE CLINICAL OUTCOME OF DRUG INTERACTIONS

The clinical importance of specific drug interactions is often either over- or underestimated, as these assessments are based primarily on clinical experience in using a particular drug combination[10]. The clinical outcome of most drug interactions is highly situational, as most patients who receive drugs with the potential for interactions do not develop adverse effects. Emphasis should be placed on those factors that increase or decrease the risk to a given patient.

In order to prevent or detect drug interactions, the physician needs to identify risk factors in each individual patient. That said, some patient groups are more likely than others to develop adverse events caused by drug interactions. Identified risk factors are listed in Table 131.1.

The *elderly* frequently experience drug interactions because of the physiologic changes that accompany the aging process and the types of drugs that older patients tend to receive[11]. Polypharmacy, which is common in the elderly, makes them particularly susceptible. In addition, medications may impair pathways of drug elimination by interfering with drug metabolism, thereby increasing the likelihood of adverse drug reactions. Alterations due to advanced age, including changes in drug–protein binding and drug distribution within tissue, may also promote drug interactions. Of note, most adverse metabolic drug interactions occur when an inhibitor or inducer is begun in a patient who previously had stable levels of a substrate drug.

HIV-infected patients also have a high rate of adverse drug reactions. In some instances, this may relate to phenotypic changes in drug metabolism, which can vary with progression of the underlying HIV infection[12]. The latter can alter enzyme function, with resultant changes in drug metabolism and a higher rate of adverse reactions in these patients. A helpful website that provides up-to-date information regarding drug interactions in HIV-infected patients is hosted by the University of Liverpool (www.hiv-druginteractions.org)[13].

A major source of interindividual differences in drug metabolism is *genetic polymorphisms*, which are inherited and can result in significant variations in the activity of drug-metabolizing enzymes. For example, the genes encoding cytochrome P450 (CYP) isoforms are highly polymorphic (see Table 131.13). In some cases, it is actually possible and useful to determine an individual's genotype[14]. Further details on genetic polymorphisms are discussed later in the chapter.

Interactions with other drugs can predispose a patient to the development of certain types of ADR. For example, coadministration of valproic acid increases the risk of severe cutaneous adverse reactions to lamotrigine[15], and allopurinol increases the risk of exanthematous eruptions to antibiotics such as amoxicillin. A disease state itself may directly affect the likelihood of an ADR. For example, active infection with Epstein–Barr virus or cytomegalovirus also increases the risk of exanthematous eruptions to amoxicillin and ampicillin. The disease state may also dictate the way in which a drug is prescribed, and this can subsequently affect the outcome. When a drug has more than one therapeutic action, an interacting drug may affect the action of the initial drug when it is used to treat one disease but not when it is used to treat another disease.

An example of intrinsic effects of disease states would be when epinephrine (adrenaline) is given to patients receiving non-cardioselective β-adrenergic blockers such as propranolol (but who do not have anaphylaxis), and this results in hypertension. In contrast, the same β-blockers inhibit the pressor response to epinephrine when the latter is given to patients with anaphylaxis[16].

An example of a dose-dependent drug interaction is the concomitant use of nonsteroidal anti-inflammatory drugs (NSAIDs) and methotrexate. Available evidence indicates that the risk of this combination

PATIENT RISK FACTORS FOR DRUG INTERACTIONS
• Multiple medications, i.e. polypharmacy
• Demographic risk factors
• Female sex
• Extremes of age – very young and elderly
• Major organ dysfunction, especially in the setting of multiple medical problems
• Liver dysfunction
• Renal insufficiency*
• Congestive heart failure
• Metabolic and endocrine risk factors
• Obesity
• Hypothyroidism
• Hypoproteinemia
• Pharmacogenetic risk factors
• Slow acetylator phenotype
• Reduced thiopurine methyltransferase (TPMT) activity
• Reduced glucose-6-phosphate dehydrogenase (G6PD) activity
• Other genetic polymorphisms (see text and Table 131.13)
• Other medical issues
• Hypothermia
• Hypotension
• Dehydration
*May be underestimated in elderly patients.

Table 131.1 Patient risk factors for drug interactions[11].

is considerably greater in patients receiving high-dose methotrexate as cancer chemotherapy than it is in patients receiving lower weekly dosages for psoriasis[17]. This is because the distribution of the drug is not very important mechanistically in determining drug interactions, but changes in drug elimination are. When larger doses of methotrexate (as used in cancer therapy) are given in combination with an NSAID, reduced drug elimination via the kidneys becomes an important issue, increasing the risk of methotrexate toxicity. However, in patients with impaired renal function, the addition of an NSAID to the lower doses used by dermatologists for psoriasis or as a steroid-sparing agent can also be associated with an increased risk of methotrexate toxicity due to the NSAID's effect on renal elimination.

Sex-related differences in pharmacokinetics may cause variations in drug bioavailability, distribution, metabolism (e.g. CYP2D6), and clearance[18]. The effect of obesity on metabolism is also cytochrome-specific. For example, obesity decreases the activity of CYP3A4 and increases the activity of CYP2E1[19].

Certain medications are clearly more likely to be involved in drug interactions. More specifically, clinically significant interactions occur more frequently with drugs that have a narrow margin of safety, i.e. a narrow therapeutic window. Drugs with the potential for such serious interactions include warfarin and cyclosporine. When prescribing a new medication that could potentially interact with warfarin, it is prudent to have the patient's international normalized ratio (INR) measured within 2–3 days of administration of the new drug.

Medication-related factors that contribute to clinical risk include the dose, route of administration and duration of administration of the *precipitant drug* (the drug that causes the interaction) as well as the sequence of administration of the interacting drugs. Most metabolic drug interactions are dose-related. That is, as the dose of the precipitant drug is increased, the magnitude of its effect on the *object drug* tends to increase. Thus, the **dose** of the precipitant drug is often an important determinant of risk. However, the dose of the object drug may also affect the risk of an adverse drug interaction. For example, a patient who takes small doses of an object drug with serum concentrations at the lower end of the target range is at a lesser risk when an enzyme-inhibiting precipitant drug is added, than would be a patient taking large doses of the same object drug. Lastly, the bioavailability of either drug may have an impact. The **route of administration** is a significant risk factor for some non-metabolic drug interactions, such as when one drug binds to another in the gastrointestinal (GI) tract. However, the route of administration can also be important for metabolic drug interactions, especially when the drug undergoes extensive first-pass metabolism in the gut wall and liver by CYP3A4 or P-glycoprotein (see below). Most drug interactions also have a typical **time course** over which the effects develop. For example, giving rifampin, a typical inducer of CYP3A4, for only a few days is unlikely to have much effect on substrates of CYP3A4, as induction of an enzyme takes weeks to occur.

In summary, there is pharmacodynamic and pharmacokinetic variability between people, as well as host variability in terms of disease state. Overall, this variability contributes to confusion, as tables and lists that outline potentially interacting medications vary amongst different sources. One reason is that various levels of evidence exist for many of these drugs in terms of their ability to contribute to/cause drug interactions. This is outlined in more detail in the next section.

LEVELS OF EVIDENCE

Drug interaction literature is often confusing due to poorly substantiated claims. This confusion occurs as a result of inaccurate or cursory evaluations of published cases or inappropriate extrapolations from the literature. Metabolic drug interactions are a major source of potential clinical problems, but their investigation during drug development is often incomplete. *In vitro* studies give very accurate data on the interactions of drugs with selective CYP isozymes, but their interpretation in the clinical context is difficult. Although *in vitro* systems have been developed to test the effects of certain drugs on the metabolism of other drugs, these systems may not accurately predict the effect in patients receiving drugs with complex metabolism. In addition, problems with the detection of adverse events after a drug has been released arise mainly because such events are rare. It takes a surveillance system with a high degree of sensitivity to detect such problems[20].

Furthermore, most *in vivo* and *in vitro* studies of drug interactions evaluate two-drug regimens, and the results may not apply to the multidrug regimens used clinically. This is especially true for a regimen consisting of three or more drugs with opposing effects on CYP3A4 metabolism. The lack of studies of multiple drug interactions provides little assistance to the prescribing physician, who is left to rely on adverse events or treatment failure to demonstrate whether an interaction has occurred. In addition, the design of *in vivo* studies is sometimes poor (choice of prototype substrate, doses, schedule of administration, number of volunteers), with the risk of minimizing the real potential for interaction. To link *in vitro* and *in vivo* studies, several authors have suggested using extrapolation techniques, based on the comparison of *in vitro* inhibition data with the active *in vivo* concentrations of the inhibitor. However, the lack of knowledge with regard to one or several important parameters, such as the role of metabolites and intrahepatocyte accumulation, often limits the ability to make safe and accurate predictions.

The uncertainty and inaccuracy of predicting the extent and duration of *in vivo* drug interactions currently stems from a lack of definitive models by which to assess likely substrate and inhibitor concentrations at the active site of metabolism. Additional issues contributing to the uncertainty of predicting drug interactions include assumptions of the contribution of presystemic drug extraction and the effect of inhibitors on the processes involved. Therefore, these methods are useful for complementing *in vivo* studies and helping to design clinically relevant *in vivo* studies, but in the near future they will not totally replace *in vivo* investigations.

ABSORPTION

Interactions that alter the absorption of drugs often lead to dramatic changes in plasma drug concentrations. Drug interactions within the GI tract can result in decreased absorption. This reduces the bioavailability or the amount of drug available to the systemic circulation and results in subtherapeutic serum concentrations. The underlying mechanisms of most drug interactions that alter GI absorption involve: (1) the formation of drug complexes that reduce absorption; (2) alterations in gastric pH; and/or (3) changes in GI motility that alter transit time[9].

Common drugs that form complexes with other drugs include antacids, sucralfate, and bile acid sequestrants (e.g. cholestyramine, colestipol, colesevelam) (Table 131.2). A significant interaction occurs between multivalent cations – such as calcium (e.g. within milk products), aluminum, iron, and magnesium – and tetracyclines or

DRUG INTERACTIONS THAT REDUCE THE EFFICACY OF SUBSTRATES			
Mechanism	**Substrate/ parent drug**	**Concomitant drugs**	**Time course**
Reduced GI absorption	Itraconazole (encapsulated) Ketoconazole‡ Posaconazole	Antacids* H_2 antihistamines Proton pump inhibitors Sucralfate	Rapid

Induction of CYP3A4†	Calcineurin inhibitors Cyclosporine Tacrolimus Oral contraceptives Corticosteroids Dexamethasone Methylprednisolone Prednisone Warfarin	Anticonvulsants Carbamazepine Phenobarbital Phenytoin Antituberculous agents Isoniazid Rifampin Dexamethasone Griseofulvin	1–2 weeks
Antagonistic effects	Epinephrine	β-Blockers	
	Cyproheptadine	SSRI antidepressants Fluoxetine Paroxetine	

*Often contain aluminum hydroxide, magnesium hydroxide, and/or calcium carbonate.
†Also A5, A7.
‡Has been withdrawn by the European Medicines Agency and per the US FDA, it is no longer indicated for *Candida* or dermatophyte infections or as first-line therapy for chromomycosis or dimorphic fungal infections.

Table 131.2 Drug interactions that reduce the efficacy of substrates. In addition, bile acid sequestrants (e.g. cholestyramine, colestipol, colesevelam) dramatically reduce GI absorption of furosemide and thiazide diuretics. GI, gastrointestinal; SSRI, selective serotonin reuptake inhibitors.

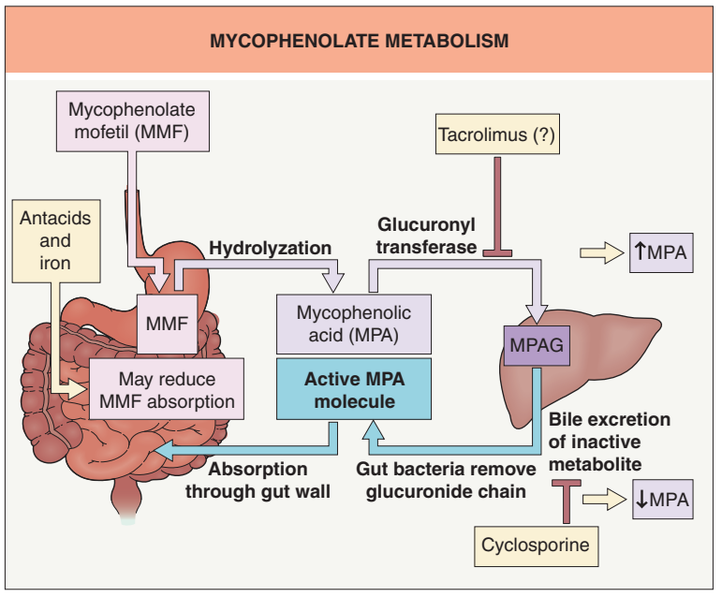

Fig. 131.1 Mycophenolate metabolism. Mycophenolate is hydrolyzed to mycophenolic acid (MPA). Following glucuronidation in the liver, inactive MPA glucuronide (MPAG) is excreted into the gut via bile acid secretion. In the gut, bacteria remove the glucuronide chain to produce MPA, the active molecule, which is then reabsorbed through the gut wall. Cyclosporine impairs MPA enterohepatic recirculation by inhibiting biliary excretion of MPAG (thereby *decreasing* MPA levels), whereas tacrolimus may inhibit UDP-glucuronyl transferase (thereby *increasing* MPA levels).

fluoroquinolone antibiotics. For example, there is an 85% reduction in the absorption of ciprofloxacin when ingested 5–10 minutes after a dose of an aluminum hydroxide/magnesium hydroxide antacid[21]. These interactions can be easily avoided by administering the fluoroquinolone at least 2 hours before or 6 hours after the antacid or multivalent cations. Alendronate, as well as other bisphosphonates prescribed for the prevention and treatment of osteoporosis, form complexes with cations and several other drugs, thereby further decreasing their already low oral absorption. However, once weekly dosing reduces the opportunity for bisphosphonate-related interactions. When mycophenolate mofetil and iron preparations were administered concomitantly, a significant decrease in mycophenolate mofetil absorption was observed (Fig. 131.1)[22].

Drugs that increase gastric pH, such as proton pump inhibitors, antacids and H_2 antihistamines, may reduce the absorption of drugs such as encapsulated itraconazole and posaconazole, which are best absorbed in an acidic environment[23]. Although itraconazole is best absorbed when the gastric pH is low, its administration with food is more important for achieving high plasma concentrations[24]. Of note, the absorption of fluconazole is unaffected by variations in gastric pH. Similarly, the coadministration of drugs that can increase gastric pH (see above) with atazanavir and raltegravir is not recommended. Drugs that affect GI motility, such as anticholinergic agents, may decrease the rate of absorption but not the extent of absorption. An overall reduction in drug absorption has more clinical significance[25].

Some drugs may interfere with the enterohepatic recirculation of a substrate drug. When the substrate is excreted into the GI tract, a second drug can bind to it and prevent its reabsorption back into the systemic circulation. The bound substrate drug is excreted in the feces, thereby effectively shortening its half-life. An example of this is the concurrent administration of warfarin and bile acid sequestrants (e.g. cholestyramine, colestipol, colesevelam) in which the half-life of warfarin is shortened.

P-glycoprotein (PGP)

Membrane-bound transport systems may also determine drug disposition[26]. These transporters are found in multiple tissues and actively pump drug molecules either out of cells (efflux) or into cells (uptake). PGP is an ATP-dependent plasma membrane glycoprotein belonging to the superfamily of ATP-binding cassette transporters that functions primarily as an efflux pump (Fig. 131.2)[27]. Other transporters include the organic anion and organic cation transporters. In humans, the multidrug resistance (MDR) genes, including *MDR1*, encode membrane glycoproteins that function as drug transporters and hence affect both drug absorption and elimination.

High levels of PGP are found in superficial columnar epithelial cells of the small intestine, the apical surface of epithelial cells in the proximal tubules of the kidney, and in the biliary canalicular membrane of hepatocytes. PGP is also detected in high concentrations in the endothelial cells of the capillaries of the blood–brain barrier, testes, uterus and placenta. An understanding of the physiologic regulation of these transporter proteins is key to designing strategies for improving the therapeutic efficacy of drugs that serve as their substrates (Table 131.3).

These membrane-bound transport systems seem to have developed as a mechanism for protecting the body from harmful substances. It appears that PGP acts as a pump whereby the efflux of drugs from the cell membrane or cytoplasm is powered by the energy from ATP hydrolysis. For example, the aminoglycoside antibiotics amikacin and tobramycin are not effectively delivered orally, perhaps because of active efflux from the brush border cells of the small intestine by the PGP pump. The most remarkable property of PGP is its ability to transport a diverse array of compounds that do not appear to share obvious structural characteristics. The range of substrates, inhibitors, and inducers of PGP is vast and expanding (Tables 131.3 & 131.4). Examples of inducers of PGP include dexamethasone, doxorubicin, phenobarbital, rifampin, trazodone, and St. John's wort.

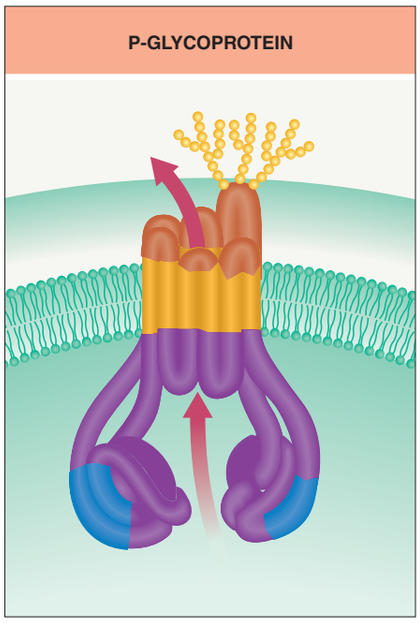

Fig. 131.2 P-glycoprotein. This is an ATP-dependent plasma membrane glycoprotein that functions as a drug transporter and hence affects both drug absorption and elimination.

Vincristine	Ondansetron	Lidocaine
		Loperamide

Table 131.3 P-glycoprotein substrates.

Because PGP blocks absorption in the gut, these glycoproteins should be considered part of the "first-pass effect". In fact, PGP can "set up" or act as "gatekeepers" for later cytochrome P450 actions. Although the inhibition and induction of intestinal CYP3A enzymes from metabolic processes result in direct changes in drug absorption, the inhibition and induction of PGP primarily affect the rate of drug absorption[28]. If one drug is a substrate of both PGP and CYP3A4 (which are found in close proximity in the intestinal wall), and a second drug is added that is an inhibitor of both PGP and CYP3A4 (e.g. erythromycin, ketoconazole), then a greater amount of the first drug will be absorbed. Because CYP3A4 is inhibited, higher levels of *unmetabolized* drug will enter the blood. The effect of PGP blockade is to "open the gates" so that the later actions of CYP3A4 inhibition will be increased.

PGP is an important component of the blood–brain barrier and an active PGP will prevent drugs from entering the brain. It has been suggested that the reason newer antihistamines do not cause sedation is that PGP activity acts as a barrier to CNS penetration. This would suggest that PGP inhibitors (see Table 131.4) could interact with and allow increased cerebral concentrations of these antihistamines, with an attendant increase in sedation[29].

Evidence also suggests that intestinal PGP plays a significant role in the first-pass elimination of cyclosporine, probably by being a rate-limiting step in absorption. Intestinal CYP3A4 is thought to play a lesser role[30]. However, the overlap of tissue distribution and substrate specificity of CYP3A4 and PGP in the intestinal wall makes it difficult to define the precise mechanisms of some drug interactions and to predict the plasma concentrations of certain drug combinations. Moreover, the involvement of CYP3A4 and PGP in drug interactions is not always complementary.

DISTRIBUTION

Drugs that are highly protein-bound (>90%) may cause interactions based on alterations in distribution. When one drug displaces another from plasma protein-binding sites, the free serum concentration of the displaced drug is increased, and its pharmacologic effect increases. However, the unbound fraction of the drug is not only more available to sites of action but is also more readily eliminated. Any enhanced pharmacologic effect occurs only transiently because of a compensatory increase in elimination, and the *effect of displacement interactions is then negligible*. Therefore, interactions involving drug displacement from binding proteins tend to be self-limiting[31]. Typically, the pharmacologic activity of the displaced drug is increased for a few days. This is followed by a return of the pharmacologic response back to the previous unbound serum concentration, even if the concomitant therapy is continued. Therefore, it is safe to say that if a patient does not manifest an adverse event from the combination therapy in the first week or so of administration, an adverse event probably will not occur.

In practice, protein-binding displacement interactions do not produce clinically significant changes in drug response unless the drug also has a limited distribution in the body, is slowly eliminated, or has a low therapeutic index[25]. For this reason, protein-binding displacement interactions may assume greater importance when the displacing drug also reduces the elimination of the substrate drug. Good examples of this principle are the interactions between NSAIDs and methotrexate (Table 131.5).

Medications that are most susceptible to interactions based on changes in drug distribution involving displacement from binding proteins include warfarin, sulfonamides, and phenytoin[11].

DRUG INTERACTIONS THAT INCREASE RISK OF SUBSTRATE DRUG TOXICITY			
Mechanism	**Substrate**	**Interactive drugs**	**Time course**

DRUG BIOTRANSFORMATION

Cytochrome P450 Enzymes

After their administration, drugs are metabolized through a series of reactions to enhance their hydrophilicity and to facilitate excretion. These drug biotransformation reactions are broadly grouped into two phases, I and II. *Phase I* reactions involve intramolecular changes such as oxidation, reduction, and hydrolysis that make the drug more polar and therefore more readily eliminated. *Phase II* reactions are conjugation reactions in which an endogenous substance combines with the functional group derived from phase I reactions to produce a highly polar drug conjugate that can be even more readily eliminated. These reactions involve glucuronidation and sulfation.

The cytochrome P450 (CYP) enzymes are the major drug-metabolizing enzymes (Fig. 131.3). They are present in the endoplasmic reticulum of many cells, but their highest concentrations are found in hepatocytes. CYP enzymes are also present in the crypt cells of the GI tract, with the highest concentrations found in the enterocytes at the tips of the villi; their presence accounts for the first-pass metabolism of many drugs. These heme-containing proteins are encoded by a gene superfamily, with the encoded isoforms exhibiting distinct but overlapping substrate specificities and isoform-specific regulatory and pharmacogenetic properties[32]. The nomenclature employs a three-tier classification consisting of the family (40% homology in amino acid sequence), the subfamily (~75% homology), and the individual protein (e.g. CYP2D6).

An increased understanding of CYP drug metabolism has solved much of the mystery behind drug interactions. While there are ~60 genes that encode CYP isoforms, over 90% of drug oxidation can be attributed to six main cytochromes: CYP1A2, 2C9, 2C19, 2D6, 2E1 and 3A4[33] (see Fig. 131.3); with regard to systemic dermatologic therapies, CYP3A subfamily is the most important[34]. The metabolism of a drug by a specific isoenzyme indicates that it is a substrate for that enzyme. *Whether enzyme inhibition or induction occurs is an entirely separate issue*. Many drugs serve only as substrates and produce no significant enzyme inhibition or induction. It is entirely possible for a drug to be a substrate for one enzyme and inhibit or induce another enzyme that is not involved with its own metabolism. Therefore, drug interactions are more aptly termed drug–protein–drug (food) interactions. These are affected by: genetics (polymorphic genes cause particular enzymes to be less effective, 2D6 being an example); drugs (a drug may inhibit or induce a cytochrome, or interfere in the chemical pathway of another drug, e.g. itraconazole reduces cyclosporine metabolism by inhibiting CYP3A4); chemicals (dioxin is an inducer of CYP3A4 while a food such as grapefruit juice is an inhibitor of CYP3A4); and the environment

(cigarette smoke is an inducer of CYP1A2). Deciding what is clinically relevant is a challenging, relatively new field of investigation.

Drug metabolism is investigated even before human exposure. With recombinant human CYP enzymes, it is possible to determine the metabolic pathways, potential genetic polymorphisms, ability to induce or inhibit drug metabolism, and possible drug interactions. Although there are limitations to the information gleaned from *in vitro* studies, nonetheless this information can be used to guide more expensive *in vivo* studies.

However, using *in vitro* tests that focus on cytochrome enzymes alone to predict clinical interactions may not always be reliable for a variety of reasons. First, it is not always possible to know the therapeutic concentration of a new drug and its primary metabolites in specific tissues[26]. Second, there are a large number of pathways and interactions, and it is impossible to test them all even in an *in vitro* system. Third, the demonstration of an *in vitro* effect does not tell physicians whether that effect is likely to occur in clinical practice, i.e. the clinical significance of an *in vitro* interaction is unknown. Fourth, the underlying disease state may contribute to the development of a drug interaction and this would be unaccounted for by *in vitro* studies alone. Until clinical data demonstrate the presence or absence of a clinically significant interaction, dosage adjustments based on *in vitro* tests are premature.

THE CONFUSING WORLD OF DRUG INTERACTIONS

Why does it take so long to learn about interactions? Some drugs come to market and their various interactions are not realized for several years[35]. One reason is that drugs are prescribed on the basis of indications that may have their own adverse effects on patient outcome. In addition, studies in healthy volunteers are not sufficient to determine the contribution of underlying diseases to the development of interactions. The latter are affected by genetics, drugs, chemicals, the underlying health status of the patient, the therapeutic index of the drug affected by the interaction, dose-related factors, the duration of coadministration, the time course of the interaction, whether active metabolites are involved, and the environment (Table 131.6). Furthermore, the multiple metabolic pathways of some drugs can make it difficult to predict the outcome of drug interactions. However, the risk of a specific drug to have a significant drug–drug interaction is usually lower when it is metabolized by multiple CYP enzymes.

Metabolism

The most clinically relevant drug interactions are those caused by alterations in drug metabolism, and CYP isoenzymes are the key players in drug metabolism. Members of the CYP3A subfamily are the most abundant of the human *hepatic* cytochromes and account for up to 70% of *GI* cytochromes. This subfamily contains the major metabolizing isoforms for many of the drugs prescribed by dermatologists (Tables 131.2, 131.5, 131.7 & 131.8; Fig. 131.4). CYP3A4 in particular has a pivotal role in xenobiotic metabolism and has been estimated to be involved in the metabolism of ~50% of the drugs in clinical use[33]. Although the most important isoform is 3A4, there is close structural homology to 3A5 and 3A7, and so these three isoforms are grouped together. Of note, CYP3A4 is also located in the placenta, uterus, kidney, lung, and fetus.

There is significant interindividual variability in the metabolic activity of CYP3A4. The extent of variability may be as much as 20-fold and the individual level of CYP3A4 activity probably has clinical relevance. Obesity also plays a role in drug metabolism in an enzyme-specific way[19] as it decreases isoform 3A4 metabolism (see Table 131.6), and more than a third of Americans are obese.

The successful application of information regarding CYP in order to prevent drug interactions and improve the therapeutic risk/benefit ratio can occur only if we know which enzyme is responsible for the metabolism of a particular drug. Drug interactions are also made more predictable by determining which compounds induce and inhibit which specific P450 enzymes. While knowing all of the major enzyme substrates, inhibitors, and inducers is a formidable task, Tables 131.7 to 131.10[36,37] are intended to summarize large amounts of this information.

Cytochrome induction

The effect of induction is to increase the amount of P450 present and to accelerate the oxidation and clearance of a drug. The onset and offset of enzyme induction are *gradual* because the induction phase depends on the accumulation of the particular inducing agent and the subsequent synthesis of new enzyme. The offset depends on elimination of the inducer and decay of the increased enzyme levels.

The most common enzyme inducers are aromatic anticonvulsants (phenobarbital, phenytoin, carbamazepine), rifampin, and other antituberculous drugs (see Tables 131.2, 131.8 & 131.9). Inducers may enhance parent drug metabolism, so that therapeutic efficacy is actually reduced if the parent drug is the active moiety (Fig. 131.5). Alternatively, inducers may enhance the metabolism of a substrate to active metabolites, with the potential for exaggerated toxicity.

Drug interactions involving enzyme induction are not as common as inhibition-based drug interactions but may be equally profound and clinically significant.

Cytochrome inhibition

Inhibition of drug metabolism is the most important mechanism for drug interactions because it can lead to an increase in plasma drug concentration, enhanced drug response, and toxicity. In contrast to the time course seen with enzyme induction, inhibition of drug metabolism begins within the first one or two doses of the inhibitor and is maximal when a steady-state concentration of the inhibitor is achieved. Therefore, the time course for inhibitory actions is usually in terms of *days* not weeks.

Inhibitory interactions can be either competitive or non-competitive. An example of *competitive* inhibition involves the tight binding of inhibitors such as macrolides, cimetidine, and ketoconazole to the heme moiety of the cytochrome P450 isozyme. As long as the inhibitor occupies this specific site of the CYP, the substrate cannot be biotransformed. As the concentration of the inhibiting drug increases, the degree of saturation of the isoenzyme increases. When the enzyme system is saturated, further metabolic activity by that enzyme system is limited. At that point, a patient becomes the equivalent of a poor metabolizer and concentrations of co-prescribed medications begin to rise. The extent of inhibition of one drug by another depends on the affinity each compound has for the CYP isoform. In addition to the concentration of substrate required to saturate the system and the half-life of the inhibitor drug, competitive inhibition clearly depends on the affinity of the substrate for the enzyme being inhibited. The onset and offset of enzyme inhibition are dependent on the time to steady state and the half-life of the inhibitor.

The significance of an elevated plasma level of a particular drug is determined largely by the therapeutic margin of the drug. Therefore, when considering the potential clinical relevance of an interaction, one must exercise more caution with drugs that have a narrow therapeutic range. *Non-competitive* inhibition is less common and occurs when the enzyme is destroyed, inactivated, or changed by the inhibitor such that it can no longer metabolize the original substrate.

HOW TO MINIMIZE THE RISK OF DRUG–DRUG INTERACTIONS

One commonly perpetuated myth is that all drugs in a given class are equally susceptible or contributory to drug interactions. Understanding the differences between drugs in a particular class with regard to potential for drug interactions is clinically relevant. Specific drugs, from a given class of drugs associated with interactions, may have little or no clinical potential for drug interactions and are therefore safer choices (Table 131.11).

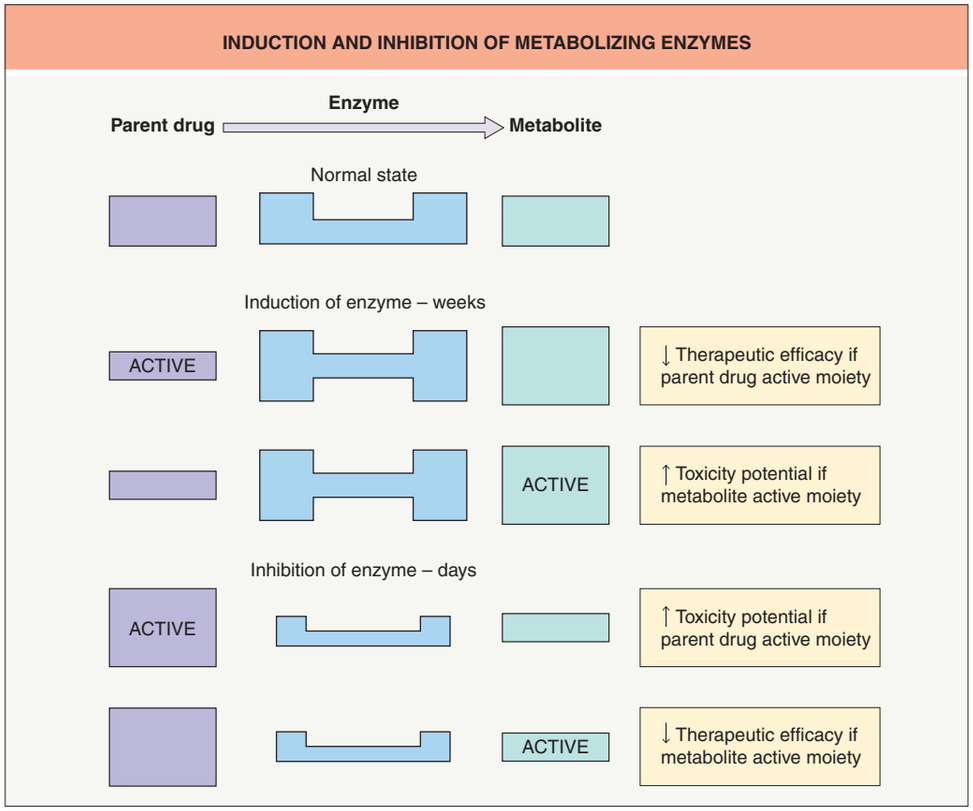

Fig. 131.5 Induction and inhibition of metabolizing enzymes. Induction of an enzyme takes 1–2 weeks to occur while inhibition can occur rapidly within days.

Various drug classes commonly encountered by dermatologists will be discussed, with emphasis on important interactions and ways to minimize risks by appropriate drug choices within a given drug class.

Allylamine Antifungals

Terbinafine is an orally active allylamine antifungal used in the treatment of dermatophytoses. Reports suggest some degree of significant inhibition of CYP2D6 and CYP1A2 by terbinafine[38]. There are four principal levels of activity of CYP2D6 in the general population: poor metabolizers (PM), intermediate metabolizers (IM), extensive metabolizers (EM), and ultrarapid metabolizers. The EM status is by far the most common and is considered "normal". Approximately 7.5% of White individuals and <2% of Asians and African-Americans are poor metabolizers. Inhibition of CYP2D6 by terbinafine would make individuals who have active enzyme (extensive metabolizers) into poor metabolizers, and this effect could possibly last for weeks after discontinuing terbinafine. This can cause two problems: there may be an accumulation of the parent drug (substrate), and this can result in dose-dependent drug toxicity, or there can be reduced formation of active metabolites, and this can result in loss of efficacy (see Fig. 131.5)[39].

Terbinafine appears to be a potent inhibitor of CYP2D6, and so clinicians should be aware of potential interactions (see Table 131.10). The area of greatest concern, because of possible severity and common use, would be bradycardia from excess *β-blockade* (e.g. propranolol) or from the accumulation of *donepezil* (used to treat Alzheimer disease)[40]. Codeine or tramadol could lose their analgesic effect, as active metabolites are not formed when CYP2D6 activity is low[39].

Azole Antifungals

The triazoles itraconazole and posaconazole as well as the imidazole ketoconazole require an acid milieu for absorption; therefore, concomitant *antacids*, *H_2 blockers*, *proton pump inhibitors*, and *sucralfate* significantly reduce absorption (see Table 131.2). The administration of these agents with carbonated cola beverages will acidify (pH <3) the stomach, thereby improving absorption of the antifungal drug. Fluconazole and voriconazole are alternatives for patients in whom drugs that reduce gastric acidity are required, as these antifungal medications do not rely on an acid milieu for absorption.

Among the systemic azole antifungals, itraconazole, voriconazole, posaconazole, and ketoconazole are CYP3A4 inhibitors that are able to

DRUGS AND FOODS WITH DIFFERING POTENTIAL FOR DRUG–DRUG INTERACTIONS BASED ON METABOLISM

Drug/food class	More potential for interaction	Less potential for interaction
ACE inhibitors and angiotensin II receptor blockers (ARBs)	NSAIDs	Acetaminophen Celecoxib
Antifungals	Azoles and triazoles (CYP3A4 inhibition)	Terbinafine
Calcium channel blockers	Diltiazem Nicardipine Verapamil	Amlodipine Nifedipine
Macrolides	Clarithromycin Erythromycin	Azithromycin
Quinolones	Ciprofloxacin Enoxacin	Levofloxacin Lomefloxacin Ofloxacin
H_2 blockers	Cimetidine	Famotidine Nizatidine Ranitidine
Protease inhibitors	Ritonavir (most potent) Indinavir	Saquinavir Nelfinavir
HMG-CoA reductase inhibitors	Simvastatin Lovastatin	Pravastatin Fluvastatin Rosuvastatin
Citrus fruit juice	Grapefruit juice	Orange juice

Table 131.11 Drugs and foods with differing potential for drug–drug interactions based on metabolism. ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

induce drug–drug interactions[41]. Many substrates are metabolized via these enzymes (see Tables 131.2, 131.5, 131.7), and moderate to severe drug interactions have been observed with several substrates, including *cyclosporine*, *warfarin*, *sirolimus*, and *everolimus*. Itraconazole is contraindicated when the patient is also receiving the following CYP3A substrate drugs: *triazolam*, *oral midazolam*, *lovastatin*, *simvastatin*, *quinidine*, or *pimozide*. Caution has been suggested with *cyclosporine, warfarin, digoxin*, and *atorvastatin*. Significant effects on the metabolism of fluvastatin or pravastatin by itraconazole do not appear to occur[42] (see Table 131.11). Fluconazole inhibition of CYP3A4 is dose-related: 100 mg/day usually has little effect on CYP3A4, but inhibition can occur at daily doses of 200–400 mg (or more), depending upon the substrate.

When the azole antifungals are administered with *cyclosporine*, concentrations of the latter are increased, requiring careful monitoring of cyclosporine levels. Similarly, frequent monitoring of the INR is required for patients on *warfarin* who require therapy with an azole antifungal. The azole antifungals reportedly increase the anticoagulant effects of warfarin by two- to threefold.

Azole antifungals also interfere with the metabolism of benzodiazepines such as *triazolam* and *midazolam*, leading to increased levels and sedation. There is also decreased metabolism of some of the HMG-CoA reductase inhibitors, e.g. *lovastatin* and *simvastatin*, leading to increased levels, as well as to rhabdomyolysis. Additional drugs whose metabolism is decreased by azoles include *tacrolimus, indinavir*, and *calcium channel blockers*. Peripheral edema due to an interaction between nifedipine and itraconazole has been reported. It was suspected that itraconazole inhibited the metabolism of this calcium channel blocker, resulting in an increased serum nifedipine concentration and leg edema. This hypothesis was confirmed by obtaining serum levels of nifedipine, itraconazole, and hydroxyitraconazole (the active metabolite of itraconazole) before and after the administration of itraconazole[43]. The authors recommended that patients receiving both azole or triazole antifungals and calcium channel blockers should be monitored for side effects such as leg edema and, more importantly, hypotension, because of the increased serum concentration of the calcium channel blocker.

Fluconazole, but not itraconazole, interacts with the angiotensin II receptor blocker *losartan*, but not valsartan or irbesartan. Fluconazole inhibits losartan's metabolism to the active metabolite E-3174[44]. The clinical significance of this interaction remains unclear, but the possibility of a reduced therapeutic effect of losartan should be borne in mind. *Phenytoin* is a substrate of CYP2C9, and concurrent fluconazole use at bedtime has resulted in several cases of phenytoin toxicity[45].

In contrast to the azole antifungals, terbinafine is an allylamine that does not inhibit CYP3A4[46]. This antifungal may be a viable therapeutic option in patients on concomitant therapy with a high likelihood of drug interactions with the azoles (see above).

Azathioprine

Azathioprine is metabolized to 6-mercaptopurine (6-MP) and there are three subsequent pathways for the metabolism of 6-MP. Both thiopurine methyltransferase (TPMT) and xanthine oxidase metabolize 6-MP to inactive metabolites, whereas hypoxanthine–guanine phosphoribosyltransferase (HGPRT) metabolizes 6-MP to active purine analogues, in particular 6-thioguanine (see Fig. 130.5). *Allopurinol* and *febuxostat* inhibit the metabolism of 6-MP via xanthine oxidase; this leads to increased levels of 6-MP (plus active purine analogues via HGPRT) and, as a result, increased antimetabolite effects and associated toxicity including pancytopenia. Combining either azathioprine or 6-MP with allopurinol or febuxostat should be avoided. If either allopurinol or febuxostat must be prescribed, an alternate immunosuppressant should be selected.

Colchicine

Colchicine is a substrate of PGP and concurrent use of PGP inhibitors has resulted in severe colchicine toxicity. It is also a substrate for CYP3A4, so inhibitors of this enzyme may result in increased plasma concentrations of colchicine. Given the possibility of fatal colchicine toxicity, few situations would warrant the concomitant use of colchicine with a *CYP3A4 or PGP inhibitor* (see Tables 131.4 & 131.8). However, if this combination must be prescribed, careful monitoring for colchicine toxicity (diarrhea, abdominal pain, fever, muscle pain or weakness, paresthesias) should be performed. If toxicity is suspected, both drugs must be discontinued immediately. Of note, grapefruit juice is an inhibitor of both PGP and CYP3A4, and colchicine toxicity has been reported with the intake of large amounts of grapefruit juice.

Cyclosporine/Everolimus/Sirolimus/Tacrolimus

Numerous drug interactions with cyclosporine have surfaced that are associated with its metabolism and presystemic metabolism (both by the CYP3A4 enzyme and by PGP), in the liver and intestine, respectively. It is thought that this GI tract metabolism may explain its erratic absorption. *Diltiazem* can decrease cyclosporine dosing by as much as 30%[47], while effects with *grapefruit juice* have been variable.

Other drugs that alter cyclosporine concentrations via cytochrome 3A4 inhibition include other calcium channel inhibitors (*verapamil*, *nifedipine*), triazoles and imidazoles (*fluconazole*, *itraconazole*, *posaconazole*, *ketoconazole*), macrolides (*erythromycin*, *clarithromycin*), and *tacrolimus*. Conversely, isoform 3A4 inducers, such as *rifampin*, *phenytoin*, *carbamazepine* and *phenobarbital*, decrease cyclosporine concentrations. Decreased cyclosporine levels have also been observed with coadministration of *trioglitazone* or *ticlopidine*[48]. More recently, acute kidney injury due to interaction of cyclosporine with methyl-1-testosterone has been reported, highlighting the danger of anabolic steroids purchased online as "supplements"[49]. Cyclosporine trough levels, as well as signs of toxicity versus adequate immunosuppressive response, should be monitored when any of these drugs are combined with cyclosporine.

Grapefruit Juice

Grapefruit juice interactions are of potential clinical relevance for a wide range of drugs. The mechanisms of grapefruit juice interactions are exclusively pharmacokinetic in nature. The effect is mediated mainly by the suppression of CYP3A4 and PGP in the small intestinal wall by either fresh or frozen grapefruit juice[50] (see Fig. 131.4). This results in a diminished first-pass metabolism, with higher bioavailability and increased maximal plasma concentrations of substrates of this enzyme and/or transporter. The effect is most pronounced in drugs with high first-pass degradation, such as *felodipine*, *nifedipine*, *saquinavir*, *cyclosporine*, *midazolam*, *triazolam*, *terazosin*, *ethinylestradiol*, *17β-estradiol*, *prednisone*, and the HMG-CoA reductase inhibitors *lovastatin* and *simvastatin*[51,52]. In the case of cyclosporine, for example, inhibition of its metabolism by grapefruit juice can lead to increased immunosuppression and toxicity.

It is not yet clear which component in grapefruit juice is to blame. Psoralen, mainly a bergamottin compound, is thought to be the major inhibitor, with a minor role attributable to flavonoids such as naringenin and quercetin[53]. Even a change in the brand or batch of grapefruit juice may influence the grapefruit juice/drug interaction to an unpredictable degree, as grapefruit juice is a natural product that is not standardized in composition. Similar interactions have not been seen with other citrus fruit juices, such as orange juice. Lack of 6,7-dihydroxybergamottin in orange juice probably accounts for the absence of inhibitory effects[54]. However, isoflavones in orange juice may mediate this food's inhibitory effect on PGP.

In general, it is recommended that patients refrain from ingesting grapefruit juice when taking a drug that is extensively metabolized, unless a lack of interaction has been documented. Orange juice is a good alternative (see Table 131.11). Another option is ingestion of the grapefruit juice an hour before or two hours after drug ingestion.

Herbal Remedies

Herbal medicines (see Ch. 133) have become a popular form of therapy. They are perceived to be "natural" by the public and thus harmless. Although many current therapeutic agents (e.g. digitalis, atropine, vincristine) have been derived from plants, little is known about the relative safety of current herbal therapies compared with prescription drugs, and even less is known when the two are co-consumed. Because of under-reporting, our present knowledge represents the tip of the iceberg. It is estimated that 80% of the world's population relies primarily on traditional medicines utilizing plant extracts or their active ingredients.

The interactions of phytomedicines with prescription medications are under-researched[55]. Of note, medications with a narrow therapeutic

index or potential life-threatening toxicity, such as cardiovascular drugs (e.g. amiodarone), immunosuppressants (e.g. everolimus, cyclosporine, sirolimus), NSAIDs (including aspirin), opioids (e.g. fentanyl, oxycodone), and warfarin are considered to be at increased risk for significant drug–herb interactions[56]. Because herbs are not sold as drugs, no proof of efficacy or warnings about side effects are required. Moreover, herbal medications are not standardized so different herbal brands have varying amounts of active ingredients and therefore may interact differently with other medications. Even different lots of the same brand may vary considerably. Also, not all, or even any, additional ingredients may be listed on the label[57].

When a drug is prescribed, the quality and dosage of the substance are assured. No such quality control exists for herbal preparations. Contamination, mislabeling, and misidentification of herbs are known problems. Some patients do not know even what they are taking, as they may purchase a product whose ingredients are listed in a foreign language only. In sum, it is important to educate patients to inform their healthcare providers of all alternative medications.

A study in 12 healthy volunteers examined the effect of the ingestion of *St John's wort* on cytochrome activity[58]. Short-term administration (less than two weeks) of St John's wort had no effect on CYP activity, whereas long-term St John's wort administration resulted in a significant and selective induction of CYP3A activity in the intestinal wall. St John's wort did not alter the activity of CYP2C9, CYP1A2, or CYP2D6. Reduced therapeutic efficacy of drugs metabolized by CYP3A should be anticipated during long-term administration of St John's wort.

See Table 131.12 for some important drug interactions between herbal medicines and dermatologic therapies.

HERBAL REMEDIES/PRESCRIPTION DRUG INTERACTIONS		
Herbal remedy	**Side effects/ contraindications**	**Drug interaction**
Berberine (Goldenseal)	Nervousness, confusion, nausea, tremors	Increases concentration of dextromethorphan via 2D6 inhibition
Coenzyme Q10[57]	Reduced efficacy of warfarin	Warfarin
Ginseng[75]	Can reduce the anticoagulant response of warfarin	Warfarin
Kava	CNS depressant	Alcohol, barbiturates, benzodiazepines, opiates
Licorice (*Glycyrrhiza glabra* or *uralensis*)	Contraindicated if hypertension, diabetes mellitus, hypokalemia, hepatic or renal disease	Cyclosporine, digoxin, prednisone, thiazides
Purple coneflower (*Echinacea angustifolia* or *purpurea*)	Recurrent erythema nodosum Caution in patients with HIV, autoimmune CTD, TB, MS, or ragweed/ sunflower allergies	Immunomodulators and cyclosporine, methotrexate, corticosteroids
Ginkgo (*Ginkgo biloba*), garlic, ginger[76]	Can cause spontaneous bleeding	Can potentiate aspirin, digoxin, NSAIDs, warfarin, heparin
St. John's wort[57] (oral) (inducer of CYP2C19, CYP3A4 & P-glycoprotein)	Photosensitivity Erectile dysfunction	Cyclosporine, digoxin, nevirapine, oral contraceptives, erlotinib, imatinib Reduced activity of macrolides, finasteride, dutasteride Reduced plasma concentrations of fexofenadine, voriconazole (>50%)
Valerian	CNS depressant	Alcohol, barbiturates, benzodiazepines, opiates
Zemaphyte (Chinese herbal therapy)	Diarrhea, transaminitis/ reversible acute hepatitis/fatal hepatic necrosis, reversible dilated cardiomyopathy, worsening of atopic dermatitis, urticaria	Methotrexate

Table 131.12 Herbal remedies/prescription drug interactions. CNS, central nervous system; CTD, connective tissue disease; MS, multiple sclerosis; TB, tuberculosis.

HMG-CoA Reductase Inhibitors

Although dermatologists may not prescribe these lipid-lowering agents, their use by family physicians and specialists is so widespread that it is fairly common to encounter patients who are taking this class of drugs. To date, all reports of significantly increased rates of myalgias from combination therapy with a "statin" plus certain other drugs involve simvastatin or lovastatin. Notably, these are the statins with the highest known metabolic dependency on the CYP3A4 pathway for elimination[59]. Fluvastatin is metabolized via CYP2C9 and therefore is not expected to interact with CYP3A4 inhibitors, but may interact with 2C9 inhibitors. Pravastatin is not metabolized by CYP3A4, nor is it cleared by PGP to a clinically significant degree[60].

Kinase Inhibitors

Kinase inhibitors represent an expanding class of drugs that has played an important role in the treatment of a wide range of malignancies including melanoma. More recently, kinase inhibitors have been used to treat inflammatory skin disorders including psoriasis and atopic dermatitis. With regard to drug–drug interactions, the most relevant kinase inhibitors for dermatologists are BRAF/MEK and Janus kinase (JAK) inhibitors.

The selective BRAF inhibitors dabrafenib, encorafenib, and vemurafenib are substrates of CYP3A4. Concomitant use of strong inducers or inhibitors of these enzymes (see Table 131.8) should be avoided or used with caution, as they could significantly alter drug levels of these BRAF inhibitors. Furthermore, dabrafenib is a substrate of CYP2C8 and a potent inducer of a variety of CYP enzymes and transporter proteins, leading to a potential risk for significant drug–drug interactions. For example, the coadministration of dabrafenib and immunosuppressive drugs (*everolimus*, *tacrolimus*) may require dosage adjustment to avoid graft rejection[61].

With regard to the JAK inhibitor baricitinib, its concentration may become elevated in the setting of concomitant therapy with probenecid due to the latter's inhibition of organic anion transporter 3[62].

Macrolide Antibiotics

When a macrolide is required in a patient who is receiving systemic *tacrolimus*, azithromycin should be used (rather than erythromycin or clarithromycin) because this does not produce significant inhibition of CYP3A4[63]. When erythromycin is prescribed to a patient on long-term *warfarin*, there is a risk of increased plasma warfarin levels, with increased anticoagulation and hemorrhage. This occurs because tacrolimus and warfarin are CYP3A4 substrates and erythromycin is a potent inhibitor. The coadministration of erythromycin plus *azole antifungals* leads to an increased risk for prolonged QT interval and torsades de pointes.

Erythromycin also inhibits the metabolism of *sildenafil*, resulting in a significant increase in serum levels of sildenafil[64]. If concurrent administration is unavoidable, reduced doses of sildenafil and *tadalafil* are recommended. In addition, an interaction between erythromycin and *carbamazepine* has been well established[65]. Erythromycin significantly inhibits hepatic metabolism of carbamazepine; the interaction is highly predictable, develops with rapid onset, and may also occur with clarithromycin or troleandomycin[65]. Concurrent use should therefore be avoided.

Quinolone Antibiotics

In the GI tract, all fluoroquinolones interact with multivalent cation-containing products, and the bioavailability of the quinolone can be reduced by up to 50% when coadministered with *iron* compounds

PHARMACOGENETICS – IMPACT OF POLYMORPHISMS ON DRUG METABOLISM		
Cytochrome P450 (CYP) isoenzyme	**Frequency of poor metabolizers**	**Examples of drugs affected**
CYP2C9	6%–8%	Glyburide, warfarin, phenytoin
CYP2C19	3%–5% of White individuals 12%–23% of Asians	Diazepam, omeprazole, pantoprazole
CYP2D6	6%–10% of White individuals 3%–6% of Mexican-Americans 2%–5% of African-Americans 1% of Asians	Codeine, imipramine, propafenone, metoprolol
CYP3A5	90%–95% of White individuals 70%–75% of Asians 30%–35% of African-Americans	Numerous (~50% of drugs are metabolized by CYP3A4/5)

Table 131.13 Pharmacogenetics – impact of polymorphisms on drug metabolism.

(ciprofloxacin and moxifloxacin are more affected than levofloxacin or gemifloxacin). There is also a significant decrease in the bioavailability of quinolones when given with *sucralfate*[65], and antibiotic treatment failure has been documented. If sucralfate cannot be discontinued, the quinolone should be taken 2–6 hours before the sucralfate. Similar decreases in bioavailability occur when a quinolone is given concurrently with an *antacid*[65]. The antacid should therefore be taken 6 hours prior to or 2 hours after the antibiotic.

Sparfloxacin is associated with cardiac manifestations in the form of QTc prolongation and it has a high phototoxicity potential. While moxifloxacin can prolong the QT interval, it does not alter the QT dispersion (QT dispersion is thought to be a more sensitive predictor of the risk of torsades de pointes). As such, the increased risk of torsades de pointes attributable to moxifloxacin is questionable[66]. Levofloxacin has no QT prolongation and a very low phototoxic potential, making it one of the safest fluoroquinolones in terms of drug interactions[67]. An enhanced anticoagulant effect of *warfarin* has been reported after coadministration with norfloxacin, ciprofloxacin, ofloxacin, or enoxacin[48].

Pimozide

Pimozide is a neuroleptic that may be used for psychogenic dermatologic problems such as delusions of parasitosis. While newer drugs may replace pimozide (see Ch. 7), as long as it is still being prescribed, dermatologists must be aware of its drug–drug interactions. Based upon case reports, pimozide may lead to prolongation of the QT interval and cardiac arrhythmias. Patients who are at risk of ventricular arrhythmias because of a prolonged QT interval or electrolyte disturbances, or who take other drugs that affect the QT interval, should use pimozide with caution. Pimozide is oxidized by two CYP isoforms, CYP3A4 and CYP1A2, with the former representing the responsible isoform at therapeutically relevant pimozide concentrations[68]. Adding a CYP3A4 inhibitor such as *clarithromycin*, *erythromycin*, or an *azole antifungal* may increase the risk of toxicity. A baseline assessment of the QT interval and reassessment 6 hours after a pimozide dose may be helpful in patients at risk who require pimozide.

Pharmacogenetics – Role of Polymorphisms

Cytochrome P450 enzymes

The genes encoding the CYP isoenzymes are highly polymorphic, and, as a result, the individuals within a general population have different levels of enzyme activity due to the presence of variant alleles. People with genetically determined low levels of activity are referred to as *poor* metabolizers. Those who have a functional enzyme are known as *extensive* metabolizers. There are yet others who have more than the usual complement of functional genes and more than the usual amounts of certain enzymes, and they are referred to as *ultrarapid* metabolizers. Still others have partially functional enzymes and are *slower* metabolizers than normal (*intermediate* metabolizers). Poor metabolizers may have a larger response and be at greater risk of toxicity than extensive metabolizers for drugs that are highly dependent on clearance to an inactive metabolite by the particular isoform[69]. On the other hand, ultrarapid metabolizers might not reach therapeutically active plasma concentrations of certain drugs, thereby not achieving the anticipated desired effect.

CYP enzymes that exhibit genetic polymorphisms include CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A5 (Table 131.13). However, provocation tests are not routinely employed in clinical practice and unfortunately there are no clinical parameters that are useful in predicting the metabolizing status of a given individual. Molecular analysis of the genes that encode the key CYP isoenzymes can be performed, i.e. testing is commercially available, but this is also not routinely done.

Other drug-metabolizing enzymes

Pharmacogenetic variation can also occur in other drug-metabolizing enzymes. Pertinent to dermatologists, the enzyme thiopurine methyltransferase (TPMT) is important in the metabolism of azathioprine and 6-mercaptopurine to non-toxic metabolites. There is a 0.3% rate of homozygous deficiency of this enzyme, putting these patients at significant risk for toxicity, especially myelosuppression[70]. Conversely, 88% of the population is homozygous for the active TPMT enzyme and may therefore require doses greater than the recommended daily dose of azathioprine (1–2 mg/kg/day) to achieve therapeutic success. Determination of the patient's TPMT level provides *a priori* information that allows the individualization of azathioprine dosing, thereby minimizing toxicity and maximizing efficacy.

Drug–Cytokine Interactions

Cytochrome P450 drug metabolism can be altered by certain proinflammatory cytokines, such as interleukin (IL)-6, IL-1, and tumor necrosis factor (TNF)[71]. These cytokines can cause a reduction in CYP3A function and they are released during periods of stress, trauma or infection, as well as administered as immunomodulators, in particular IL-2[72].

Drug–Virus Interactions

Human herpes virus (HHV) 6/7

The pathogenesis of drug reaction with eosinophilia and systemic symptoms (DRESS)/drug-induced hypersensitivity syndrome (DIHS) is a complex adverse reaction to medications. It is thought to involve: (1) genetic factors, including deficiencies of detoxifying enzymes and associations with specific HLA haplotypes such as HLA-B*57-01/abacavir and HLA-B*58-01/allopurinol (see Table 21.3); (2) virus-drug interactions, in particular HHV-6 reactivation; (3) drug-induced immunosuppression followed by an inflammatory immune recovery syndrome; and (4) drug-specific T cells, with the latter having been isolated from the blood and skin in lamotrigine- and carbamazepine-induced DRESS.

Human immunodeficiency virus (HIV)

A helpful website that contains current information regarding drug interactions in patients receiving antiretroviral medications is www.hiv-druginteractions.org[13]. For example, the coadministration of pimozide with most of the protease inhibitors or delavirdine is contraindicated because of the risk of inducing ventricular arrhythmias. In addition, there are reports of adrenal suppression and iatrogenic Cushing syndrome when patients on ritonavir-based antiretroviral therapy received inhaled, intra-articular, and even topical corticosteroids[73]. Moreover, recreational and illicit drug use may cause drug-drug interactions with antiretroviral medications[73a].

Hepatitis C virus

With respect to drug interactions, multi-drug direct-acting antiviral regimens, such as elbasvir/grazoprevir, sofosbuvir/velpatasvir, sofosbuvir/velpatasvir/voxilaprevir, and glecaprevir/pibrentasvir, are safely administered[73b]. However, interactions with other drugs do exist, e.g., plasma concentrations of glecaprevir/pibrentasvir can be decreased by inducers of PGP and CYP3A. A useful website for screening potential interactions is www.hep-druginteractions.org[73c].

CONCLUSION

Dealing with drug interactions is a challenge in clinical practice. Although no one can be expected to know all drug interactions, useful resources are available. One of the best pocket reference guides is *The Top 100 Drug Interactions* by Hansten and Horn (www.hansten-andhorn.com)[57]. This handbook is concise, up-to-date and, unlike most desk references, it is not limited by class-related statements that may falsely and unnecessarily restrict therapeutic options. A helpful website that contains comprehensive information regarding drug interactions related to CYP isoenzymes is The Flockhart Table™ (drug-interactions.medicine.iu.edu)[74].

More research during the early stages of drug development is required to identify new interactions, define mechanisms of older interactions, and examine the safety of new drugs from classes that are known to cause interactions. We also need more sensitive post-marketing surveillance tools to identify important drug interactions that become evident over time in diseased hosts and that were not seen in pre-marketing studies of healthy volunteers. Physicians need better tools, but, in the meantime, understanding the nuances of the cytochrome P450s will help take the fear out of prescribing.

Because the best evidence for clinically relevant drug interactions comes from case reports, prescribing physicians can have a major impact. Observations of drug interactions should be confirmed, if possible, by serum drug concentrations. Then they should be reported to regulatory bodies and submitted to journals. By understanding the mechanisms behind drug interactions and staying alert for toxicities, we can help make drug therapy safer and reduce the fear of drug interactions.

Photoprotection Strategies and Sunscreen Recommendations . 2352

Key features

- Modern sunscreens were first developed during the 1940s with the primary aim of preventing sunburn. Today, sunscreens are also used to prevent other aspects of photodamage, including carcinogenesis and photoaging
- The active ingredients in sunscreens include: (1) soluble organic filters, i.e. "chemical" compounds, that absorb UV radiation; and (2) insoluble metal oxide filters, i.e. "physical" agents, that both absorb and scatter UV radiation
- The ability of sunscreens to prevent actinic keratoses and cutaneous squamous cell carcinoma has been demonstrated in human studies, and there is growing evidence that they can also prevent photoaging and cutaneous melanoma
- Following topical application, common organic filters are absorbed systemically at levels that exceed the FDA threshold requiring additional safety studies; however, to date there has been no evidence of harm related to their use
- Established side effects from sunscreens include irritation (which is common) and allergy (which is rare)
- In the laboratory, exposure to oxybenzone was found to be associated with coral bleaching; as a result, some localities have passed legislation prohibiting the sale of oxybenzone-containing sunscreens
- Photoprotection and sun avoidance may lead to a decrease in vitamin D levels in some individuals; optimum vitamin D levels can be achieved with a balanced diet and oral supplementation

INTRODUCTION AND HISTORY

Sun Exposure

Evidence exists that even ancient civilizations sought protection from the damaging effects of the sun. The concept of excessive sun exposure as unhealthy or at least cosmetically unacceptable eventually spread to Northern Europe, especially among the aristocracy, and continued into the nineteenth century until the period of the Industrial Revolution. In 1890, Palm noted that children in urban slums of England had rickets whereas those in similar housing conditions in sunny India did not, and linked the lack of sun to the development of rickets[1]. Physicians then began to treat such children with artificial UV radiation. At the same time, Finsen began to treat a number of other diseases, including cutaneous tuberculosis and, interestingly, lupus erythematosus, with artificial light; he was awarded the Nobel Prize for this work in 1903. At the turn of the twentieth century, the image of tanned skin as aesthetically pleasing began to emerge. The French fashion designer Coco Chanel is often credited with developing the concept of tanned skin as beautiful that still persists today. Indeed, for decades consumers applied various oils to the skin and used metal reflectors to enhance tanning. However, the twentieth century also saw the recognition of sunburn as an effect of UVB, the discovery of UVB-specific DNA mutations, and establishment of UVB as a complete carcinogen.

During the 1990s, dermatologists and other healthcare professionals made serious efforts to educate consumers regarding the damaging effects of excessive sun exposure as well as exposure to artificial tanning devices. Despite these efforts, recent studies show that while understanding of the adverse effects of exposure has increased, there has been very little positive change in behavior. This is especially true for adolescents and young adults, who continue to suffer sunburns and who continue to seek tans through natural and artificial exposure. For example, a systematic review in 2014 reported the prevalence of exposure to indoor tanning in the US, Europe, and Australia to be 36% for adults, 55% for university students, and 19% for adolescents[2]. Even in children and adolescents with a parental history of melanoma, sun protection was noted to be suboptimal[3], and some studies have found that sunscreen usage has actually been declining[4,5].

Sunscreens

Sunscreens attenuate UV wavelengths which would otherwise interact with molecules in the skin (chromophores) to generate photochemical reactions, leading to photobiologic change. These preparations are usually combinations of active filters that absorb or scatter incident radiation, and they are dispersed in a variety of topical vehicles. The active ingredients are not meant to be absorbed in any large quantity into the living epidermis, dermis, or general circulation.

In 1928, the first modern sunscreen, a product containing benzyl salicylate and benzyl cinnamate, was introduced in the US. However, widespread use of sunscreens did not occur until World War II, when the US military provided preparations containing red petrolatum to prevent sunburn in troops stationed in sunny areas. After the war, there was an increased interest in UV-absorbing chemicals, and para-aminobenzoic acid (PABA), patented in 1943, was the first of these to gain widespread usage. It was not until the mid-1970s that sunscreens gained a degree of consumer acceptance.

While solar radiation reaching the surface of the earth and human skin includes ultraviolet, visible, and infrared rays (see Fig. 134.1), the initial sunscreens were formulated primarily to prevent sunburn and therefore contained primarily UVB-absorbing agents (Fig. 132.1). As scientific evidence grew documenting the deleterious effects of longer-wavelength UVA radiation and as manufacturers strove to develop higher levels of protection against burning, agents with absorption in the longer wavelengths (e.g. benzophenones) were combined with UVB absorbers. The inorganic sunscreens (e.g. titanium dioxide) were used from the early days of sunscreen manufacturing, but because of large particle size, were not cosmetically acceptable in high concentrations. Newer technology allowed for micronization of such particles, with an increase in transparency and therefore greater cosmetic acceptability. More recently, chemical agents with greater UVA absorption have been introduced (see below) and are gaining in popularity.

Today, a wide array of sunscreen-containing preparations, including foundations, moisturizers, and lipsticks, are commercially available. Another improvement in sunscreen products has been the development of agents with increased substantivity. Such agents, usually marketed as "sports" products, have bases which persist on the stratum corneum for longer than do the usual bases, allowing for vigorous outdoor activity, sweating, and even swimming with retained photoprotection.

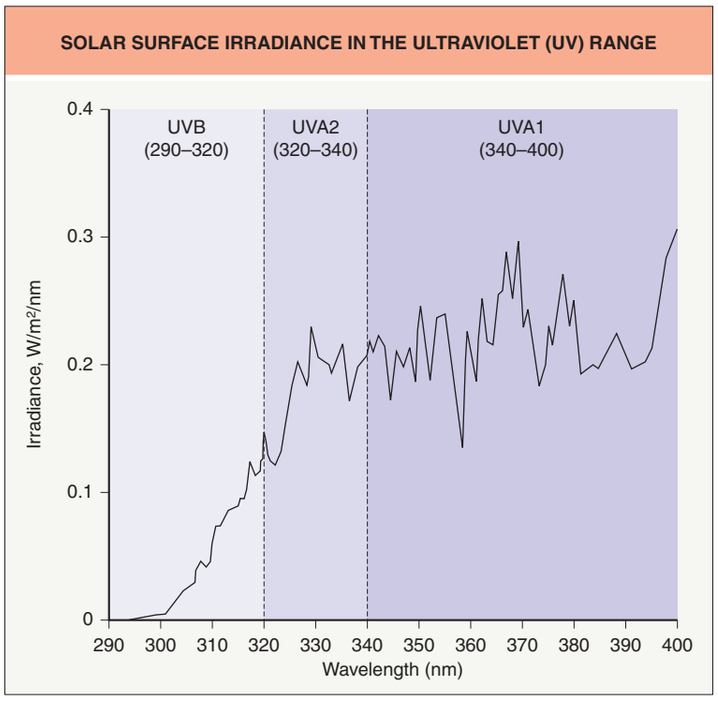

Fig. 132.1 Solar surface irradiance in the UV range. Note that the defined boundary between UVB and UVA differs between the International Commission on Illumination (315 nm) and the FDA (320 nm). *Courtesy Mark Naylor, MD.*

SUNSCREEN REGULATION

Globally, the manufacturing and regulation of sunscreens vary, including efficacy testing and labeling (Table 132.1). Since sunscreens alter the structure or function of skin, they are considered over-the-counter (OTC) drugs in the US and are regulated by the Food and Drug Administration (FDA). FDA regulations include the maximum concentration of active ingredients, safety labeling, and the methodology for determining the sun protection factor (SPF).

Sun Protection Factor (SPF)

Sunscreen efficacy is assessed based upon its SPF, which is determined by cutaneous phototesting utilizing artificial sunlight (Table 132.2). The methodology for measuring SPF, which predominantly represents UVB protection, has been standardized. If properly tested and applied, a product with an SPF of 15 would allow 15 times as much time in the sun with the same resultant level of erythema as without the product in a given individual (by attenuating 93.3% of the UV reaching the skin). Similarly, an SPF 50 product would allow 50 times as much exposure with the same result (via 98% UV blockage). Since the SPF is calculated as a ratio, the theoretical percentage of UV filtering basically levels off at SPF 30 and above (Fig. 132.2).

Testing for UVA Protection

Since scientists became aware of the damage that can be caused by photons longer than 315–320 nm, many attempts have been made to develop a standard method of testing for protecting against long-wave or UVA radiation. Because there is no easily reproducible cutaneous biologic endpoint that is relatively specific for UVA radiation (as erythema is for UVB), photobiologists have suggested a number of assays, including both *in vivo* and *in vitro* methodologies, to determine the UVA protection factor (UVA-PF).

The most commonly utilized human skin-based assays include immediate pigment darkening (IPD) and persistent pigment darkening (PPD), each with endpoints that measure a different aspect of the skin's tanning response to UVA radiation. The former, as discussed in Chapter 86, is dependent upon radiation-induced darkening of pre-existing melanin, while the latter is a more complex response which involves *de novo* synthesis and transfer of melanin. Both endpoints can be produced with relatively small amounts of UVA radiation, making them reasonable for human phototesting. In Japan, the assay for PPD is favored[6].

The most commonly accepted *in vitro* method for assessing UVA protection is the critical wavelength (CW) determination, which is utilized in the European Union, Australia, and the US. This is a relatively simple assay in which the sunscreen is dissolved in solvent and the absorption spectrum is determined by a spectrophotometer. The CW for the product represents the wavelength at which the *cumulative* absorption of solar-simulated radiation above 290 nm is 90%[7] (Fig. 132.3).

Evolution of FDA Sunscreen Standards

In 1999, the FDA published sunscreen regulations for 16 approved active ingredients that included: (1) limiting the maximum allowable SPF value on the label; and (2) changing the terminology for rating substantivity. As a result, manufacturers had to limit their labeling and marketing of efficacy claims regarding protection from sunburn. Methods for testing and labeling UVA protection were not addressed.

Based upon additional input from industry, dermatologists, and photobiologists, the FDA published its Final Rule for "Labeling and Effectiveness Testing: Sunscreen Drug Products for Over-the-Counter Human Use" in 2011. The major label on each product consisted of the SPF value and, if efficacy in the UVA range was deemed sufficient, the term "Broad Spectrum". UVA testing was limited to an *in vitro* CW determination (see Fig. 132.3 & Table 132.1), with a CW ≥370 nm meriting the broad spectrum designation. Substantivity ratings were limited to "Water Resistant (40)" and "Water Resistant (80)", with the number reflecting minutes. The maximum SPF was capped at 50+.

In 2019, the FDA released a proposed rule for a final sunscreen monograph, notable for its provisions regarding evaluation of safety data (Table 132.3). In order to determine that an active ingredient is *g*enerally *r*ecognized *a*s *s*afe and *e*ffective (GRASE), there is a requirement to conduct trials under maximal usage conditions to assess systemic absorption of active ingredients. If an appropriately conducted maximal usage trial detects a steady-state plasma level >0.5 ng/ml, further studies of carcinogenicity as well as reproductive and developmental toxicity may be required. Each of the 16 approved active ingredients was assigned to one of three categories (see Table 132.3): (1) GRASE; (2) not GRASE; or (3) insufficient data to support positive GRASE determination. Currently, the only GRASE ingredients are inorganic zinc oxide and titanium dioxide. The two non-GRASE ingredients, PABA and trolamine salicylate, are no longer marketed in the US. For the remaining 12 organic UV filters, while additional safety data are needed, this does not imply that they are unsafe.

The 2019 proposal also raised the maximum labeled SPF value from 50+ to 60+ (Table 132.4). To ensure sufficient UVA protection, broad spectrum sunscreens would need to possess a UVA1/UV ratio of ≥0.7 in addition to the CW ≥370 nm required in the 2011 monograph (see Fig. 132.3). Updated labeling requirements are designed to make it easier for consumers to locate a sunscreen's active ingredients.

Per the Sunscreen Innovation Act (SIA; 2014), the FDA was required to issue a final sunscreen monograph by November 2019, but the deadline was postponed. Under the 2020 CARES Act, the OTC monograph process was to be reformed. In September 2021, the FDA released a proposed final order for sunscreens that was not substantially different from the 2019 proposal, but it was intended to aid in the transition to the new processes created by the CARES Act[7a].

An additional issue in the US has been the limited number of active sunscreen ingredients approved by the FDA. A process for approval of new sunscreen agents, termed the Time and Extent Application (TEA), is available; studies of efficacy and safety conducted outside of the US are accepted in the application. The SIA mandates timelines for regulatory review of novel sunscreens, especially those that are already marketed in other countries. Nonetheless, to date, the FDA has not approved a new active sunscreen ingredient since 1999.

MECHANISMS OF SUNSCREEN ACTION

When applied properly, sunscreens form a film or coating on the surface of the stratum corneum that attenuates or "filters out" radiation that would otherwise reach the living epidermis and dermis. The active

GLOBAL COMPARISON OF EFFICACY TESTING AND LABELING OF SUNSCREENS					
	US	**Canada**	**European Union**	**Australia, New Zealand**	**Japan**

Ultraviolet A					
Efficacy testing					
• CW ≥370 nm	√	√	√	√	• UVA-PF (*in vitro*) • PPD • PA system
• UVA-PF (*in vitro*) to SPF ratio ≥0.33		√	√	√	
• PPD (*in vivo*) to SPF ratio ≥0.33		√			
Label descriptors	Broad spectrum	Broad spectrum	UVA seal	Broad spectrum	PA+ (2–4), PA++ (4–8), PA+++ (8–16), or PA++++ (>16)

Table 132.1 Global comparison of efficacy testing and labeling of sunscreens. The ratio of ≥0.33 for UVA efficacy means that protection in the UVA range must be at least one-third as great as in the UVB range (SPF). The UVA protection factor (UVA-PF) is calculated from the measured *in vitro* transmittance after irradiation and is weighted with the persistent pigment darkening (PPD) action spectrum and with the "standard" output spectrum of a UVA-filtered solar simulator. CW, critical wavelength; PA, protection grade of UVA; SPF, sun protection factor.

DETERMINATION OF THE SUN PROTECTION FACTOR (SPF)

- 10 human subjects
- Skin type I or II
- Irradiation: light source which mimics solar spectrum
- Procedure: determine minimal erythema dose (MED) in sunscreen-protected* and unprotected skin
- $\text{SPF} = \frac{\text{MED protected}}{\text{MED unprotected}}$
- To test substantivity – after application and before MED testing:
  - Water resistant (40): 2 × 20-min water immersions (whirlpool bath)†
  - Water resistant (80): 4 × 20-min water immersions (whirlpool bath)†

*Sunscreen product applied at 2 mg/cm^2.
†Air drying in between immersions.

Table 132.2 Determination of the sun protection factor (SPF).

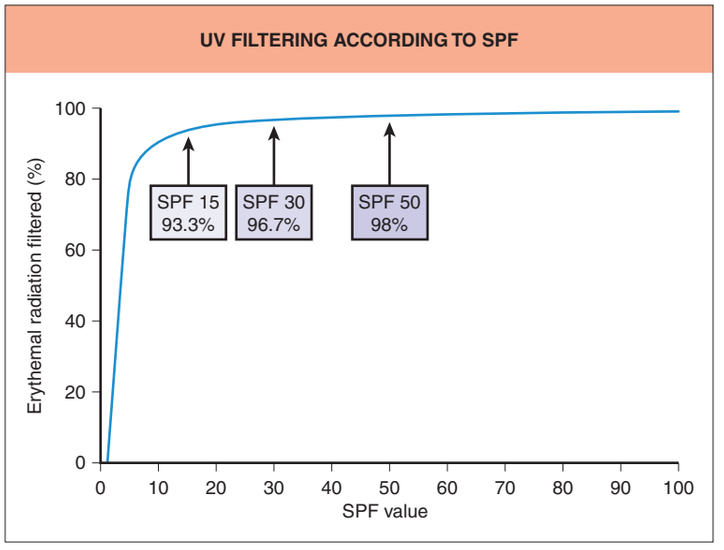

Fig. 132.2 Relationship between sun protection factor (SPF) and the amount of UV radiation that is filtered by a sunscreen. The percentage of UV blockage basically levels off above SPF 30.

agents in sunscreen products do this by either absorbing or scattering photons before they penetrate the skin surface. Nowadays, many sunscreen products contain combinations of agents that work by one or both mechanisms. Active sunscreen ingredients have conventionally been divided into so-called organic "chemical" agents which are water- or oil-soluble and function through photon absorption *versus* inorganic metal oxide "physical" agents which are insoluble and scatter light energy. However, there are limitations and exceptions to this seemingly clear-cut distinction.

When organic sunscreen agents absorb radiation, they are initially raised to a higher-energy, excited molecular state. Upon reverting to their ground state, this stored energy is usually dissipated in the form of heat, which is barely perceptible and non-damaging to the skin. However, some sunscreen agents, once excited, can undergo photochemical reactions with other sunscreen components (e.g. ecamsule), resulting in loss of their photoprotective efficacy. As a result, such agents (particularly avobenzone) lack photostability, i.e. they are deemed to be photolabile. In order to preserve efficacy, sunscreen agents such as avobenzone are combined with photostabilizers (e.g. salicylates, octocrylene).

In the past, opaque topical sun protection products consisting of insoluble metal oxide filters were considered "sunblockers", but since 1999 the FDA has not considered the concept of achieving complete blockage via topical photoprotection to be valid. Whereas *absorption* of solar radiation is directly related to *chemical structure*, optical *physical scattering* (and reflection) by inorganic agents is based primarily on *particle size*. Because sunscreens formulated with large-particle inorganic agents are cosmetically unacceptable due to their opaque appearance, particles are now micronized and the resultant products are significantly less visible. However, there is evidence that within the UV spectrum these inorganic agents such as particulate titanium dioxide, especially when micronized, also exhibit significant direct photon absorption that may be more important than their photon scattering effects[8].

ACTIVE INGREDIENTS IN SUNSCREENS

Currently, most sunscreens contain a combination of two or more agents in order to achieve broad spectrum protection. Fig. 132.4 lists, according to type of activity and spectrum of protection, the active agents currently used in sunscreens[9].

Organic (Soluble) Filters

Para-aminobenzoic acid and derivatives

PABA and its derivatives, including padimate O (octyl dimethyl PABA), are highly effective UVB absorbers. PABA is no longer marketed in the US, due in part to safety concerns.

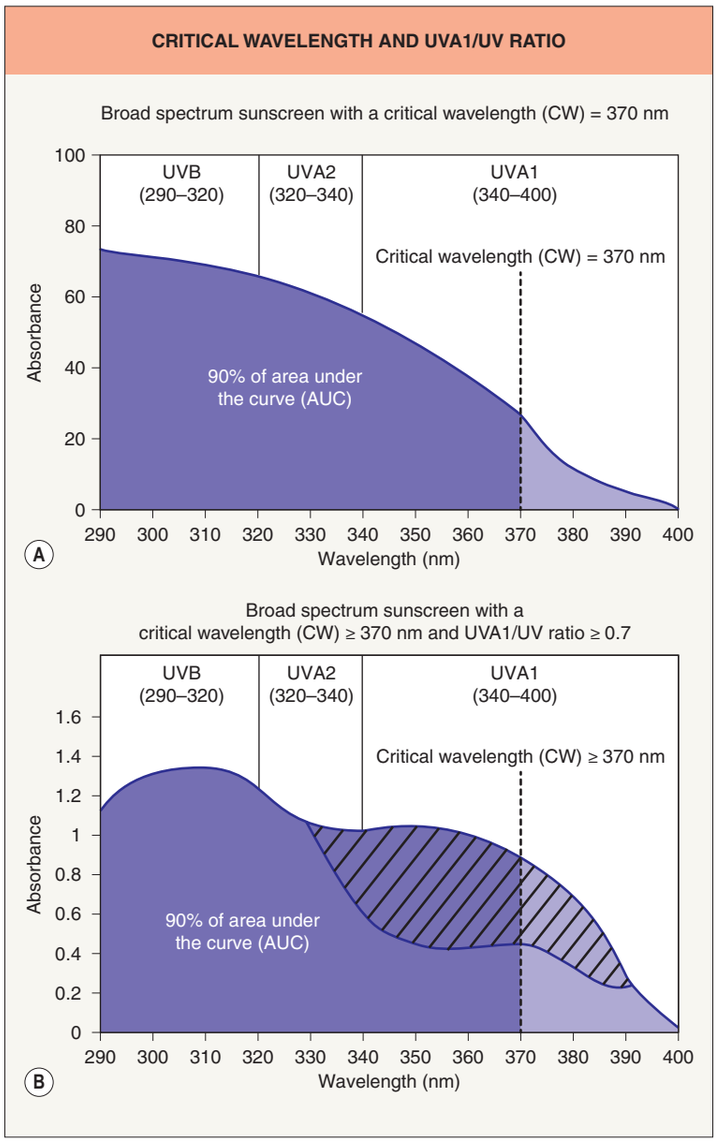

Fig. 132.3 Critical wavelength and UVA1/UV ratio. Critical wavelength (CW) represents the wavelength at which 90% of solar-simulated radiation above 290 nm is cumulatively absorbed by the sunscreen. **A** A broad spectrum sunscreen with CW = 370 nm. **B** A broad spectrum sunscreen with both a CW ≥370 nm and a UVA1/UV ratio of ≥0.7. The area with parallel lines represents the absorption needed for a sunscreen to have a UVA1/UV ratio of ≥0.7. *Adapted from Diffey BL, Tanner PR, Matts PJ, et al. In vitro assessment of the broad spectrum ultraviolet protection of sunscreen products. J Am Acad Dermatol 2000;43:1024–35 and the Federal Register 2019;84:6204–75.*

Cinnamates

Octyl methoxycinnamate (octinoxate) is a good UVB absorber but is not as potent as PABA and its esters. Presently, it is one of the most common sunscreen ingredients in the US.

Salicylates

The salicylates are relatively weak UVB absorbers but have the ability to stabilize other agents, thereby preventing photodegradation. Consequently, they are used in combination with other organic filters and include octisalate, homosalate, and trolamine salicylate. The latter is no longer included in US sunscreens, due in part to safety issues.

Benzophenones

Benzophenones are good UVA absorbers, although their effectiveness is primarily in the UVA2 range. Oxybenzone is the most commonly used agent in this group and actually affords both UVB and UVA protection. Sulisobenzone and dioxybenzone have similar protective spectra but are infrequently utilized.

Other organic filters

Octocrylene is a commonly used UVB filter which is primarily employed to stabilize photolabile agents. *Ensulizole* is likewise a photostable UVB absorber. *Avobenzone* is an excellent UVA filter with absorption well into the UVA1 range, but is very photolabile. It is therefore combined with other agents which assist in stabilizing its protective ability. *Menthyl anthranilate* is a UVA filter with a maximum absorption in the UVA2 range, but its efficacy is relatively weak. *Ecamsule* has maximum absorption at 345 nm, but was FDA-approved for use in only a single line of commercial products.

Agents currently awaiting approval in the US include amiloxate (UVB), enzacamene (4-methyl-benzylidene camphor; UVB), ethylhexyl triazone (UVB), iscotrizinol (UVB and UVA), drometrizole trisiloxane (UVB and UVA), bisoctrizole (UVB and UVA), and bemotrizinol (UVA) (see Fig. 132.4).

Inorganic (Insoluble) Filters

The two major inorganic sunscreens are titanium dioxide and zinc oxide. These inorganic compounds are the sole sunscreens in so-called "chemical-free" products but they are also combined with organic filters. Micronized zinc oxide appears to have better activity in the UVA1 range than does titanium dioxide at comparable concentrations[10]. With the advent of nanotechnology (see below), smaller particles of inorganic agents can be incorporated into sunscreen products.

Other Photoprotective Agents

Dihydroxyacetone is the compound most commonly used in sunless tanners. This agent, which when applied is colorless, binds to and

FDA PROPOSED ORDER (2021) FOR GRASE STATUS OF SUNSCREEN ACTIVE INGREDIENTS AND DOSAGE FORMS			
	GRASE	**Not GRASE**	**Insufficient data to support positive GRASE determination**
Active sunscreen ingredients	Zinc oxide Titanium dioxide	Para-aminobenzoic acid* Trolamine salicylate*	Avobenzone, cinoxate, dioxybenzone, ensulizole, homosalate, meradimate, octinoxate, octisalate, octocrylene, oxybenzone, padimate O, sulisobenzone
Dosage forms†	Lotions, creams, ointments, oils, gels, butters, pastes, sticks, sprays‡	Sunscreen–insect repellent combinations¶	Powders

*Not currently marketed in the US.
†Wipes, towelettes, body washes, shampoos, and other dosage forms are categorized as "new drugs" because the FDA has not yet received enough information about their efficacy and safety.
‡Sprays are approved as GRASE subject to testing, including particle size restrictions to avoid inhalation toxicity; flammability testing; and related safety labeling requirements.
¶Data suggest that combining some sunscreen active ingredients with some insecticides may increase absorption of one or both components. CDC recommends that if applying both a sunscreen and an insect repellent, apply the sunscreen first and then the insect repellent.

Table 132.3 FDA proposed order (2021) for GRASE status of sunscreen active ingredients and dosage forms. Each of the 16 approved active ingredients was assigned to one of three categories: (1) GRASE (*g*enerally *r*ecognized as *s*afe and *e*ffective); (2) not GRASE; or (3) insufficient data to support positive GRASE determination. For the third group, the FDA requires additional information to determine whether or not sunscreens with these ingredients and dosage forms are GRASE. Of note, this does not mean that the FDA has concluded that these ingredients and dosage forms are unsafe. *Adapted from US Food and Drug Administration. Proposed Order (OTC000008): Amending Over-the-Counter (OTC) Monograph M020: Sunscreen Drug Products for OTC Human Use. 2021. https://dps-admin.fda.gov/omuf/omuf/sites/omuf/files/primary-documents/2022-09/Proposed%20Administrative%20Order%20OTC000008_Amending%20M020_Sunscreen_Signed24Sept2021.pdf.*

FDA PROPOSED ORDER ON SUNSCREENS (2021) – ULTRAVIOLET B (UVB) AND ULTRAVIOLET A (UVA) PROTECTION AND LABELING REQUIREMENTS
Ultraviolet B (UVB) protection
• Raise the maximum proposed labeled SPF from 50+ to 60+ • Allow marketing on sunscreen products formulated up to an SPF of 80
Ultraviolet A (UVA) protection

• Require any sunscreen with SPF 15 or higher to be BROAD SPECTRUM
• Requirement for all BROAD SPECTRUM sunscreens with an SPF ≥15: as the SPF increases, so too does the magnitude of protection against UVA
• Require that BROAD SPECTRUM sunscreens provide adequate protection against UVA
  • UV absorbance critical wavelength of ≥370 nm (90% of the area under the curve [AUC])
  • UVA1/UV ratio of ≥0.7

Substantivity*
• WATER RESISTANT (40 minutes) or WATER RESISTANT (80 minutes) • The following designations are prohibited: "WATERPROOF", "SUNBLOCK", "ALL DAY PROTECTION", or "SWEAT PROOF"
Additional labeling
• Include an alphabetical listing of active ingredients on the front of the packaging • If the SPF of the sunscreen is <15, then it must have the following Skin Cancer/Skin Aging Alert: "Spending time in the sun increases your risk of skin cancer and early skin aging. This product has been shown only to help prevent sunburn, not skin cancer or early skin aging" • Require font and placement changes to ensure the terms SPF, BROAD SPECTRUM, and WATER RESISTANT are obvious on the label • Optional: If a sunscreen has an SPF ≥15 *and* is BROAD SPECTRUM, then can state that the product can help to reduce the risk of skin cancer and the risk of early skin aging, when used regularly and as directed in combination with other sun protection measures
*These changes were proposed and implemented in the 2011 FDA final rule for "Labeling and Effectiveness Testing: Sunscreen Drug Products for Over-the-Counter Human Use"

Table 132.4 FDA proposed order on sunscreens (2021) – ultraviolet B (UVB) and ultraviolet A (UVA) protection and labeling requirements. Active ingredient safety nd dosage forms are addressed in Table 132.3. For an explanation of critical wavelength and UVA1/UV ratio, see text and Fig. 132.3. SPF, sun protection factor. *Adapted from US Food and Drug Administration. Proposed Order (OTC000008): Amending Over-the-Counter (OTC) Monograph M020: Sunscreen Drug Products for OTC Human Use. 2021. https://dps-admin.fda.gov/omuf/omuf/sites/omuf/files/primary-documents/2022-09/Proposed%20Administrative%20Order%20OTC000008_Amending%20M020_Sunscreen_Signed24Sept2021.pdf.*

"stains" the stratum corneum to produce a tanned appearance. Although it has a very low SPF, it does offer some protection from long-wave radiation (even into the visible range). Iron oxide offers protection across the UV spectrum and into the visible range, and is used as a colorant in some products (e.g. tinted sunscreens)[11].

Other "active" ingredients have been added to sunscreens, with claims of increasing efficacy of the finished products[9]. The most popular of these are antioxidants, including vitamins E and C and green tea polyphenols, some of which have decreased UV-induced damage in *in vitro* and *in vivo* assays[11a]. However, factors including chemical structure, concentration, and stability in a finished product cannot be determined from package labels, so at this point there are no accepted standards whereby clinicians and consumers can judge efficacy.

SUNSCREEN BENEFITS

An effective sunscreen should protect against sunburn, carcinogenesis, photoaging, photoimmune suppression, and photosensitivity. Efficacy of a given sunscreen product is usually assumed if the combined absorption spectra of the agents in a product match the action spectrum of a given adverse event. The action spectra for the adverse effects of sun exposure are listed in Table 132.5. There is abundant evidence that sunburn, photoaging, keratinocyte carcinoma induction, and photoimmune suppression are all most efficiently produced by UVB radiation. However, studies have shown that for some of these events, UVA also plays a greater or lesser role. For example, UVB is about 1000 times as effective at inducing erythema in human skin as is UVA. On the other hand, photoaging was originally thought to be primarily due to UVB radiation, but UVA penetrates more deeply into the dermis and is likely to have an important role in this process. Similarly, although most studies (in a number of model systems) demonstrated that the maximally effective radiation for inducing photoimmune suppression is in the UVB range, sunscreens providing only UVB protection were not totally effective in blocking this effect[12].

With regard to cutaneous squamous cell carcinoma (SCC), epidemiologic and animal studies, combined with the identification of UVB and UVA "signature" mutations in human SCCs, strongly support causation primarily by UVB, but UVA may also play a role[13]. Most evidence also supports the role of UVB in basal cell carcinoma (BCC) induction, but the action spectrum for melanoma remains controversial. Still, UVB seems the most likely culprit. For example, in transgenic mice in which melanocytes are aberrantly located in the epidermis, a single erythemal (burning) dose to neonatal mice greatly enhanced melanoma formation[14].

It must also be remembered that even though UVA may be less effective at inducing a given event in the skin when compared to UVB, there is 10 to 20 times more UVA than UVB in sunlight. In terms of the relative UV doses received by the skin, this ratio is even higher when an individual wears a UVB-protective sunscreen, especially if the SPF is ≥8; this allows a person to stay in the sun longer and results in relatively higher levels of UVA absorption[15]. Therefore, the use of broad spectrum sunscreens should be a goal of any photoprotection strategy.

Although the effectiveness of the protection of a given product might be predicted from a comparison of the action spectrum (see Table 132.5) versus the absorption spectrum (see Fig. 132.4), the most valid measures of efficacy are prospective studies in human subjects. However, for skin cancer and photoaging, such studies are difficult to conduct because these photobiologic processes have such a long latency period. Animal models can be utilized, as has often been done for photoaging and SCC induction, but their availability has been quite limited for BCC (e.g. mice with only one normal allele for *Ptch*) and melanoma (e.g. opossums). Another approach has been to employ assays that measure the effect of sunscreens on biologic endpoints known to be important pathophysiologic precursors, but before the development of recognizable lesions. Examples would be studying the effects of sunscreens on the development of actinic keratoses or assaying for DNA damage or mutated genes in human skin[15].

Much of the information on sunscreen efficacy is based on retrospective case–control studies. Because of the lower level of validity of these studies, the variability of study design, and especially inherent recall bias, many such studies arrive at conflicting results.

Sunburn

Myriad unpublished SPF studies performed during the pre-marketing testing of sunscreens attest to their ability to prevent sunburn. However, controlled human studies in "real world" settings have found that sunscreen usage does not always prevent sunburn[16]. The major reason for this discrepancy is that individuals actually do not apply sunscreens at the same surface density as is utilized in controlled SPF testing, i.e. 2 mg/cm^2. Some studies have shown that most sunscreen users apply only 20%–50% of that quantity[17]. This means that the SPF is correspondingly reduced, i.e. applying only one-half of the standard amount of an SPF 15 product may result in protection comparable to a product with an SPF of 7.5 or even less[17]. The proper quantity of sunscreen to cover the skin of an adult is ~30–45 ml or 2–3 tablespoons. Strategies to improve compliance include applying the product twice to gain the proper surface density, which also reduces the occurrence of "skip" areas, or to use a product with twice the SPF as desired[18,19]. A recent randomized, double-blind trial demonstrated significantly greater sunburn protection with SPF100+ sunscreen compared to SPF50+ sunscreen during five days under actual use conditions[20].

Photoaging

In an actinic keratosis study, a significant reduction in dermal elastosis was noted with daily sunscreen use over a 2-year period[21]. A shorter-term study found that sunscreens with broad spectrum coverage that extended significantly into the UVA spectrum prevented many biochemical measures of sun damage (from solar-simulated radiation) in human volunteers[22]. More recently, 903 Australian

*Currently not FDA-approved. **This agent was approved for use by the FDA in a single line of commercial products under an Individual New Drug (IND) process. ***Depending on particle size, with micronized particles shifting protection toward UVA2; inorganic filters, especially when micronized, have been shown to function primarily by photon absorption rather than by scattering in the UV range[8] .

Fig. 132.4 Active components of sunscreens. Lighter colored bars represent variable efficacy. "Boosters" that are not UV filters are also added to sunscreen products, e.g. tiny spheres that scatter incoming radiation and agents that increase the spread of the sunscreen on the skin.

adults were studied for a period of 4.5 years. Half were instructed to use sunscreen daily while the remainder were allowed discretionary use of sunscreens. At the conclusion of the study, the daily sunscreen group showed no detectable increase in photoaging whereas skin aging was 24% higher in the discretionary group[23].

Photoimmunologic Suppression

Immune suppression by UV radiation was first reported in animal studies which showed that mice could no longer reject UV-induced skin tumors if they had been irradiated with non-tumorigenic doses of UV before transplantation of the tumors. This immunosuppressive

ACTION SPECTRA FOR PHOTODAMAGE				
Effect	Spectrum of light			Type of evidence
	UVB	UVA	Visible	
Sunburn	++++	+		1
Photoaging	++++	++	?	3,4
Squamous cell carcinoma	++++	+		2,3,4
Basal cell carcinoma	+++	+		2,4
Cutaneous melanoma	++	+		3,4
Photoimmune suppression	++++	++		1,3,4
Photosensitivity	+	+++	+	1 (varies with disease)

Table 132.5 Action spectra for photodamage (relative values). 1, human studies; 2, epidemiologic studies; 3, animal studies; 4, *in vitro* studies of associated biologic endpoints.

effect of UV has been shown to affect delayed-type hypersensitivity and contact sensitivity as well as tumor rejection and it occurs in humans as well as animals[24,25]. While the responsible action spectrum has been shown to be predominantly in the UVB range, in experimental studies UVB sunscreens have not always afforded protection against immune suppression[26]. In an elegantly designed study in a large number of human volunteers, Kelly and colleagues[27] reported that sunscreen did offer some protection against immune suppression but the level of protection was not as great as for sunburn. The researchers quantified photoprotection from immune suppression as the immune protective factor (IPF) and compared the IPF with the erythema protection factor (EPF), a measure similar to SPF. In their study, the IPF was only 4.9, while the EPF was 14.2. The authors postulated that this difference was due to UVA radiation not blocked by the applied sunscreen[27]. Some investigators concerned about the effect of photoimmune suppression on various aspects of human health have suggested that sunscreens should be tested and labeled for IPF as well as SPF, although its clinical relevance is not directly apparent.

Actinic Keratoses and Keratinocyte Skin Cancer

Because of the long latency period for the development of SCC and BCC, the first two prospective studies in humans examining the effect of sunscreen on cancer prevention tracked actinic keratoses, precursors of SCC, as surrogates for SCC development. In a group of 53 individuals with a previous history of actinic keratoses, an SPF 29 sunscreen was applied daily over a 2-year period[28]; the sunscreen-treated group had significantly fewer actinic keratoses over the 2-year period compared with the placebo group. The difference between the two groups with regard to skin cancers was not significant, probably due to the relatively short duration of the trial.

During a single Australian summer, 588 individuals (>40 years of age) were randomized to daily application of an SPF 17 sunscreen versus vehicle cream[29]. A significant reduction in the number of actinic keratoses in the sunscreen-treated group was observed. Several years later, a prospective Australian study compared an active intervention group, in which SPF 17 sunscreen was supplied and its daily use encouraged, against the background rate of sunscreen use in the general population[30]. The number of SCCs was found to be significantly less in the sunscreen-treated group, but there was no difference in the number of BCCs between the two groups. From clinical observations regarding anatomic distribution, the relationship between UV radiation and BCC is known to be more complex than with SCC.

In a prospective trial involving 120 solid organ transplant recipients (all of whom received education regarding sun protection), 60 individuals were given free broad spectrum sunscreen to apply daily to the head and neck, forearms, and hands[31]. Over a period of 24 months in which an average of 5.6 applications per week was recorded, significantly fewer *new* actinic keratoses and SCCs developed in the sunscreen group as compared to the control group. While the baseline actinic keratosis count was equal in the two groups, there was also a significant overall reduction in the number of actinic keratoses and fewer invasive SCCs in the sunscreen group. The reduction in BCCs was not statistically significant.

Cutaneous Melanoma

Developing sunscreen efficacy studies for decreasing the risk of melanoma is difficult and some might not consider them to be ethical. As with SCC and actinic keratoses, a number of researchers have used the development of melanocytic nevi in children as a surrogate marker for melanoma risk. The number of nevi has been related not only to sun exposure in children, but also to an enhanced risk for melanoma[32]. In several retrospective epidemiologic studies, researchers have actually reported that children who used sunscreens had an increased number of nevi[33]. However, in the only prospective controlled study published to date, it was demonstrated that sunscreens could suppress the development of melanocytic nevi[34]. This latter study was conducted over a 3-year period with an SPF 30 sunscreen in a total of 485 Canadian schoolchildren 6 to 9 years of age.

Retrospective case–control studies of melanoma patients have produced conflicting results with regard to sunscreen usage and the risk of developing melanoma. Some of these studies showed a decreased risk, while others actually showed an increased risk. Meta-analyses of the published studies by two different groups concluded that sunscreen usage did not increase the risk of developing melanoma, but the analyses could not confirm a protective effect from using sunscreen[35,36].

This dichotomy of results has led to a significant controversy concerning the use of sunscreens. The controversy is based on two different but related lines of reasoning. The first relates to the action spectrum for induction of melanoma. If in fact the action spectrum for melanoma is in the UVA range (as suggested by studies in fish but not other animal models), then wearing sunscreens with UVB protection will allow individuals to stay in the sun longer and receive larger doses of UVA, thereby increasing their risk of developing melanoma. The second theory is based on the concept that sunscreen usage decreases vitamin D levels in humans. Because vitamin D has been shown to reduce proliferation and increase differentiation of various normal and tumor cells, low vitamin D levels might increase the risk of developing some cancers, including melanoma[37].

However, in a prospective study, 1621 Australians (ages 25–75 years) were randomly assigned to daily or discretionary sunscreen application to the head and arms (in combination with 30 mg β-carotene or placebo supplements) for a period of 4 years[38]. They were then followed for another 10 years, and over that time period, 11 new primary cutaneous melanomas were identified in the daily sunscreen group and 22 in the discretionary group. This represented a reduction in the observed rate in the former group (hazard ratio [HR], 0.50; 95% CI, 0.24 to 1.02; $p = 0.05$); the reduction in invasive melanomas was more substantial: 3 in the daily group versus 11 in the discretionary group.

Photosensitivity Disorders (see Ch. 87)

Some of these reactions are caused by UVB radiation, but the majority of affected individuals react to UVA and/or visible light. Therefore, they require photoprotection with agents that absorb or reflect longer wavelengths and a small number of studies have confirmed the efficacy of such agents[37]. Currently, the most protective formulations appear to be avobenzone- and ecamsule-containing products[39]. Other useful agents include inorganic titanium and zinc oxides and benzophenones. The self-tanners containing dihydroxyacetone in combination with regular sunscreen usage may offer some benefit and iron oxide-containing products may also be helpful. In general, conventional sunscreens are of limited value in patients with cutaneous porphyria because the Soret band includes the violet–blue visible range (see Ch. 49).

SUNSCREEN SAFETY

Sunscreens have been utilized for decades with an excellent safety record, but usage patterns and recommendations have evolved significantly over time. In the past, sunscreens were primarily applied intermittently during times of intense sun exposure; however, as knowledge of their protective effects grew, this led to the current recommendation for daily use. Sunscreens are also incorporated into a broad array of personal care products. In the 2003–2004 National Health and

Nutrition Examination Survey, high exposure to organic UV filters was demonstrated in that oxybenzone was detected in 96.8% of urine samples[40].

The major established adverse effects of sunscreens are minor skin irritation, which is common, and allergic contact dermatitis, which is rare[41]. These reactions are often due to ingredients in the base of the product, such as fragrance or preservatives. Between 1999 and 2009, the organic compounds most often responsible for the rare instances of allergy or photoallergy in North America were oxybenzone and avobenzone[41a]. However, in Europe there has been an increasing number of reports of contact allergy and photocontact allergy to octocrylene. One speculation is that this is due to the use of topical NSAIDs (particularly ketoprofen) which cross-react with octocrylene and benzophenones[42].

Concerns have been raised, especially in the lay press, suggesting that some sunscreen agents are mutagenic or carcinogenic or have adverse hormonal effects in various *in vitro* and animal studies[43]. These concerns relate primarily to retinyl palmitate, benzophenones, and nanoparticle titanium and zinc oxides. Although retinoids are known to be anticarcinogenic, there is evidence that *retinyl palmitate*, when used as an additive in sunscreens and other personal care products, may absorb radiation and could theoretically lead to photodamage. *Nanoparticles* of titanium and zinc oxides could theoretically cause toxicity if they were to penetrate into the dermis, but studies show that such penetration does not occur in normal human epidermis (but can occur via hair follicles)[44]. While nanosized metal oxides may generate reactive oxygen species (ROS) when exposed to UV light, potential toxicity from ROS production is minimized by coating the particles with compounds such as silica or aluminum oxide. Finally, in animal studies, *benzophenones* were found to have estrogen-like effects and there is a single study in which decreased fecundity was reported in men with high exposure to these agents[45].

In 2019–2020, the FDA published two randomized trials assessing plasma concentrations of organic UV filters under maximal use conditions. In the initial pilot study of 24 participants, sunscreens containing avobenzone, oxybenzone, octocrylene, and ecamsule were applied at 2 mg/cm^2 to 75% BSA four times daily for four days[46]. Plasma concentrations of all four filters were >0.5 ng/ml after four applications on day 1. The expanded follow-up study included 48 volunteers who applied sunscreens with six active ingredients (avobenzone, oxybenzone, octocrylene, homosalate, octisalate, and octinoxate), again at 2 mg/cm^2 to 75% BSA, but with a modified dosing protocol of one application on the first day followed by four times daily on days 2–4[47]. All six filters reached systemic concentrations above the threshold following only one application.

The clinical effects of systemic absorption of organic UV filters are presently unknown. At the time of writing, no available data suggest that any organic filters need to be avoided for safety reasons. While ongoing evaluation of sunscreen safety is appropriate, physicians should stress that the overall risk–benefit analysis favors sunscreens as safe and a necessary component of a preventive health strategy. Concerned patients may use physical blockers containing zinc and titanium oxides, acknowledging that a possible association of sunscreen use with frontal fibrosing alopecia has been reported in observational studies, but there is a lack of causal evidence to date to support the relationship[48].

In 2021, a private laboratory undertook a study to examine 293 batches of sunscreens and after-sun products from multiple manufacturers for the presence of benzene, a known carcinogen. Benzene was identified at concentrations >2 ppm (the maximum concentration allowed by the FDA when use is unavoidable) in 4.7% of the products, primarily spray and gel formulations. This was followed by manufacturer recalls[48a].

Environmental Effects

Questions have also been raised as to the possible environmental impact of ubiquitous sunscreen use[49]. Organic UV filters are detectable in surface water throughout the world, even reaching the Arctic[50]. A major concern is that organic filters, in particular oxybenzone, may promote bleaching of coral reefs. Bleaching represents a response to environmental stressors in which corals expel symbiotic algae and turn white; coral death may follow.

A 2016 study reported an association between oxybenzone exposure and coral bleaching under laboratory conditions, as well as *in vitro* toxicity to coral cells[51]. The possibility of conversion of oxybenzone to phototoxic glucoside conjugates by sea anemones and corals has been raised[51a]. However, limited conclusions can be drawn from these results, which may not accurately reflect real-world exposure conditions[52]. Perhaps more importantly, coral bleaching is thought to be primarily driven by climate change, among other factors unrelated to sunscreen[41]. Nonetheless, this study influenced legislation passed in Hawaii and other localities prohibiting sale and distribution of sunscreens containing oxybenzone and octinoxate. In 2021, the FDA published a notice of intent to prepare an environmental impact statement for oxybenzone and octinoxate under the National Environmental Policy Act. While awaiting more definitive data, conscious consumers should be directed to use inorganic filters, which pose fewer environmental concerns.

Sunscreen and Vitamin D Status

Some researchers believe that sunscreens may actually be deleterious to health by blocking the production of vitamin D. The first step in the production of this important nutrient is the photochemical conversion within the epidermis of 7-dehydrocholesterol to previtamin D_3 by UVB radiation (see Fig. 51.11). Sunscreens that are effective at filtering UVB photons can result in decreased levels of vitamin D. However, the majority of human studies that measured serum vitamin D levels in sunscreen users (as compared to non-users) found that the levels, though reduced, remained within the normal range[53]. In addition, studies have shown that darkly pigmented individuals, women, and in the wintertime individuals who live in northerly climes all have reduced levels[54].

Recently, scientists in the fields of nutrition and bone metabolism have presented data suggesting that individuals who have serum vitamin D levels in the low normal range may actually have insufficient vitamin D for optimum health. Some of these studies suggest that not only do these low normal or "insufficient" levels of vitamin D adversely affect good musculoskeletal health, but they may also increase the risk of cancer, immune dysfunction, and a broad range of other diseases[55]. A recent systematic review found an association between vitamin D deficiency (<20 ng/ml) and greater Breslow depth and higher mortality rate in patients with melanoma, but causality has not been established[56].

Controversy has arisen in part because scientists cannot agree on what constitutes the "normal" range for serum 25-OH vitamin D levels and similarly cannot agree on the minimum recommended daily intake for the vitamin. Although vitamin D can be obtained from foods such as fish oils, in developed countries the more common sources are vitamin D-fortified milk and milk products, as well as vitamin supplements. In 2010, the Institute of Medicine issued a consensus statement regarding the recommended dietary allowance for vitamin D – 600 IU per day, except for those over 70 years of age in whom 800 IU per day was recommended. Unfortunately, the tanning salon industry continues to promote the concept that UV light exposure and tanning represent the optimum way to assure healthy vitamin D metabolism[57].

PHOTOPROTECTIVE CLOTHING

The broad range of textiles used in the manufacture of clothing results in highly variable degrees of sun protection. While other countries have mandated the testing required for the labeling of textiles claiming to be photoprotective, no US governmental agencies have regulatory control of such testing. However, the Federal Trade Commission does have the authority to regulate advertising claims regarding the sun protection of textiles.

The European Committee for Standardization published the methodology for determining the UV Protection Factor (UPF). It is based upon *in vitro* spectrophotometric measurements and standards whereby apparel textiles with a UPF >40 (similar to SPF) are labeled "UPF 40+". In addition, UVA transmission needs to be <5%[58]. In the US, textile industry organizations have developed a similar system that covers both UVB and UVA protection. Labeling includes the UPF plus a descriptor, from Good UV Protection (UPF 15–24) to Excellent UV Protection (UPF 40–50+); ratings <15 are not allowed[59].

Important factors that determine the protection afforded by a given textile include fabric porosity, type, color, weight, and thickness as well as the addition of absorbers. In the absence of UPF ratings, porosity is probably the most important factor, with the tighter the weave the greater the protection[60].

PHOTOPROTECTION STRATEGIES AND SUNSCREEN RECOMMENDATIONS

There is ever-increasing evidence that although the public is aware of the damaging effects of sun exposure, there does not seem to be a significant degree of alteration in behavior. Thinking of sunscreens as "the last line of defense" against UV damage to the skin emphasizes the importance of wearing hats and tightly woven clothing and seeking shade when considering the overall approach to sun safety (Table 132.6).

Special Populations

Sunscreens are not approved for use in infants younger than 6 months of age. Concerned parents can therefore limit their infant's time in the sun and use protective clothing. In older children, there is the possibility of using only inorganic filters, e.g. titanium and zinc oxides, in non-nanoparticle formulations. The same can be recommended for concerned pregnant women. In the future, formulations may use nanoparticles that are bioadhesive such that they stay on the skin surface and do not enter hair follicles.

GUIDELINES FOR PHOTOPROTECTION
• Avoid direct sun exposure between 10 AM and 4 PM whenever possible
• Seek the shade to shelter you from direct sun exposure
• Wear protective clothing, hats, and sunglasses whenever possible
• Apply sunscreen to all exposed skin when you will be outdoors
• Use a sunscreen with an SPF 30 or greater that is labeled as BROAD SPECTRUM
• Use up to 1 to 2 ounces of sunscreen to cover exposed skin (in an adult)
• Apply the sunscreen 15 minutes before sun exposure
• Use a water resistant sunscreen if you are going to swim or perspire heavily
• Re-apply sunscreen every 2 hours or after swimming or excessive sweating

Table 132.6 Guidelines for photoprotection. SPF, sun protection factor.
