Biology of the Extracellular Matrix

95

Alexander Nyström and Leena Bruckner-Tuderman

Key features

- Extracellular matrices (ECMs) represent specifically organized networks of collagens, elastin, glycoproteins, and proteoglycans that have distinct structural roles and specific functional properties
- ECMs are biologically active, interact with cells, and regulate their functions during development, regeneration, and normal tissue turnover
- Mutations in ECM genes cause a broad spectrum of human diseases, from Ehlers–Danlos syndrome to epidermolysis bullosa. ECM components are also targeted in autoimmune diseases, e.g., bullous pemphigoid, bullous systemic lupus erythematosus, lichen sclerosus
- The collagen family contains 28 different subtypes. All collagens consist of three polypeptide α-chains folded into a triple helix. In each chain, every third amino acid is glycine (Gly), and thus the sequence can be expressed as $(Gly\text{-}X\text{-}Y)_n$. A hallmark of collagens is the presence of hydroxyproline (Hyp) in the Y position of this repeat sequence. Collagens are expressed in all tissues of the human body, and distinct sets of collagens co-polymerize into highly organized suprastructures, e.g., fibrils and filaments, in a tissue-specific manner
- Elastin provides tissues with elasticity. Elastin monomers contain repetitive hydrophobic sequences and are highly cross-linked. The cross-links between several individual molecules provide both elasticity and insolubility to elastic fibers, which can be stretched by 100% or more and still return to their original form. The elastic fibers in the dermis contain a microfibrillar component that connects the fibers to surrounding structures

INTRODUCTION

The different types of extracellular matrix (ECM) represent specifically organized assemblies of the matrix macromolecules listed in Table 95.1. These macromolecules have characteristic patterns of aggregation into insoluble suprastructures with a high degree of order at successive hierarchic levels[1]. Each of these structures is tissue-specific and adapted to the particular needs of a given tissue. The major constituents are often similar in functionally diverse ECMs. However, various types of less abundant proteins associate with the major ECM components, and differences in their relative composition determine tissue-specific organization of ECM suprastructures. The matrix suprastructures can be compared to alloys, with each having metallurgic properties that differ from each other and those of the pure metals.

Individual ECM macromolecules are usually oligomers composed of one or several polypeptides. Intimate contacts between the subunits are formed by coiled-coil structures, such as the collagen triple helix or supercoiled α-helices comprised of three or more polypeptides. In addition, large matrix macromolecules can be regarded as linear sequences of structural modules that are similar in a large variety of proteins[1]. The modules can be recognized by several cellular receptors, but receptor clustering is determined in a tissue-specific manner, and the response may be different in different tissues.

Our knowledge of matrix macromolecules has increased dramatically due to advances in molecular genetics and proteomics. Numerous molecules have been characterized and their expression, regulation, tissue specificity, and functions discerned[2]. The assembled ECM structures are generally adhesive, enabling the attachment of tissue-specific cells, leukocytes, tumor cells, and even microorganisms (Fig. 95.1). Through integrin-mediated interactions with cells, matrix molecules control cell proliferation, differentiation, and migration, especially during development and regenerative processes. Without contact with the ECM, many cells undergo a form of apoptosis known as *anoikis*. Furthermore, the ECM can function as a reservoir of information; certain proteoglycans and proteins bind growth factors (e.g. transforming growth factor [TGF]-β), releasing and activating them as needed to control cellular functions[2]. To date, mutations in >50 different genes encoding ECM molecules have been found to cause heritable disorders in humans and mice.

COMPONENTS OF THE EXTRACELLULAR MATRIX	
Collagens (28 types)	Laminins (15 types)
Elastin	Proteoglycans (Table 95.3)
Fibrillins (3 types)	Glycoproteins (Table 95.4)
LTBPs (4 types)	Integrins
Fibulins* (7 types)	Enzymes that modify ECM assemblies
*Fibulins are believed to function as intra-molecular bridges that stabilize ECM structural networks (e.g. elastic fibers, microfibrils, basement membrane structures).	

Table 95.1 Components of the extracellular matrix (ECM). They belong to several protein superfamilies, and the molecules assemble into mixed fibrils and networks in a tissue-specific manner. Integrins are the main cellular receptors for the ECM. LTBP, latent TGF-β binding protein.

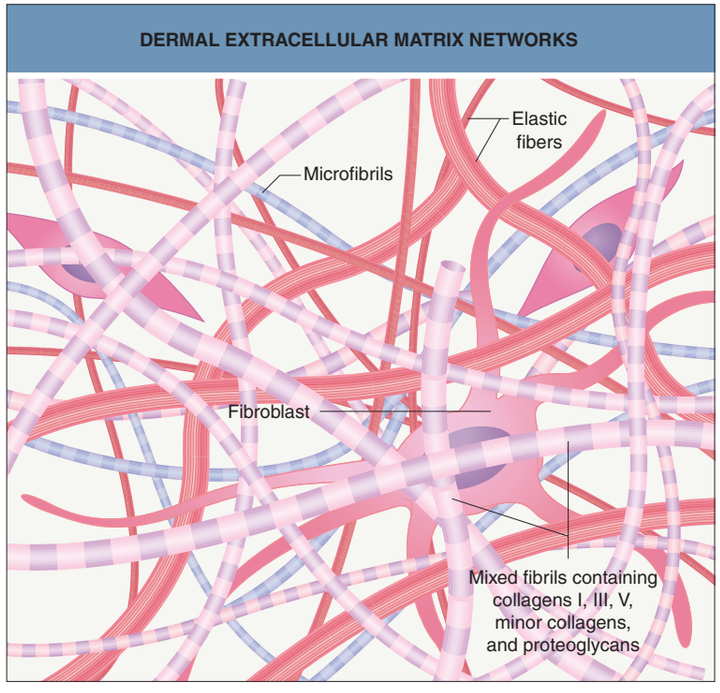

Fig. 95.1 Dermal extracellular matrix networks. Different molecules polymerize into distinct fibril networks and within the mesh of the networks, cells are embedded in the amorphous extrafibrillar matrix. The fibril networks interact with each other, with the extrafibrillar matrix and with the cells. These networks have a dual function: support of the tissue and regulation of cellular functions.

STRUCTURE AND FUNCTION OF THE EXTRACELLULAR MATRIX

Collagens

Collagens play an important role in maintaining the integrity of most tissues. The collagen family includes 28 proteins formally defined as collagens[3] (Table 95.2); they contain 44 distinct polypeptide chains, each encoded by a different gene. At least 15 other proteins have collagen-like domains, e.g. macrophage scavenger receptor 1 and 2, ectodysplasin, pulmonary surfactant proteins.

Collagen triple helix

All collagens consist of three polypeptide chains, known as α-chains, which are folded into a triple helix. In some collagens, the α-chains are identical (homotrimers), while others contain two or three different α-chains (heterotrimers). In the collagenous repeat of each polypeptide chain, every third amino acid is glycine (Gly). The sequence of an α-chain can be expressed as $(Gly\text{-}X\text{-}Y)_n$, where X and Y represent other amino acids and *n* varies according to the length of the repeat. Proline (Pro) and hydroxyproline (Hyp) residues commonly occupy the X and Y positions, respectively, and hydrogen bonds between the hydroxyl groups of Hyp contribute to the stability of the helix. The prototype

THE COLLAGEN FAMILY OF PROTEINS			
Type	**Chains**	**Gene**	**Tissue distribution**
Fibril-forming collagens			
Collagen I	α_1(I), α_2(I)	*COL1A1, COL1A2*	Skin, most ECM
Collagen II	α_1(II)	*COL2A1*	Cartilage, vitreous humor
Collagen III	α_1(III)	*COL3A1*	Skin (including fetal skin), lung, vasculature
Collagen V	α_1(V), α_2(V), α_3(V)	*COL5A1, COL5A2, COL5A3*	Skin, with collagen I heterotypic fibrils
Collagen XI	α_1(XI), α_2(XI)	*COL11A1, COL11A2*	With collagen II heterotypic fibrils
Collagen XXIV	α_1(XXIV)	*COL24A1*	Developing bone and cornea
Collagen XXVII	α_1(XXVII)	*COL27A1*	Cartilage, eye, ear, lung
FACITs			
Collagen IX	α_1(IX), α_2(IX), α_3(IX)	*COL9A1, COL9A2, COL9A3*	With collagen II heterotypic fibrils
Collagen XII	α_1(XII)	*COL12A1*	Skin, tissues containing collagen I
Collagen XIV	α_1(XIV)	*COL14A1*	Skin, tissues containing collagen I
Collagen XVI	α_1(XVI)	*COL16A1*	Skin, many tissues
Collagen XIX	α_1(XIX)	*COL19A1*	Basement membranes, fetal muscle
Collagen XX	α_1(XX)	*COL20A1*	Skin, cornea, cartilage, tendon
Collagen XXI	α_1(XXI)	*COL21A1*	Many tissues, including skin
Collagen XXII	α_1(XXII)	*COL22A1*	Tissue junctions (including between the anagen hair follicle and dermis)
Basement membrane collagen			
Collagen IV	α_1(IV), α_2(IV), α_3(IV), α_4(IV), α_5(IV), α_6(IV)	*COL4A1, COL4A2, COL4A3, COL4A4, COL4A5, COL4A6*	All basement membranes, isoforms vary Skin: α_1(IV), α_2(IV), α_5(IV), and α_6(IV)
Microfibrillar collagen			
Collagen VI	α_1(VI), α_2(VI), α_3(VI)	*COL6A1, COL6A2, COL6A3, COL6A5,COL6A6*	Skin, other microfibril-containing tissues
Network-forming collagens			
Collagen VIII	α_1(VIII), α_2(VIII)	*COL8A1, COL8A2*	Skin, subendothelial matrices
Collagen X	α_1(X)	*COL10A1*	Hypertrophic cartilage
Anchoring fibril collagen			
Collagen VII	α_1(VII)	*COL7A1*	Skin, mucous membranes, cornea
Transmembrane collagens			
Collagen XIII	α_1(XIII)	*COL13A1*	Skin, many tissues
Collagen XVII	α_1(XVII)	*COL17A1*	Skin, mucous membranes, cornea
Collagen XXIII	α_1(XXIII)	*COL23A1*	Lung, cornea, brain, skin, tendon, kidney
Collagen XXV	α_1(XXV)	*COL25A1*	Brain, neurons
Multiplexins			
Collagen XV	α_1(XV)	*COL15A1*	Many tissues; parent molecule of restin*
Collagen XVIII	α_1(XVIII)	*COL18A1*	Many tissues, including skin, subendothelial matrices; parent molecule of endostatin*
Other collagens			
Collagen XXVI	α_1(XXVI)	*COL26A1*	Testis, ovary
Collagen XXVIII	α_1(XXVIII)	*COL28A1*	Schwann cells; fetal skin and calvaria

*Inhibitors of angiogenesis.

Table 95.2 The collagen family of proteins. The names of types found in the skin are in ***bold italics***. Multiplexins are collagens with multiple triple helix domains and interruptions. ECM, extracellular matrix; FACITs, fibril-associated collagens with interrupted triple helices.

collagen (type I) has an uninterrupted Gly-X-Y repeat sequence of almost 1000 amino acid residues; this forms a rigid, rodlike structure with a diameter of 1.5 nm and length of 300 nm. In some collagens, the $(Gly\text{-}X\text{-}Y)_n$ repeats are interrupted by one or more amino acids. The interruptions may be numerous and longer than the $(Gly\text{-}X\text{-}Y)_n$ repeats and they provide the molecule with flexibility, which is important for its specific functions[3].

Biosynthesis of collagens

Collagen biosynthesis involves a number of post-translational modifications (Fig. 95.2). Some collagens are first synthesized as procollagens that have propeptide extensions at their N-terminus, C-terminus, or both. The main intracellular steps in collagen biosynthesis include the following:

- cleavage of signal peptides
- hydroxylation of certain Pro and lysine (Lys) residues to 4-Hyp, 3-Hyp, and hydroxylysine (Hyl)
- glycosylation of some of the Hyl residues to galactosyl-Hyl and glucosylgalactosyl-Hyl
- glycosylation of certain asparagine residues
- association of the α-chains in a specific manner
- formation of intra- and interchain disulfide bonds
- folding of the triple helix

After the chains have become associated and sufficient Hyp residues have been formed in each chain, a nucleus of the triple helix forms (usually in the C-terminal region), and the triple helix propagates towards the other end of the molecule in a zipper-like fashion[4]. The procollagen molecules are then transported from the endoplasmic reticulum across the Golgi apparatus without leaving the lumen of the Golgi cisternae. During this transport, the triple helices begin to aggregate laterally and form early fibrils ready for secretion[5]. The folding and transport of these large, rigid collagens require special machinery[6,7]. Deficiencies in the proteins that interact with collagens during these intracellular events can lead to phenotypes similar to collagen deficiency disorders[8]. The *extracellular* steps in biosynthesis include cleavage of the N- and/or C-terminal propeptides, assembly into suprastructures with other collagens and non-collagenous components, and formation of covalent cross-links.

The specific enzymes involved in the biosynthesis of collagens include prolyl-4-hydroxylase and prolyl-3-hydroxylase, which hydroxylate Pro residues to Hyp, and three lysyl hydroxylases, which hydroxylate Lys residues to Hyl. These enzymes require O_2, Fe^{2+}, α-ketoglutarate, and ascorbate as cofactors. In the rough endoplasmic reticulum, glycosyltransferases add glucosylgalactosyl disaccharides onto the α-chains. The same intracellular enzymes modify all collagen chains[4], whereas extracellular processing enzymes have a higher substrate specificity. Procollagen I N-proteinase cleaves the N-propeptide of procollagens I and II. This enzyme is a member of the disintegrin and metalloproteinase (ADAM) proteinase family and is also referred to as ADAM with *t*hrombospondin type 1 motif (ADAMTS)-2. Procollagen C-proteinases that cleave the C-propeptide of collagens I, II, III, V, and VII belong to the astacin family and include bone morphogenetic protein-1 (BMP-1) and tolloid-like proteins; meprins in this family can cleave both N- and C-termini of collagens[9].

Cross-linking between collagen molecules involves the ε-amino groups of Lys and Hyl and is catalyzed by lysyl oxidase, a copper-requiring enzyme[4]; this process can be regulated by proteoglycans[10]. Another enzyme that catalyzes cross-linking of some collagens is tissue transglutaminase[3].

The collagen family

The length and continuity of the triple helical domains vary among the collagen types. For practical purposes, the collagens have been divided into groups according to their ability to form supramolecular aggregates (Fig. 95.3). The types and tissue distributions of the collagens in each group are listed in Table 95.2, and more detailed information is available in reviews[1,3,4].

Collagens of the skin

Collagens account for 75% of the dry weight and 20%–30% of the volume of the dermis. Different collagens polymerize into distinct suprastructures and have specific functions in the dermis as well as in epidermal and vascular basement membranes. Collagen fibrils are always mixtures of several collagens and other molecules, e.g.,

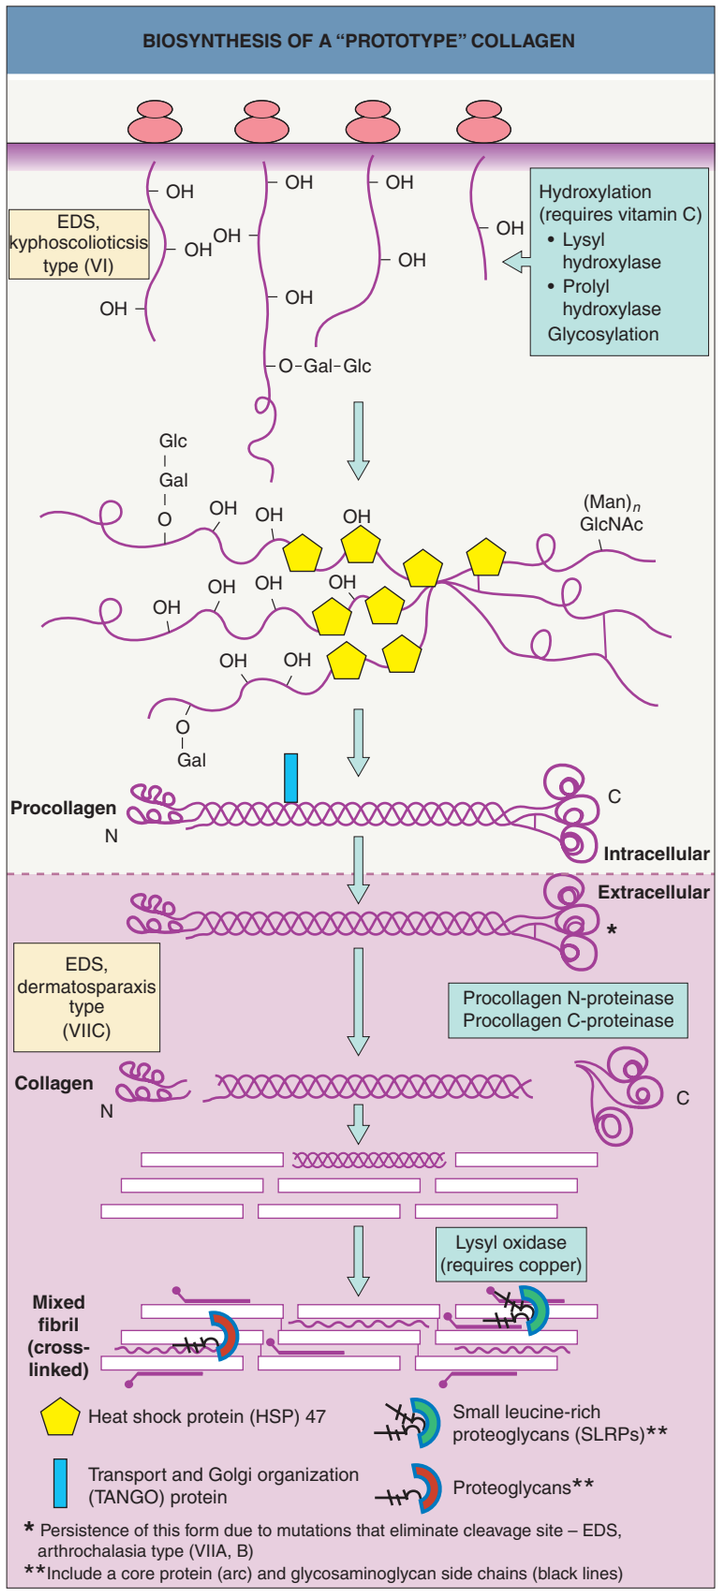

Fig. 95.2 Biosynthesis of a "prototype" collagen. The procollagen α-chains are synthesized by ribosomes in the rough endoplasmic reticulum (ER). Already during the synthesis of the nascent polypeptide, certain prolyl and lysyl residues are hydroxylated and modified by glycosylation. Three α-chains associate to form a trimer and fold into a triple helix. This process is facilitated by heat shock protein (HSP) 47, a collagen-specific molecular chaperone in the ER. The transport and Golgi organization (TANGO) protein 1 mediates secretion of the newly formed triple helical procollagen into the extracellular space, where the N- and C-terminal propeptides are cleaved by specific proteases. The mature collagen molecules assemble to form mixed fibrils with other collagens and non-collagenous molecules. The suprastructures are stabilized by covalent cross-links. Small leucine-rich proteoglycans (SLRPs) and other proteoglycans have roles in the regulation of collagen fibrillogenesis and cross-linking. EDS, Ehlers–Danlos syndrome. *Adapted from Myllyharju J, Kivirikko KI. Collagens, modifying enzymes and their mutations in humans, flies and worms. Trends Genet 2004;20:33–43.*

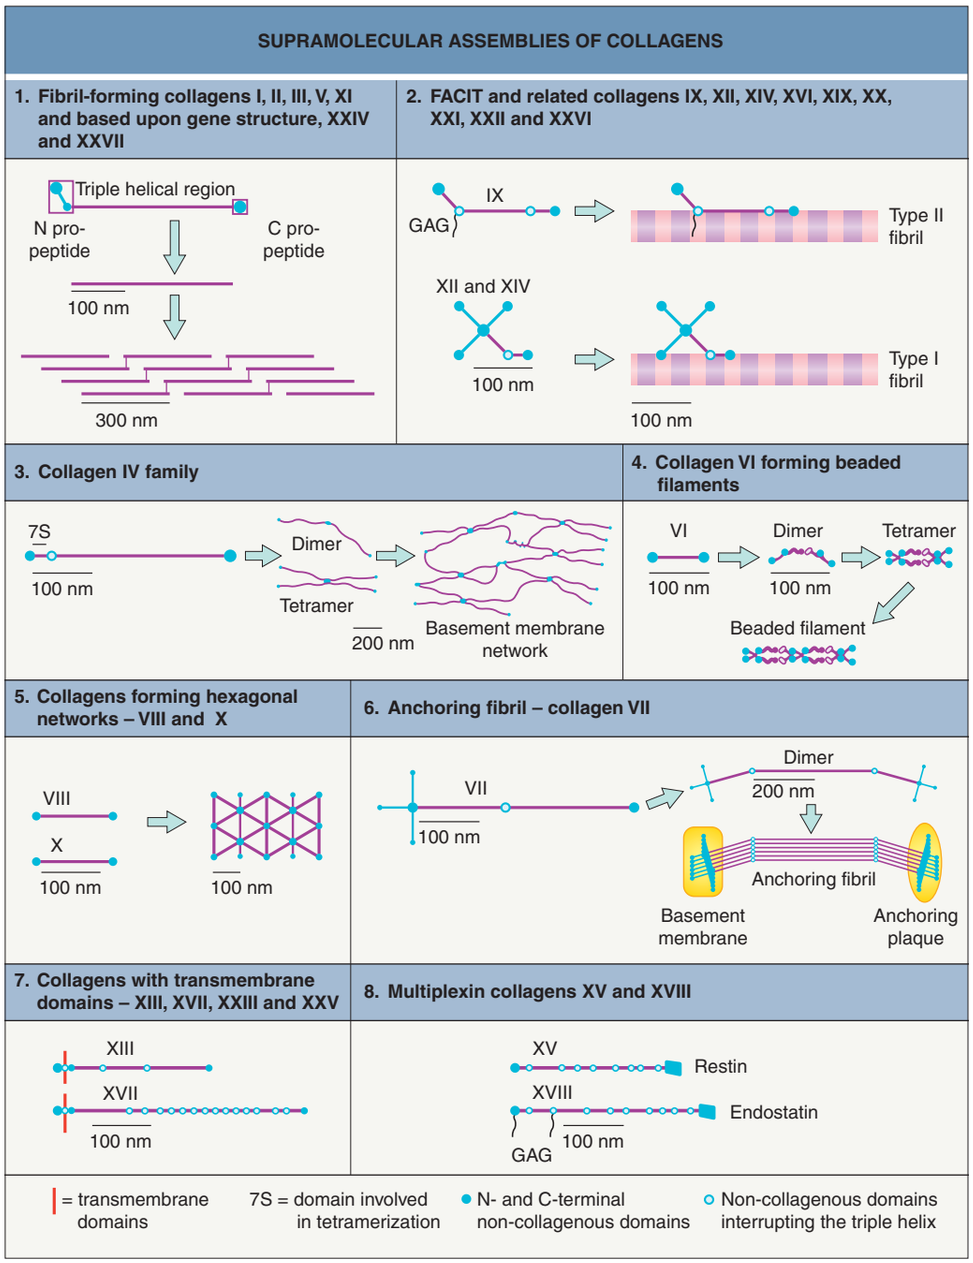

Fig. 95.3 Supramolecular assemblies of collagens. The suprastructures formed by different collagens are shown. Non-collagenous components also interact with the fibrils and networks. The suprastructural organization of the transmembrane collagens XIII and XVII and the multiplexin collagens XV and XVIII is not known yet (panels 7 and 8). These collagens are in close vicinity to basement membranes and are likely to participate and/or interact with the different basement membrane networks. FACIT, fibril-associated collagens with interrupted triple helices; GAG, glycosaminoglycans. *Adapted from Myllyharju J, Kivirikko KI. Collagens, modifying enzymes and their mutations in humans, flies and worms. Trends Genet 2004;20:33–43.*

proteoglycans[1]. Classic, ultrastructurally recognizable, cross-banded fibrils in the dermis contain collagens I, III, V, XII, and XIV. The characteristic cross-banding with a periodicity of 64 nm results from precise lateral packing of the different collagens within the fibrils (Fig. 95.4; see Fig. 95.3). Collagen I is the major component of the fibrils, and the amount of other collagens varies. For example, during embryonic development and wound repair, the relative content of collagen III increases.

Collagen VI, a highly glycosylated and disulfide-bonded collagen, is a component of almost all tissues, including the skin. *In vitro*, it polymerizes to form beaded filaments (see Fig. 95.3), but *in vivo* in the dermis, the ultrastructure of the collagen VI fibrils is reminiscent of microfibrils.

The collagen IV molecules in different basement membranes contain six genetically distinct but structurally homologous α-chains, which form three major networks – α_1/α_2, $\alpha_3/\alpha_4/\alpha_5$, and $\alpha_1/\alpha_2/\alpha_5/\alpha_6$[3]. In the skin, the α_1/α_2 network dominates within the dermal–epidermal junction (see Ch. 28), but the $\alpha_1/\alpha_2/\alpha_5/\alpha_6$ network is also present[11].

Two collagens are essential for the cohesion of the epidermis and dermis (see Ch. 28). Collagen VII is the major, if not sole, component of the anchoring *fibrils* that connect the basement membrane to the dermal ECM. Collagen XVII (also known as bullous pemphigoid antigen 2) is a component of the anchoring *filaments* that bind the basal keratinocytes to the lamina densa of the basement membrane. It is a transmembrane collagen in type II orientation with a long extracellular C-terminal region containing a multiply-interrupted triple helix referred to as collagenous domains 1–15 (see Fig. 31.9). The ectodomains of collagen XVII can be cleaved by transmembrane proteases and then shed, a process important for regulating cell adhesion and migration. Basal keratinocytes also express other transmembrane collagens, such as collagens XIII, a component of focal contacts, and XXIII[12].

The vascular basement membranes in the skin contain collagens VIII and XVIII. Collagen VIII forms hexagonal networks (see Fig. 95.3) below the endothelial basement membranes, thereby strengthening the vascular wall. Collagen XVIII is present in both epidermal basement membranes and the dermal side of vascular basement membranes. Its C-terminal fragment, endostatin, is proteolytically released from the collagen molecule and has independent antiangiogenic and anti-scarring activities[3].

Most collagens in the skin are synthesized by dermal fibroblasts. Exceptions include: (1) collagen XVII, a surface component of epidermal keratinocytes; (2) collagen VII, which is synthesized by both keratinocytes and fibroblasts; and (3) collagens VIII and XVIII, which can also be produced by endothelial cells. Several genetic and acquired diseases are associated with abnormalities of skin collagens or the enzymes that process them (see Table 95.5 & 95.6 and below).

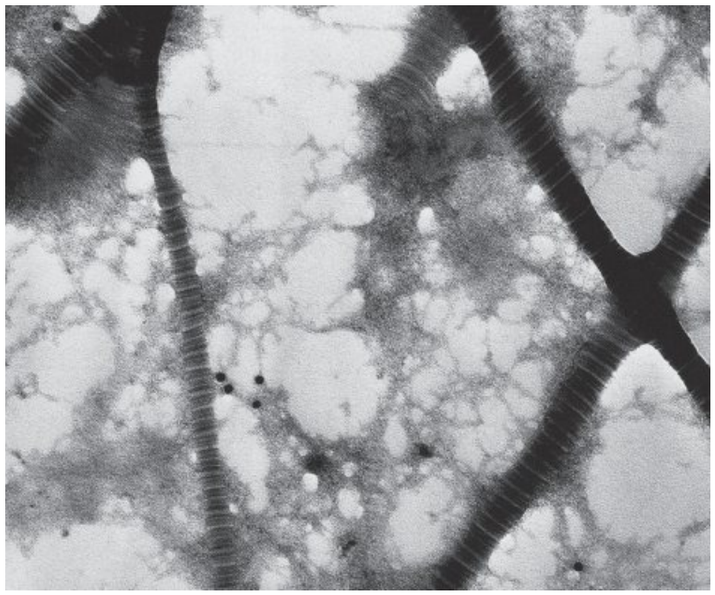

Fig. 95.4 Fibrillar and filamentous networks extracted from human skin. The large cross-banded fibrils represent dermal mixed fibrils containing collagens I, III, V, other minor collagens, and decorin (a proteoglycan). The cross-banding has a characteristic periodicity of 64 nm. The filamentous network in the background contains microfibrillar and basement membrane components. In this immuno-electron photomicrograph, the black dots are colloidal gold particles coupled to anti-collagen IV antibodies, indicating that basement membrane networks are strongly associated with the dermal fibrillar networks. *Courtesy Dr Uwe Hansen.*

Elastic Fibers

The elasticity of many tissues, including the skin, depends upon the structure of elastic fibers, which have variable compositions. A characteristic property of these fibers is that they can be stretched by 100% or more and still return to their original form. Their main components are elastin and microfibrils.

Elastin

Elastin is a highly cross-linked protein[13]. Its monomer, tropoelastin, exists in several tissue-specific splice variants. Ala- and Lys-rich repeats form critical cross-linking domains within a background of hydrophobic amino acid repeats. Lysyl oxidase, the same enzyme that catalyzes collagen cross-linking, catalyzes the formation of desmosine cross-links between elastin molecules, which account for the elasticity and insolubility of the elastic fibers. Elastin makes up ~90% of mature elastic fibers. During fiber assembly, tropoelastin self-assembles and interacts with fibulins 4 and 5, fibrillin 1, and microfibril-associated glycoprotein-1 (MAGP-1). A model for this spatially and temporally regulated process is shown in Fig. 95.5[13].

Microfibrils

Microfibrils (10 to 12 nm in diameter) insert into the basement membrane in a perpendicular orientation (classically referred to as "oxytalan fibers") and extend into the papillary dermis, where they gradually merge with the elastic fibers that form a plexus parallel to the dermal–epidermal junction (classically referred to as "elaunin fibers"). These fibers appear to be continuous with the elastic fibers in the reticular dermis, which contain more abundant elastin. Microfibrils consist mainly of fibrillins[13] but also contain and associate with other

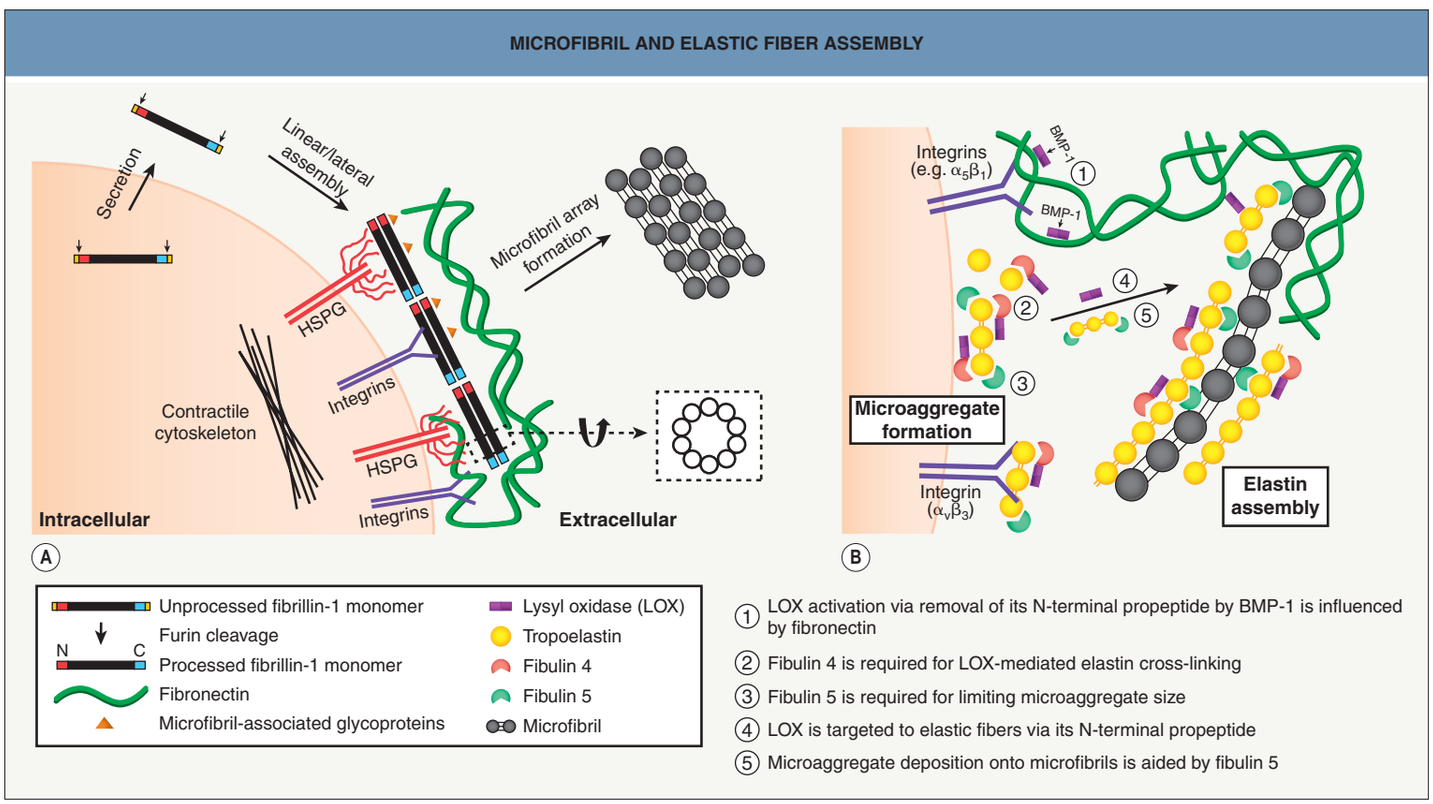

Fig. 95.5 Microfibril and elastic fiber assembly. A Following secretion of fibrillin 1, its N- and C-termini are processed by furin and then interact homotypically; this leads to axial and lateral fibrillin 1 assembly to form microfibrils. Beads may arise from folding of terminal regions, and transglutaminase cross-links provide stabilization. Fibronectin is thought to act as a microfibril assembly template and/or to facilitate assembly at fibrillar adhesions by stimulating cytoskeletal tension through $\alpha_5\beta_1$ integrin. Fibrillin 1 interacts with $\alpha_5\beta_1$, $\alpha_v\beta_3$, and $\alpha_v\beta_6$ integrins during microfibril assembly. Heparan sulfate proteoglycans (HSPGs) are thought to facilitate cell surface–fibrillin 1 interactions, and heparin inhibits microfibril assembly. Fibrillin 1 also binds microfibril-associated glycoproteins, tropoelastin, fibulins, and latent transforming growth factor (TGF)-β binding protein. **B** Elastic fiber formation includes pericellular elastin "microassembly" and subsequent "macroassembly" on a microfibrillar scaffold. Secreted tropoelastin forms globules at the cell surface, which become cross-linked by lysyl oxidase (LOX); this process may involve $\alpha_v\beta_3$ integrin interactions with tropoelastin, as well as interactions of HSPGs with integrins and tropoelastin. Fibulin 4 and fibulin 5 contribute to elastin cross-linking by lysyl oxidase and are also thought to direct the deposition of elastin globules onto preformed fibrillin-containing microfibrils, thereby forming elastic fibers. Microfibrils and elastic fibers are important matrix storage sites for bone morphogenic proteins (BMPs) and latent TGF-β1. *Adapted from Baldwin AK, Simpson A, Steer R, et al. Elastic fibres in health and disease. Expert Rev Mol Med 2013;15:e8.*

proteins, such as MAGPs, latent TGF-β binding proteins (LTBPs), fibulins, elastin microfibril interface (EMILIN)-1, and (in the papillary dermis) collagen XVI[3,13]. Fibrillins 1–3 are large glycoproteins that contain both epidermal growth factor (EGF) and cysteine (Cys) repeats. The EGF repeats bind calcium, which is required for protein stabilization. Fibrillin 1 interacts with perlecan in the epidermal basement membrane to attach microfibrils to the dermal–epidermal junction. Fibrillin interactions with heparan sulfate proteoglycans and integrin receptors also contribute to microfibril assembly (see Fig. 95.5)[13,14].

In addition to guiding elastic fiber assembly and providing structural support, fibrillins function together with LTBPs to regulate cell signaling[13]. The four members of the LTBP family are high-molecular-weight glycoproteins characterized by EGF-like and 8-Cys repeats, and they all associate with the small latent complex of TGF-β (see below; Fig. 95.6). The LTBP-1/latent TGF-β complex (referred to as the large latent complex) binds to fibrillin-containing microfibrils. Together, they control the bioavailability of TGF-β in the skin and other tissues. LTBPs contain multiple proteinase-sensitive sites, providing the means to solubilize the large latent complex from ECM structures. Another group of signaling molecules that can bind to fibrillins are bone morphogenetic proteins (BMPs)[13]. BMPs are secreted as cross-linked dimeric complexes that are associated through their prodomains, which interact directly with the N-terminus of fibrillin. Fibrillins and LTBPs, therefore, have important roles in targeting latent, activatable TGF-β and BMPs into different ECMs. Thus, microfibrils serve not only as a force-bearing element and scaffolding for elastin deposition in the dermis, but also as an important repository for signaling molecules in the skin[2,13].

The Extrafibrillar Matrix

The dermal fibril networks and cells are embedded in an amorphous extrafibrillar material that binds water and provides the hydrated consistency of the skin. Previously, this amorphous material was presumed to be biologically unstructured and inert and was called "ground substance". This prediction turned out to be incorrect; the extrafibrillar matrix is molecularly and structurally diverse, highly organized, and biologically active. It contains a number of proteoglycans and glycoproteins, hyaluronic acid, and water. The functions of the extrafibrillar matrix are adapted to the biologic needs of each tissue. For example, during embryonic development, water-binding proteoglycans and glycosaminoglycans (GAGs) provide a hydrated milieu for cell migration and proliferation. During development and tissue remodeling, glycoproteins of the extrafibrillar matrix are essential for the formation of the correct tissue architecture.

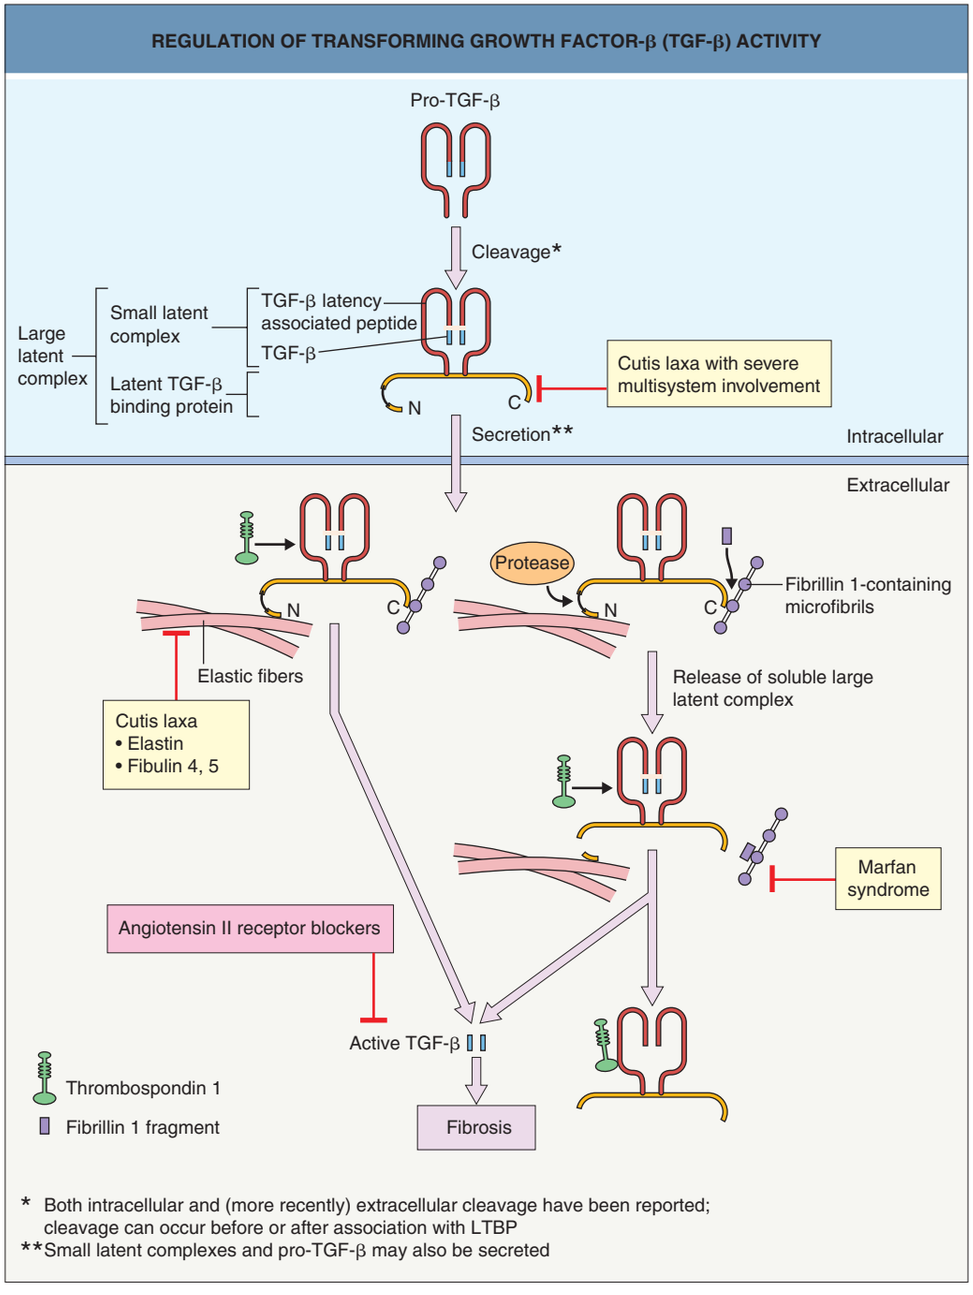

Fig. 95.6 Regulation of transforming growth factor-β (TGF-β) activity. TGF-β is synthesized as an inactive homodimeric propeptide, pro-TGF-β. After cleavage, mature TGF-β is sequestered in an inactive form via its continued association (now noncovalent) with the latency-associated peptide (LAP; forming the small latent complex) and covalent linkage of the LAP to the latent TGF-β binding protein (LTBP; forming the large latent complex). In addition, the large latent complex becomes attached to the extracellular matrix (ECM) via covalent linkage of the LTBP N-terminus with ECM proteins and noncovalent association of the LTBP C-terminus with fibrillin 1 (a member of the LTBP/fibrillin superfamily). Solubilization of the large latent complex from the ECM can occur via proteolytic cleavage of susceptible hinge regions within the LTBP and disruption of the fibrillin 1–LTBP interaction by fibrillin 1 fragments. Binding of ECM glycoproteins such as thrombospondin 1 to the LAP results in the release of active TGF-β that can bind to its receptors and promote fibrosis. *Adapted from August P, Suthanthiran M. Transforming growth factor beta signaling, vascular remodeling, and hypertension. N Engl J Med 2006;354:2721–3.*

Glycosaminoglycans and proteoglycans

GAGs are polysaccharides composed of sulfated and acetylated sugars with negative charges that bind large amounts of ions and water. The most prominent and ubiquitous *protein-free* GAG is hyaluronic acid, a giant polysaccharide composed of thousands of N-acetylglucosamine/glucuronic acid disaccharides. However, other GAGs bind to proteins via a serine hydroxyl group, forming proteoglycans (Fig. 95.7)[15]. There are four classes of proteoglycans based upon their tissue localization: intracellular, cell-surface, pericellular, and extracellular[15]. Proteoglycans differ remarkably in their protein content as well as the number, type, and length of their GAG side chains (Table 95.3).

Four known GAGs can bind proteins to form proteoglycans; they are chondroitin sulfate, dermatan sulfate, keratan sulfate, and heparan sulfate[15]. The correct balance of chondroitin sulfate and dermatan sulfate is necessary for skin function and integrity[16]. Versican, which contains these two GAGs, is an important dermal proteoglycan that can be synthesized by fibroblasts, smooth muscle cells, and epithelial cells. It is associated with the elastic fiber system and forms large complexes with hyaluronic acid, which provide the skin with its tautness (see Fig. 95.7).

Heparan sulfate chains sequester growth factors (e.g. fibroblast growth factors [FGFs], vascular endothelial growth factors [VEGFs]) and present them to their receptors. Perlecan is a major heparan sulfate-containing proteoglycan found in all basement membranes, including the epidermal basement membrane. Collagen XVIII, a collagen/heparan sulfate hybrid, is also present in epidermal and vascular basement membranes as well as the skin[17]. Syndecans are transmembrane heparan sulfate proteoglycans that control cell adhesion to the ECM and cytoskeletal organization. Syndecans 1, 2, and 4 are expressed in the skin and can be found in keratinocytes, dendritic cells, and fibroblasts, where they are thought to mediate "outside-in" cell signaling[15]. Glypicans are membrane-anchored heparan sulfate proteoglycans that interact with growth factors and other extracellular proteins in the skin to regulate developmental and regenerative events[18].

Small leucine-rich proteoglycans (SLRPs) have a protein core of Leu-rich repeats and Cys-bonded loops, with one to five GAG chains. Decorin and biglycan are SLRPs that have multiple functions in the skin via interactions with a variety of proteins, including collagen fibrils (thereby regulating fibrillogenesis), receptor tyrosine kinases, and TGF-β. SLRPs, hyaluronic acid, and versican modulate inflammatory responses through Toll-like receptor signaling[19]. Fibromodulin, keratocan, and lumican are other SLRPs involved in collagen fibril formation, and fibromodulin also regulates intermolecular collagen cross-linking[10,15].

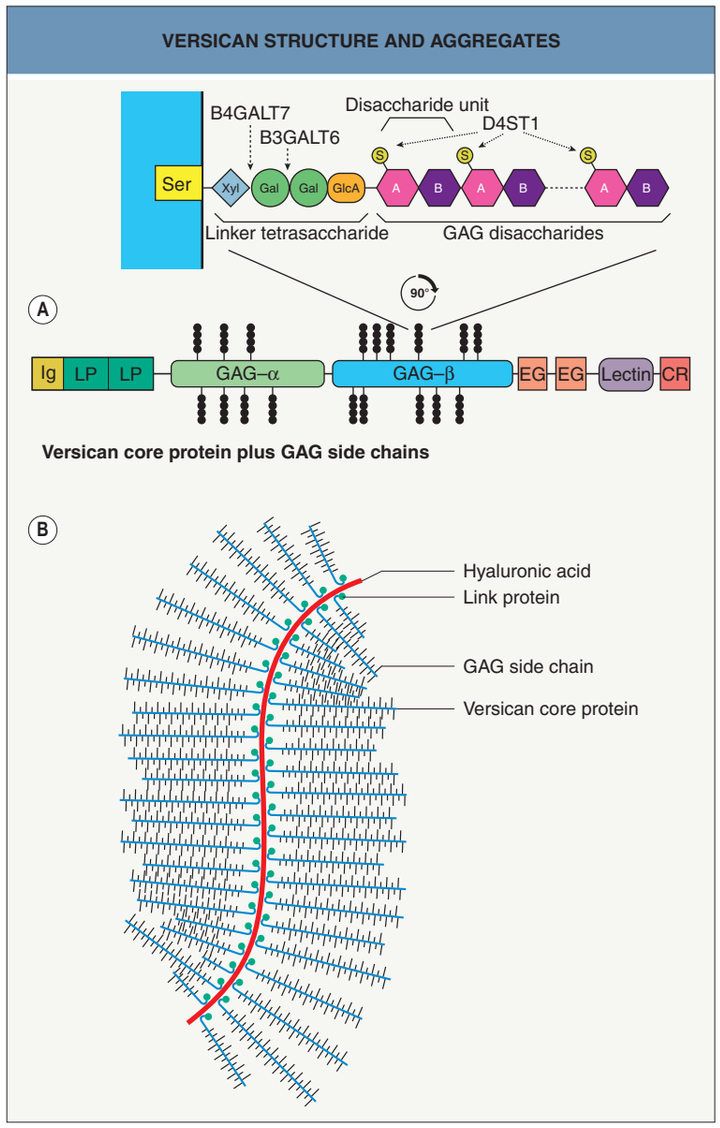

Fig. 95.7 Versican structure and aggregates. A The core protein contains several structural motifs important for glycosaminoglycan (GAG) and ligand binding. The N-terminal immunoglobulin-type repeat (Ig) is followed by two consecutive link-protein type modules (LP), which are involved in mediating the binding of the core protein to hyaluronic acid. The GAG binding domain, which comes in tissue-specific alternative splice variants, GAG-α and/or GAG-β, carries the GAG side chains. It is followed by structural motifs, including two EGF-like repeats (EG), a C-type lectin domain (Lectin), and a complement regulatory protein-like module (CR). The ***inset*** shows an enlarged view of a GAG side chain, which is attached to a serine residue (Ser) of the core protein via a linker tetrasaccharide. In chondroitin sulfate, the disaccharides are composed of N-acetylgalactosamine (GalNAc) [position A] and glucuronic acid [position B]. In dermatan sulfate, the disaccharides are composed of GalNAc [position A] and iduronic acid (IdoA) [position B]. β-1,4-galactosyltransferase 7 (B4GALT7) and β-1,3-galactosyltransferase 6 (B3GALT6) add the first and second galactose (Gal), respectively, to the xylose (Xyl) of the linker tetrasaccharide (dashed arrows). Dermatan-4-sulfotransferase 1 (D4ST1) then adds the active sulfate to the 4-O position of GalNAc (dotted arrows) on dermatan sulfate. Mutations in the genes encoding these enzymes lead to forms of Ehlers–Danlos syndrome (see text and Table 95.5). **B** In the dermis, versican can form huge aggregates with hyaluronic acid (red). The core protein (blue), which carries a number of GAG side chains (black), is bound to hyaluronic acid via its link-protein domain (green; LP module in the scheme in panel **A**). The aggregates can bind large amounts of water, and thus provide for the tautness of the skin. GlcA, glucuronic acid. *Adapted from Iozzo RV. Ehlers-Danlos syndrome associated with glycosaminoglycan abnormalities. Adv Exp Med Biol 2014;802:145–59.*

Laminins and Other Glycoproteins

Laminins, a family of basement membrane molecules with 15 distinct members, are expressed in all tissues. Each laminin isoform is a trimer consisting of an α-, β-, and γ-chain. Combinations of the three chains vary[20,21], with nomenclature based on the chain composition[22]; for example, the laminin composed of α_3, β_3, and γ_2 chains is referred to as laminin 332 (formerly known as laminin 5). In the skin, the epidermal basement membrane contains laminins 332, 311, and 511, and the vascular basement membrane contains laminins 411 and 511. The structure, biologic functions, and genetic defects of laminins expressed in the skin are discussed in more detail in Chapters 28 and 32.

Other glycoproteins with important functions in the skin are listed in Table 95.4[23].

Functions of the Extracellular Matrix

Structural role of the extracellular matrix

In the past, the ECM was simply regarded as a structural scaffold that gave organs their shape and consistency. However, there has been much progress in our understanding of the broad spectrum of ECM suprastructures and their specific functions. Basement membranes are sheets with limited tensile strength but important tissue-specific properties that enable particular cell attachments; they also regulate morphogenesis, differentiation, and barrier functions. At the dermal–epidermal junction, specific basement membrane-associated aggregates ensure strong adhesion of the epidermis to the dermis and thus resistance against external shear forces. In the dermis, different ECM networks are embedded in the water-binding extrafibrillar matrix, maintaining the elasticity, resilience, and tautness of the skin. The specific ECM compositions and post-translational modifications determine the elastic properties and stiffness of a given tissue.

PROTEOGLYCANS OF THE SKIN			
Proteoglycan	**Gene**	**Size of the core protein (kDa)**	**Glycosaminoglycan (GAG) side chains (number)**
Versican	*CSPG2*	265–370, splice variants	Chondroitin/dermatan sulfate (10–30)
Perlecan	*HSPG2*	400–467	Heparan/chondroitin sulfate (3)
Decorin*	*DCN*	40	Chondroitin/dermatan sulfate (1)
Fibromodulin*	*RMOD*	42	Keratan sulfate (2–3)
Lumican*	*LUM*	38	Keratan sulfate (3–4)
Keratocan*	*KERA*	38	Keratan sulfate (3–5)
Biglycan*	*BGN*	40	Chondroitin/dermatan sulfate (2)
Syndecans 1, 2, 4	*SDC1* *SDC2* *SDC4*	35–120	Heparan/chondroitin sulfate (3–5)
Glypican 1	*GPC11*	62	Heparan sulfate (3)
*Small leucine-rich proteoglycan.

GLYCOPROTEINS OF THE SKIN	
Glycoproteins	**Key functions**
Fibronectin	Cell adhesion and migration
Vitronectin	Cell adhesion and migration
Thrombospondins (4 types)	Cell-to-cell and cell-to-matrix communication
Matrilins (4 types)	Matrix assembly, cell adhesion
Tenascins (4 types)	Regulation of cellular function
Cartilage oligomeric matrix protein (COMP)	Matrix assembly, calcium binding, protein folding

Table 95.4 Glycoproteins of the skin.

Regulation of cellular functions

In addition to their structural roles, ECMs are biologically active. *In vitro* studies as well as transgenic and knockout mouse models (see Ch. 3) have demonstrated the importance of ECMs as potent regulators of cellular functions during development, regeneration, wound healing, inflammation, and tumorigenesis. ECM macromolecules can influence a wide range of cellular processes, including adhesion, migration, cytoskeletal organization, division, differentiation, polarization, and apoptosis.

Cells use a variety of receptors, such as integrins and cell surface proteoglycans, to recognize signals from the ECM[2]. The β_1 integrin family represents the most prevalent class of matrix receptors. The α-subunit of the integrin determines the specificity for individual matrix protein ligands, but the affinity and degree of specificity vary. Some integrins recognize only one ligand, while others can bind to several matrix proteins.

"Outside" signals from the ECM can have different effects on the cell[24]. For example, they may induce clustering of integrins on the cell surface and lead to the formation of protein complexes between the cytoplasmic domains of the integrins and the cytoskeleton, thereby influencing cell shape. Alternatively, activation of integrins by the ECM can stimulate signal transduction pathways involving focal adhesion kinase (protein tyrosine kinase 2), paxillin, and tensin. ECM–integrin interactions may also induce mitogen-activated protein kinase-mediated regulation of transcription, cell proliferation, and differentiation. Further regulation of ECM–integrin signaling is mediated by divalent cations, phospholipids, and other agents[25]. Integrins also sense and respond to ECM rigidity through mechanisms involving changes in integrin binding dynamics, stretch-activated ion channels, and unfolding of mechanosensitive proteins (e.g. talin, vinculin) in focal adhesions (see Fig. 28.3B)[24]. These events regulate cell migration and stem cell fate.

Growth factors in the TGF-β family are potent regulators of ECM formation, in addition to their immunomodulatory functions and regulatory role in cell growth[2]. They are secreted from cells as latent complexes containing TGF-β and its propeptide latency-associated peptide (LAP). In most cells, LAP is covalently linked to LTBP, forming the large latent complex (see Fig. 95.6). Secreted large latent complexes associate covalently with ECM proteins. TGF-β can be released from these complexes by a variety of mechanisms including mechanical forces and matrix-degrading proteinases originating from fibroblasts or inflammatory cells. In addition to LTBPs, several other ECM molecules, including proteoglycans and thrombospondin, can bind and modulate the activity of TGF-β.

DISEASES RELATED TO ECM DEFECTS

Molecular studies of the genes and proteins involved in ECM disorders have produced a wealth of information regarding the normal biology of the ECM[13,16,23,26,27]. Putative functions for many matrix macromolecules were found or confirmed when mutations in their genes were defined in diseases. For example, the fundamental roles of collagens VII and XVII in dermal–epidermal adhesion became clear when mutations in the corresponding genes were discovered in patients with hereditary epidermolysis bullosa (EB)[26]. Inherited ECM diseases with cutaneous manifestations are listed in Table 95.5, and the molecular mechanisms and pathophysiology of selected conditions are delineated below. Ehlers–Danlos syndrome (EDS), cutis laxa, and pseudoxanthoma elasticum (PXE) are covered in more depth in Chapter 97, and EB is discussed in Chapter 32.

Ehlers–Danlos syndrome

Collagens and tenascin-X

The quantitatively major components of the collagen fibrils found in the ECMs of many tissues (e.g. skin, tendon, bone, cartilage) are collagens I, II (absent from skin), and III. Smaller amounts of minor collagens (e.g. types V, IX, XI, XII, XIV) are expressed in a tissue-specific manner[3]. Mutations in the genes encoding major and minor collagens can result in distinct abnormalities in different organs[3]. For example, defects in *COL3A1*, which encodes collagen III, are responsible for the vascular type of EDS[16], an autosomal dominant condition that presents with thin translucent skin, excessive bruising, and life-threatening arterial, gastrointestinal, and uterine ruptures. Mutations in *COL3A1* have also been found in patients whose primary clinical manifestation is arterial aneurysms.

Alterations in genes encoding minor fibrillar collagens can also cause severe connective tissue diseases, suggesting pivotal functions for these quantitatively minor components. Collagen V nucleates fibrillogenesis involving collagens I and III; this interaction limits the solubility of macromolecules in fibrils and regulates the geometry of lateral aggregation as well as the overall shapes and sizes of the collagen aggregates. Consistent with this concept, the classical type of EDS occasionally results from mutations in *COL1A1* (encodes the α_1-chain of collagen I), whereas mutations in *COL5A1* and *COL5A2* (encode the α_1- and α_2-chains of collagen V) account for ~50% of patients. Patients with classical EDS exhibit variable degrees of skin hyperelasticity and fragility, atrophic scarring, and joint hypermobility (Fig. 95.8A). Mutations in the gene encoding tenascin-X, a glycoprotein in the extrafibrillar matrix, can cause a recessive form of EDS with similar clinical findings of hyperextensible skin and joint hypermobility[16].

SELECTED GENETIC EXTRACELLULAR MATRIX DISEASES OF THE SKIN				
Protein	**Gene**	**Inheritance**	**Disease**	**Phenotypic features in the skin* and other organs**
Collagen I	*COL1A1*	AD	EDS, arthrochalasia	***Skin hyperextensibility and fragility***, joint hypermobility, congenital hip dislocation†
		AD	EDS, classic (rare cause of this EDS type)	See below
	COL1A2	AD	EDS, arthrochalasia	See above
		AR	EDS, cardiac valvular	Cardiac valve defects, otherwise similar to classic EDS (see below)
Collagen III	*COL3A1*	AD	EDS, vascular	***Translucent, fragile skin with extensive bruising;*** arterial fragility, intestinal and uterine rupture‡
Collagen V	*COL5A1 COL5A2*	AD	EDS, classic	***Skin hyperextensibility and fragility***, joint hypermobility
Collagen VI	*COL6A1, COL6A2, COL6A3*	AD, AR	Ullrich congenital muscular dystrophy Bethlem myopathy	***Puffy skin, atrophic scarring, follicular hyperkeratosis***, distal joint hypermobility, muscular dystrophy
Collagen VII	*COL7A1*	AD, AR	Dystrophic epidermolysis bullosa	***Skin fragility and blistering***
Collagen XII	*COL12A1*	AD, AR	EDS, myopathic Bethlem myopathy	***Soft/doughy skin, atrophic scarring, variable follicular hyperkeratosis***, proximal joint contractures and distal hypermobility, congenital myopathy, hypotonia
Collagen XVII	*COL17A1*	AR	Junctional epidermolysis bullosa	***Skin fragility and blistering***
Fibrillin 1	*FBN1*	AR	Marfan syndrome Marfanoid–progeroid–lipodystrophy syndrome	***Striae***, characteristic body habitus, aortic dilation/dissection‡ ***Skin atrophy***, extreme reduction of subcutaneous fat
Elastin	*ELN*	AD > AR	Cutis laxa, AD > AR	***Lax, redundant skin***
EGF-containing fibulin-like extracellular matrix protein 2 (fibulin 4)	*EFEMP2 (FBLN4)*	AR	Cutis laxa, AR type 1B	***Lax, redundant skin;*** pulmonary emphysema and arterial anomalies
Fibulin 5	*FBLN5*	AR > AD	Cutis laxa, AR type 1A or AD	***Lax, redundant skin;*** pulmonary emphysema and arterial anomalies (AR form)
Latent TGF-β binding protein-4	*LTBP4*	AR	Cutis laxa, AR type 1C	***Lax, redundant skin;*** severe pulmonary, gastrointestinal and urinary abnormalities; dysmorphic facies, joint hyperextensibility, hypotonia
TGF-β receptors 1 & 2, TGF-β2 & -β3, SMAD family member 3	*TGFRB1, TGFRB2, TGFB2, TGFB3, SMAD3*	AD	Loeys–Dietz syndrome‡	***Translucent or velvety skin, easy bruising, atrophic scarring, striae, milia, eczematous dermatitis*** (skin findings vary); aortic aneurysms, arterial tortuosity; craniofacial anomalies (variable), skeletal anomalies, joint hypermobility
Tenascin-X	*TNXB*	AR	EDS, classic-like type 1	***Skin hyperextensibility and fragility***, joint hypermobility, foot deformities, muscle weakness (type 1), osteopenia (type 2)
Aortic carboxypeptidase-like protein	*AEBP1*	AD	EDS, classic-like type 2	
Extracellular matrix protein-1	*ECM1*	AR	Lipoid proteinosis	***Hyalin deposition in the dermis*** and submucosal tissues, ***waxy papules*** on the face (including eyelid margins), ***depressed scars***, hoarse voice, intracranial calcifications
ABCC6 transporter	*ABCC6*	AR	Pseudoxanthoma elasticum (PXE)	***Yellowish papules, lax skin***, retinal angioid streaks, cardiovascular disease
ATPase, Cu^{2+}-transporting, α-polypeptide	*ATP7A*	X-R	Occipital horn syndrome	***Lax skin***, tortuous arteries, joint hypermobility, occipital calcifications
Glucose transporter 10	*GLUT10*	AR	Arterial tortuosity syndrome	***Lax or hyperextensible skin*** (variable), ***telangiectasias on the cheeks***, tortuous arteries, joint hypermobility
Solute carrier family 39, member 13 (zinc transporter ZIP13)	*SLC39A13*	AR	EDS, spondylodysplastic	***Skin hyperextensibility and fragility, wrinkled palms***, joint hypermobility, hypotonia, short stature, developmental delay

*Elastosis perforans serpiginosa can also develop in patients with EDS and pseudoxanthoma elasticum.
†A phenotype with features of both EDS and osteogenesis imperfecta has also been reported.
‡The phenotype of Loeys–Dietz syndrome (LDS) can mimic either Marfan syndrome or vascular EDS; eczematous dermatitis and elevated immunoglobulin E levels suggestive of a hyper-IgE syndrome have also been reported.

Table 95.5 Selected genetic extracellular matrix diseases of the skin.

Continued

SELECTED GENETIC EXTRACELLULAR MATRIX DISEASES OF THE SKIN				
Protein	**Gene**	**Inheritance**	**Disease**	**Phenotypic features in the skin* and other organs**
Lysyl hydroxylase 1	*PLOD1*	AR	EDS, kyphoscoliotic (type VIA[¶])	***Skin hyperextensibility and fragility***, ocular fragility, joint hypermobility, scoliosis
Lysyl hydroxylase 3	*PLOD3*	AR	Generalized connective tissue disorder	***Skin fragility and skin blistering***, bone fragility with contractures, dysmorphic facies, hypoplastic nails, osteopenia, cataracts, delayed growth and development
ADAMTS-2 (procollagen N-proteinase)	*ADAMTS2*	AR	EDS, dermatosparaxis	***Sagging, doughy, fragile skin with easy bruising***; characteristic facies
Dermatan-4-sulfotransferase 1	*CHST14*	AR	EDS, musculocontractural[§]	***Skin hyperextensibility and fragility, wrinkled palms***, ocular fragility, joint contractures and hypermobility, scoliosis, craniofacial abnormalities
Dermatan sulfate epimerase	*DSE*	AR		
Galactosyltransferase-I (β-1,4-galactosyltransferase 7)	*B4GALT7*	AR	EDS, spondylodysplastic (formerly progeroid)	***Skin hyperextensibility***, variable joint hypermobility and contractures, progeroid facies, osteopenia, hypotonia, short stature, developmental delay
Galactosyltransferase-II (β-1,3-galactosyltransferase 6)	*B3GALT6*	AR		
Glucuronosyltransferase I (β-1,3-glucuronyltransferase 3)	*B3GAT3*	AR	Larsen-like syndrome	***Wrinkled acral skin***, joint dislocations, craniofacial dysmorphism, short stature, congenital heart defects
Filamin A (actin-binding protein 280)	*FLNA*	X-D	EDS, periventricular nodular heterotopia variant	***Skin hyperextensibility*** (variable), aortic dilation, periventricular nodular heterotopia, joint hypermobility
Zinc finger protein 469, PR domain-containing protein 5	*ZNF469, PRDM5*	AR	Brittle cornea syndrome	***Soft or hyperextensible skin, wrinkled acral skin, atrophic scarring*** (skin findings vary), thin fragile corneas, blue sclerae, joint hypermobility, scoliosis, hearing loss
FK506-binding protein 14	*FKBP14*	AR	EDS, kyphoscoliotic	***Skin hyperextensibility***, joint hypermobility, progressive kyphoscoliosis, myopathy, hypotonia from birth, impaired hearing
Complement C1r, C1s	*C1R, C1S*	AD	EDS, periodontal	***Excessive bruising, mildly hyperextensible skin***, small joint hypermobility, early-onset periodontitis, marfanoid habitus, increased infections
ATPase, H^+ transporting, lysosomal V0 subunit A2	*ATP6V0A2*	AR	Cutis laxa, AR type 2A Wrinkly skin syndrome	***Lax skin***, facial dysmorphism, large fontanelles, microcephaly, delayed development ± growth, strabismus, joint hypermobility
Pyrroline-5-carboxylate reductase 1	*PYCR1*	AR	Cutis laxa, AR type 2B and 3B (de Barsy syndrome B)	***Lax skin***, facial dysmorphism, large fontanelles, microcephaly, delayed development and growth, joint hypermobility; corneal opacities, cataracts, & athetosis in de Barsy syndrome
Pyrroline-5-carboxylate synthetase	*ALDH18A1*	AD, AR	Cutis laxa, progeroid AD Cutis laxa, AR type 3A (de Barsy syndrome A)	***Lax skin***, facial dysmorphism, delayed development, joint hypermobility, corneal opacities
Ectonucleotide pyrophosphatase/phosphodiesterase 1	*ENPP1*	AR	Generalized arterial calcification of infancy	***Yellowish papules, lax skin***, retinal angioid streaks, severe arterial calcification, hypophosphatemic rickets
γ-glutamyl carboxylase	*GGCX*	AR	PXE-like disorder with multiple coagulation factor deficiency	***Yellowish papules, lax skin***, retinal angioid streaks, cardiovascular disease, bleeding diathesis
Golgin, RAB6-interacting	*GORAB*	AR	Gerodermia osteodysplastica	***Lax skin (primarily on dorsal hands and feet)***, progeroid facies with prognathism, short stature, osteoporosis
Ras and Rab interactor 2	*RIN2*	AR	Macrocephaly, ***alopecia, cutis laxa***, and scoliosis (MACS)	Features in name of disorder, facial dysmorphism, gingival hypertrophy, joint hyperextensibility

[¶]Historical numerical classification of EDS.
[§]Exists on a spectrum with adducted thumb–clubfoot syndrome, which is caused by mutations in the same gene.

Table 95.5 Selected genetic extracellular matrix diseases of the skin. Diseases and phenotypic features are colored based on the primary cutaneous manifestation (when applicable) as follows: *orange*, hyperextensible skin (as in classic EDS); *pink*, extensively bruised skin (as in vascular EDS); *peach-tan*, skin fragility with blistering (as in epidermolysis bullosa); *light blue*, lax skin (as in cutis laxa); *dark blue*, yellowish papules ± lax skin (as in pseudoxanthoma elasticum). ABCC6, ATP-binding cassette subfamily C member 6; AD, autosomal dominant; ADAM, a disintegrin and metalloproteinase; *AEBP1*, adipocyte enhancer binding protein 1; *ALDH18A1*, aldehyde dehydrogenase 18 family, member A1; AR, autosomal recessive; *CHST14*, carbohydrate sulfotransferase 14; EDS, Ehlers–Danlos syndrome; TGF, transforming growth factor; X-D, X-linked dominant; X-R, X-linked recessive.

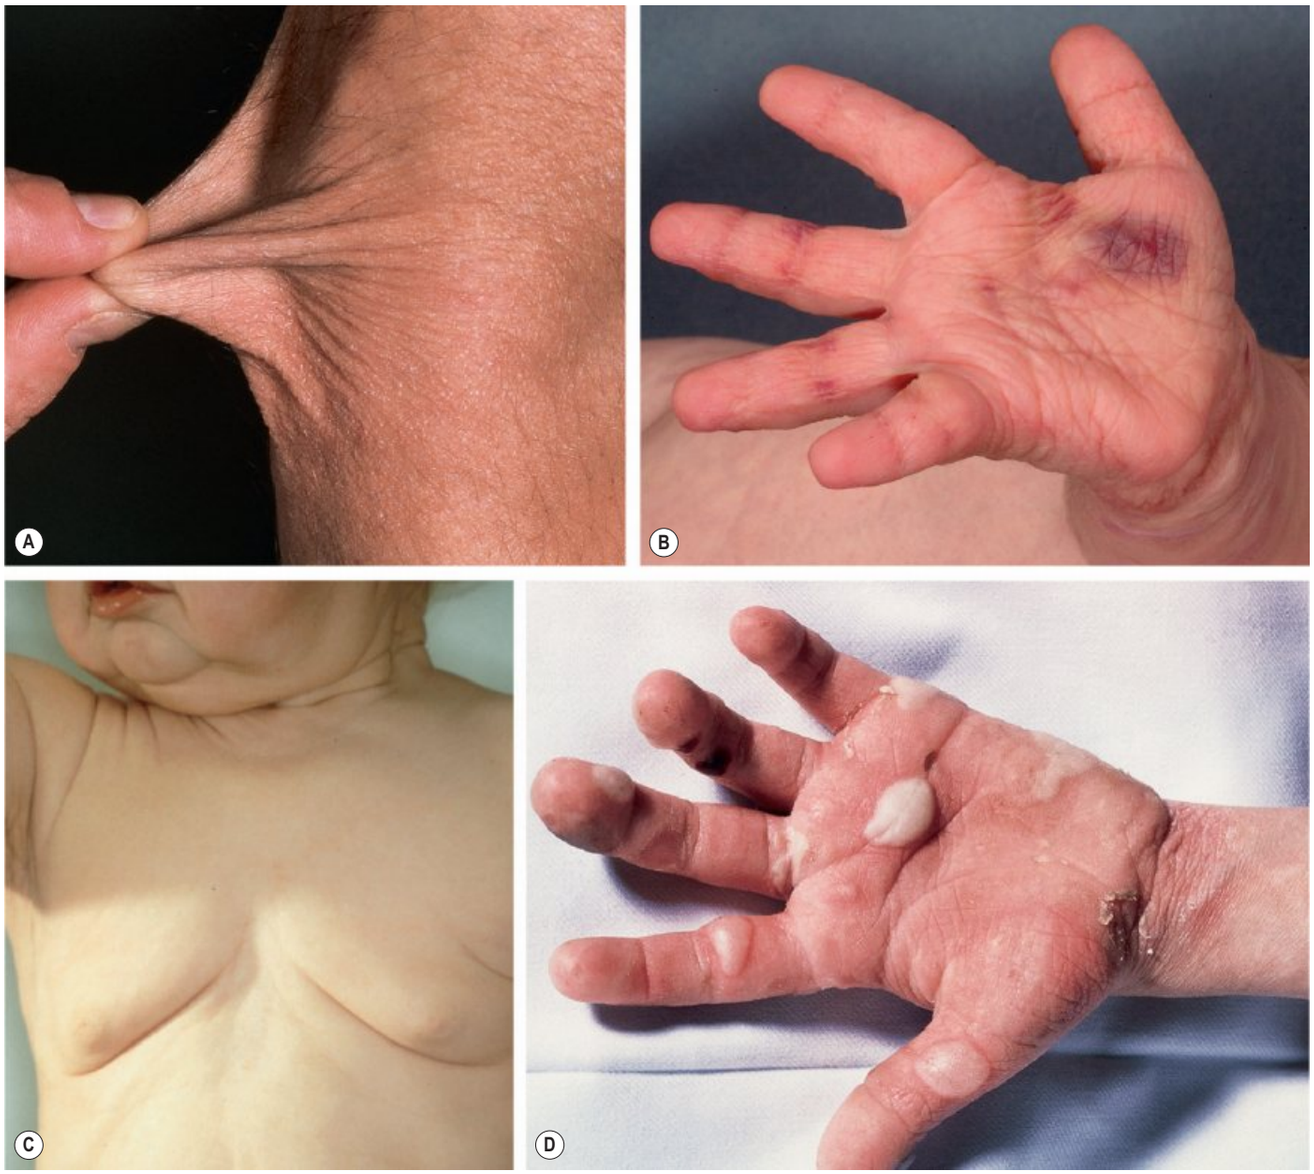

Fig. 95.8 Phenotypic manifestations of genetic extracellular matrix defects. A Ehlers–Danlos syndrome type II with slightly overstretchable skin results from mutations in the collagen V genes. **B** Dermatosparaxis showing fragile skin with purpura and a "doughy" texture due to mutations in the gene for ADAMTS-2. **C** Autosomal dominant cutis laxa is associated with mutations in the elastin gene. **D** Junctional epidermolysis bullosa with skin blisters after minimal friction can be caused by mutations in the collagen XVII gene. *B, Courtesy Julie V. Schaffer MD; C, Courtesy Thomas Schwarz, MD.*

Post-translational modification of collagen

Mutations in genes encoding proteins involved in post-translational modification of collagen (see above and Fig. 95.2) have been found to underlie other forms of EDS. For example, loss-of-function mutations in the lysyl hydroxylase 1 gene lead to abnormal lysyl hydroxylation and glycosylation of collagens in a subset of patients with the kyphoscoliotic type of EDS, a recessive disease characterized by hyperextensible and fragile skin as well as hypermobile joints, scoliosis, and ocular fragility. Failure to cleave the N-propeptide from procollagen I causes the arthrochalasia type of EDS, a dominant disorder that features severe joint hypermobility, including dislocations. The persistence of this propeptide on collagen I drastically alters fibrillogenesis, and the fibrils that form are thin and irregular in diameter. Affected individuals typically have a splice-site mutation in *COL1A1* or *COL1A2* that causes exon skipping and elimination of the cleavage site for ADAMTS-2 (procollagen I N-proteinase) in the proα_1(I) or proα_2(I) chain. Loss-of-function mutations in *ADAMTS2* cause the dermatosparaxis type of EDS (Fig. 95.8B); as in the arthrochalasia type, procollagen I N-propeptides persist and sterically disturb polymerization of the collagen fibrils. Dermatosparaxis has a distinct phenotype that includes characteristic facies and fragile, sagging skin with a doughy consistency. Mutations in the zinc finger protein 469 gene (*ZNF469*) or PR/SET domain 5 (*PRDM5*), which are involved in transcriptional regulation of fibrillar collagens, result in corneal fragility as well as variable skin hyperextensibility and wrinkling[16].

Proteoglycan processing

As discussed above, dermal proteoglycans have important roles in collagen fibril organization. Accordingly, mutations in *B3GALT6* and *B4GALT7*, which encode galactosyltransferases that initiate GAG synthesis, cause a spondylodysplastic type of EDS[16,28,29]. Mutations in *B3GAT3*, which encodes a glucuronosyltransferase that catalyzes the formation GAG-protein linkages, can lead to wrinkled acral skin[30]. The musculocontractural type of EDS is caused by mutations in *CHST14* and *DSE*, which encode dermatan-4-sulfotransferase 1 and dermatan sulfate epimerase, respectively[16,31]. Loss of these enzymes' activity in dermatan sulfate synthesis leads to a reduced dermatan sulfate : chondroitin sulfate ratio, which disrupts decorin function and thereby impairs collagen fibrillogenesis[16].

Cutis laxa

Cutis laxa is an uncommon ECM disease characterized by genetic heterogeneity and clinical variability (see Ch. 97); acquired variants also exist[23]. The primary diagnostic feature is loose, sagging skin with

decreased resilience and elasticity, leading to an appearance of "too large skin" and premature aging (Fig. 95.8C). The skin changes are often accompanied by extracutaneous manifestations, including pulmonary emphysema, bladder diverticula, hernias, and arterial anomalies. Histologically, there is fragmentation or diminution of elastic fibers.

Recessive and dominant forms of cutis laxa can result from mutations in multiple genes, including those that encode the elastic fiber components elastin, fibulin 4, and fibulin 5[32] (see Table 95.5). A severe form of cutis laxa associated with extensive pulmonary, gastrointestinal, and urinary abnormalities is caused by mutations in the latent TGF-β binding protein-4 gene (*LTBP4*), demonstrating the central role of TGF-β signaling in ECM assembly during development[32].

Other inherited disorders are characterized by secondary effects on elastic fiber deposition or degradation[23]. For example, elastic fibers are calcified and fragmented secondary to decreased activity of anti-mineralization proteins in pseudoxanthoma elasticum (see below and Ch. 97). In patients with α_1-antitrypsin deficiency and some forms of acquired atrophoderma, elastic fibers are prematurely degraded due to unregulated elastase activity. Decreased or aberrant deposition of elastic fibers in certain tissues is also characteristic of Marfan syndrome (see below).

Marfan syndrome

Fibrillin 1 is the major component of microfibrils and therefore has an important structural role in elastic fibers. Fibrillin 1 mutations cause Marfan syndrome, an autosomal dominant disorder with variable connective tissue weakness in the skin as well as skeletal, ocular, and cardiovascular systems[13,23]. Cutaneous manifestations include striae and elastosis perforans serpiginosa. In addition to structural disturbances in elastic fibers and microfibrils, fibrillin mutations may decrease the sequestration of latent TGF-β complexes (see Fig. 95.6), thus rendering them more prone to activation. This leads to unproductive tissue remodeling, abnormal cellular behavior, and loss of ECM integrity.

The highly homologous fibrillin 2 exhibits different spatial and temporal expression during development, and the functional relationship between the two molecules is not fully understood. Mutations in the gene encoding fibrillin 2 lead to congenital contractural arachnodactyly, which features skeletal abnormalities in the absence of ocular and cardiovascular features[13].

Loeys–Dietz syndrome

Heterozygous mutations in the genes encoding the TGF-β receptors 1/2 or TGF-β2/3 can cause Loeys–Dietz syndrome, which is characterized by aortic aneurysms, generalized arterial tortuosity, variable craniofacial malformations (e.g. bifid uvula, cleft palate, hypertelorism), skeletal anomalies, and joint laxity. A subset of patients has cutaneous manifestations similar to those of the vascular type of EDS, including translucent skin, easy bruising, and atrophic scarring[13,16]. The phenotypic overlap with Marfan syndrome and vascular EDS is not surprising, considering the association between fibrillin and latent TGF-β and the role of TGF-β in regulating collagen expression.

Other fibrillin-associated syndromes

Genetic mutations that alter the C-terminus of fibrillin 1 cause *marfanoid–progeroid–lipodystrophy syndrome*, which is characterized by an extreme reduction in subcutaneous fat. Mutations affecting the integrin-binding site of fibrillin 1 lead to abnormal microfibril assembly and cause *stiff skin syndrome*, which features diffusely thickened skin since birth, limited joint mobility, nodules over the distal interphalangeal joints, and short stature. In addition, fibrillin 1 deficiency represents a cause of *Weill–Marchesani syndrome*[13], characterized by thick skin, short stature, shortened digits, and ectopia lentis. Mutations in *ADAMTSL2*, which encodes the extracellular ADAMTS-like protein 2 that interacts with TGF-β and fibrillin[33], alter TGF-β bioavailability. This results in *geleophysic dysplasia*, which presents with thick skin, short stature, and joint contractures.

Pseudoxanthoma elasticum

PXE is a heritable disorder characterized by cutaneous, vascular, and ocular involvement that results from the accumulation of fragmented and calcified elastic fibers in the dermis, arterial walls, and Bruch's membrane, respectively (see Ch. 97). The skin findings – laxity and yellowish papules and plaques – are the most common and often the earliest manifestation of PXE.

Although PXE has traditionally been considered as a prototypic heritable ECM disorder, it is caused by mutations in the gene for the ATP-binding cassette (ABC) subfamily C member 6 (ABCC6) transporter, which is primarily expressed in the liver[34]. The absence of functional ABCC6 results in reduced ATP secretion from hepatocytes, which leads to reduced plasma concentrations of inorganic pyrophosphate (PPi), a physiologic inhibitor of mineralization (see Fig. 97.5)[34]. Mutations in the γ-glutamyl carboxylase gene (*GGCX*) can lead to a PXE-like phenotype together with a deficiency in vitamin K-dependent coagulation factors. GGCX catalyzes vitamin K-dependent γ-glutamyl carboxylation, which activates coagulation factors and the matrix gla protein (MGP), an inhibitor of pathologic mineralization.

Epidermolysis bullosa

EB represents a group of hereditary diseases characterized by mechanical fragility of the skin that results in blister formation[26,35] (see Ch. 32). Mutations in the collagen VII gene (*COL7A1*) cause both dominant and recessive forms of *dystrophic EB*[36]. Because collagen VII is a component of the anchoring fibrils, cleavage occurs just below the lamina densa in the uppermost dermis; as a result, blisters tend to heal with scarring. Patients with severe forms of recessive dystrophic EB harbor mutations that lead to premature termination codons[36], and collagen VII and anchoring fibrils are absent. Milder forms of dystrophic EB are associated with missense mutations in one or both copies of *COL7A1* and anchoring fibril dysfunction.

Mutations in *COL17A1*, which encodes the α_1 chain of collagen XVII, a homotrimeric transmembrane collagen localized to the hemidesmosome-anchoring filament complex of basal keratinocytes, can cause *junctional EB*. This recessive EB subtype is characterized by cleavage within the lamina lucida of the basement membrane. Patients with two null alleles of *COL17A1* tend to have widespread blistering (Fig. 95.8D), whereas those with missense mutations and some preservation of collagen XVII function exhibit milder clinical phenotypes[37].

Laminin 332 is a major structural component of the lamina densa, where it secures epidermal adhesion by linking $\alpha_6\beta_4$ integrin on the cell surface to collagen VII of the anchoring fibrils (see Fig. 28.3). Like defects in collagen XVII, mutations in the genes encoding the three polypeptide chains of laminin 332 cause *junctional EB*, with the most severe form resulting from null mutations and a complete lack of laminin 332 in the skin[37].

Other hereditary matrix diseases with skin symptoms

Ullrich congenital muscular dystrophy and *Bethlem myopathy* are caused by mutations in *COL6A1*, *COL6A2*, and *COL6A3* which encode the α_1(VI), α_2(VI), and α_3(VI) chains of collagen VI[3]. This collagen forms microfibrils in several tissues, including muscle and skin. Extramuscular manifestations – a puffy consistency of the skin (primarily in Ullrich), atrophic scarring, and joint hyperlaxity – likely reflect abnormalities of the microfibrillar networks in the dermis and synovia. Deficiency of FK506-binding protein 14, which may act as a chaperone in the endoplasmic reticulum with a role in ECM assembly, leads to a phenotype that includes hyperelastic skin as well as muscular dystrophy.

Via glucosyltransferase and galactosyltransferase activities, lysyl hydroxylase 3 plays a role in the post-translational modification of collagens. Loss-of-function mutations in both copies of *PLOD3*, which encodes lysyl hydroxylase 3, underlie a severe, multi-organ connective tissue disease[38,39]. Affected individuals have fragile skin that is prone to both bruising and blistering, with a reduction in anchoring fibril density and cleavage below the lamina densa similar to that observed in recessive dystrophic EB[39].

Extracellular matrix components as autoantigens

The binding of autoantibodies to ECM components disrupts their supramolecular aggregation or ligand binding, leading to dysfunction and corresponding clinical symptoms. Several ECM components are targeted in autoimmune diseases that affect the kidney, cartilage, and skin (Table 95.6). Autoantigens in these conditions include: the α_3- and α_5-chains of collagen IV in Goodpasture disease[40]; collagen II in relapsing polychondritis; collagen VII in EB acquisita; collagen XVII in bullous pemphigoid; and the γ1-chain of laminin 311 and 511 in

EXTRACELLULAR MATRIX COMPONENTS AS TARGETS IN AUTOIMMUNE DISEASES		
Disease	**Autoantigen**	**Biologic and clinical features**
Goodpasture disease	Collagen IV, α_3 and α_5 chains	Glomerulonephritis, pneumonitis with hemoptysis
Relapsing polychondritis, arthritis	Collagen II; collagen IX	Chondritis of ear, nose, larynx, and trachea; arthritis
Pemphigoid (various subtypes)	Collagen XVII (BP, PG, MMP)*; laminin 332 (MMP), laminin γ1 chain (p200 pemphigoid)	Skin blistering
Epidermolysis bullosa acquisita	Collagen VII	Skin blistering, fragility
Bullous eruption of systemic lupus erythematosus (SLE)	Collagen VII	Skin blistering with underlying SLE
Scleroderma†	Fibrillin 1; PDGF receptor	Skin fibrosis
Lichen sclerosus	Extracellular matrix (ECM) protein-1	Inflammation, epidermal atrophy, hyalinization of the dermis

*Also the autoantigen in linear IgA bullous dermatosis.
†Not confirmed in large patient cohorts.

Table 95.6 Extracellular matrix components as targets in autoimmune diseases. BP, bullous pemphigoid; MMP, mucous membrane (cicatricial) pemphigoid; PDGF, platelet-derived growth factor; PG, pemphigoid gestationis.

anti-p200 (anti-laminin γ1) pemphigoid[37,41]. Antibodies to fibrillin 1 have been described in systemic sclerosis patients, especially those of Choctaw Native American or Japanese descent, and in individuals with linear and generalized subtypes of morphea. The extracellular matrix-1 (ECM-1) protein is the target of autoantibodies in patients with lichen sclerosus and is dysfunctional in individuals with lipoid proteinosis; both conditions feature dermal hyalinization[42]. The immunodominant epitopes in autoimmune diseases are often localized to one or several distinct structural domains, allowing recombinant domains to be employed for diagnostic testing.

Skin aging and other acquired ECM abnormalities

Changes in the dermal ECM contribute to both chronologic and photo-induced skin aging. Morphologic hallmarks of aged skin include reduced microfibrils in the papillary dermis, disorganized elastic fibers, and reduction or weakening of other ECM fibril networks. The structurally perturbed dermal networks cannot bind adequate amounts of hyaluronic acid and, consequently, water, which leads to lax and wrinkled skin. Reduced synthesis of dermal collagens by fibroblasts is a prominent feature of aging that is mediated by decreased TGF-β and connective tissue growth factor (CTGF) signaling. Increased degradation of ECM components also occurs and destabilizes network structures. The deleterious effects of UV irradiation include release of cytokines from the epidermis and generation of reactive oxygen species. These mediators induce inflammatory processes and stimulate expression and activation of matrix metalloproteinases and serine proteinases such as elastase, which can degrade ECM networks[33].

Weakened ECMs lead to disturbed wound healing and a bruising tendency in scurvy, a disease resulting from an insufficient supply of ascorbic acid (vitamin C). This vitamin is an essential cofactor for prolyl- and lysyl-hydroxylases, which modify collagens during their biosynthesis and are required for cross-linking[4].

In fibrotic disorders such as systemic sclerosis (scleroderma) and keloids, thickened skin reflects excessive dermal ECM. Upregulation of ECM synthesis (e.g. collagen, fibrillins, proteoglycans) via TGF-β and CTGF is believed to have a pathogenic role (see Fig. 43.1). The histopathologic abnormalities of keloids due to perturbed ECM assembly and regulation are outlined in Table 98.3.

Animal Models

Mouse models for ECM diseases have provided new insights into pathomechanisms, allowed for further assessment of abnormalities observed in human diseases, and enabled testing of novel therapeutic approaches. For example, fibrillin 1 transgenic mouse models have demonstrated associations of fibrillin 1 with microfibril assembly and TGF-β signaling, showing that a defect in the latter is central to Marfan syndrome pathogenesis and other phenotypes[13,43]. In addition, mice with mutations in the integrin binding sites of fibrillin 1 represent a model of scleroderma[44].

Collagen VII-deficient mice, rats, dogs, and sheep have recapitulated the clinical, genetic, immunohistochemical, and ultrastructural characteristics of recessive dystrophic EB in humans[23]. Collagen VII knockout mice die during the first 2 weeks of life, while mice with hypomorphic mutations have a severe phenotype but live into adulthood[37]. These mice have provided insights into the molecular pathogenesis of recessive dystrophic EB and have been useful for testing cellular and molecular approaches to therapy[45]. Mice with conditional deletion of collagen VII have furthered the understanding of this protein's role in regeneration. Rats with spontaneous *Col7a1* mutations have revealed a gene-dosage effect in dystrophic EB and demonstrated the importance of modifier genes in determining disease phenotype[46,47]. Collagen XVII knockout and mutant mice exhibit a moderately severe form of junctional EB and are also being used to study novel therapeutic approaches.

Mice harboring disrupted proteoglycan genes have demonstrated the importance of these molecules for skin integrity and tautness[15]. The decorin knockout mouse has fragile skin with markedly reduced tensile strength that is associated with irregular, coarse ECM fibers in the skin and tendons; these findings established the fundamental role of decorin in regulating collagen fibrillogenesis *in vivo*.

Abnormalities in collagen-processing enzymes also occur spontaneously in animals. Bovine dermatosparaxis is a recessively inherited connective tissue disorder that, like the human form of the disease, features extremely fragile, doughy skin as well as joint laxity. Both human and bovine dermatosparaxis result from mutations in the gene encoding ADAMTS-2, which excises the N-propeptide of procollagens I and II[23].

Potential for Biologically Valid Molecular Therapies

Genetic, proteomic, and other molecular approaches have led to a better understanding of the mechanisms underlying ECM disorders[48]. This has provided the bases for novel therapies in diseases such as recessive forms of EB caused by a lack of collagen VII, collagen XVII, or laminin 332. Treatment strategies for EB range from employment of gene- and RNA-based technologies to methods utilizing cells or proteins (see Ch. 32). Many of these experimental modalities are currently being evaluated in preclinical models or clinical trials[49].

In a remarkable example of gene therapy, laminin-β3-deficient skin of a child with severe junctional EB was corrected by transplantation of stem cell-enriched epidermal grafts transduced *ex vivo* with a retroviral vector expressing normal *LAMB3* cDNA. Treatment of ~80% of the body surface area resulted in synthesis of functional laminin 332 and an absence of blistering in the corrected epidermis that was sustained for >5 years[50]. *In vivo* topical gene therapy with beremagene geperpavec (B-VEC), a *COL7A1*-containing herpes simplex virus type 1 vector, was recently FDA-approved as a treatment to promote wound healing in patients with dystrophic EB[50a]. Other clinical trials of gene therapy for different types of EB are in progress, and novel vectors and gene editing approaches to correct patient stem cells or induced pluripotent stem (iPS) cells are under development. Intriguingly, patients with junctional and dystrophic EB can develop patches of skin that do not blister due to spontaneous "correction" via revertant mosaicism. This raises the possibility of natural gene therapy by expanding stem cells or generating iPS cells from the corrected patches[51].

Systemic therapy using allogeneic bone marrow-derived stem cell transplantation after total or partial myeloablation has led to homing of donor cells to the skin, increased collagen VII deposition at the dermal–epidermal junction, and variably decreased blistering in children with recessive dystrophic EB[52]. Long-term follow-up studies are needed to evaluate the therapeutic potential of this approach. Alternative strategies under investigation in patients with recessive dystrophic EB include intravenous or intradermal injections of allogeneic mesenchymal stem cells. Protein replacement therapy with intradermal or

intravenous injection of collagen VII has also been explored in animal models of recessive dystrophic EB[53].

For the treatment of dominant disorders, strategies to silence expression of the mutated allele (mitigating dominant-negative effects) or to supplement with the normal protein (correcting haploinsufficiency) hold promise. For dominantly inherited connective tissue disorders, cellular rescue mechanisms such as the unfolded protein response contribute to disease and small molecule therapies such as chemical chaperones may have benefit.

Better understanding of disease mechanisms disclosed an unexpected pharmacologic approach to the treatment of Marfan syndrome[54]. Since excessive TGF-β signaling contributes to the development of aortic aneurysms in affected individuals, it was hypothesized that TGF-β antagonists might prevent or even reverse this disease manifestation. Angiotensin II is known to stimulate TGF-β signaling, and angiotensin II receptor blockers are successfully employed to prevent aortic root dilation in patients with Marfan syndrome[54] (see Fig. 95.6). These agents have also been shown to reduce dermal fibrosis and digital fusion in mice with recessive dystrophic EB[55]. Analogous treatments could potentially be developed for other inherited ECM disorders based on recognition of the pathogenic role of growth factors and other regulatory molecules[56].

Future development of successful therapies for ECM disorders will also depend on the progress in our understanding of functional suprastructure formation by matrix macromolecules. This endeavor will be facilitated not only by the analysis of aggregate formation by matrix macromolecules or their mixtures *in vitro*, but also by the elucidation of further genetic defects and their consequences in animal or human diseases, as well as the generation of transgenic animals as models for human disorders. This information will help us to understand and treat not only inherited ECM diseases but also many common disorders currently considered as acquired.

Perforating Diseases 96

Ronald P. Rapini

Synonyms: ■ Hyperkeratosis follicularis et parafollicularis in cutem penetrans: Kyrle disease ■ Acquired perforating dermatosis: acquired reactive perforating collagenosis, acquired reactive perforating dermatosis, perforating disorder of uremia

Key features

- Group of disorders with transepidermal elimination of collagen, elastic tissue, or necrotic dermal connective tissue
- Papules or nodules with keratotic plugs
- Elastosis perforans serpiginosa is associated with genetic diseases or penicillamine administration and involves elastic tissue; lesions are typically annular and most commonly occur in flexural sites, in particular the neck
- Reactive perforating collagenosis occurs after minor trauma, involves collagen, and often involves the upper extremities
- Acquired perforating dermatosis is almost always associated with diabetes mellitus and/or the pruritus of chronic kidney disease (stages 4–5); it favors the lower extremities of adults
- Broadband or narrowband UVB phototherapy appears to be the most effective treatment for acquired perforating dermatosis

INTRODUCTION

The perforating diseases are a group of papulonodular skin disorders characterized by keratotic plugs or crusts in which dermal connective tissue "perforates" or is eliminated through the epidermis (Table 96.1). There are two prototypic perforating diseases, both of which can be inherited. *Reactive perforating collagenosis* (RPC) is associated with transepidermal elimination of primarily collagen fibers[1], whereas in *elastosis perforans serpiginosa* (EPS), primarily elastic fibers are extruded through the epidermis. The third major perforating disease is *acquired perforating dermatosis*, which usually develops during adulthood in association with diabetes mellitus and/or the pruritus of chronic kidney disease (stages 4–5)[2]. Many textbooks traditionally list "perforating folliculitis" as the fourth perforating disease[3], but, in the opinion of the author, this seems unjustified. It does not appear to be a specific entity, since perforation or rupture of follicles occurs in a wide variety of diseases classified as folliculitis, regardless of whether the pathogenesis involves bacteria, fungi, *Demodex* mites, drugs, physical trauma, or other mechanisms.

Some authorities have expanded the concept of the preceding so-called "primary" perforating diseases to include a variety of unrelated "secondary" perforating disorders in which transepidermal elimination of a substance occurs as a secondary component of a primary dermatosis (Table 96.2). As in most of the preceding perforating disorders, the epidermis often becomes hyperplastic, eventually surrounds the material to be extruded, and subsequently causes the material's elimination via normal keratinocyte maturation. Some of these disorders are discussed elsewhere in this text and involve perforation of endogenous substances, exogenous foreign material, infectious organisms, granulomas, and even neoplastic cells[4].

HISTORY

In 1916, Kyrle reported a diabetic woman with generalized hyperkeratotic nodules, which he called "hyperkeratosis follicularis et parafollicularis in cutem penetrans". Lutz first described EPS as "keratosis follicularis serpiginosa" in 1953, and, in 1955, Miescher described the histologic findings, naming it "elastoma intrapapillare perforans verruciforme". Mehregan, Schwartz, and Livingood reported the first child with RPC in 1967. A year later, Mehregan and Coskey expanded the concept of perforating disease to include perforating folliculitis in their article.

EPIDEMIOLOGY

The perforating diseases are found worldwide, without any clear racial predilection. The very rare childhood-onset form of RPC is commonly familial, and childhood-onset EPS is occasionally familial. Although the exact inheritance pattern for both is still uncertain, isolated inherited EPS may have an autosomal dominant pattern. EPS affects men more often than women, with a ratio of ~4:1, whereas the sex distribution is nearly equal in RPC and acquired perforating dermatosis. Perforating folliculitis is said to be more common in women. In patients receiving maintenance hemodialysis, acquired perforating dermatosis is observed in an estimated 4.5% to 11% of patients[5]. Acquired perforating dermatosis is more commonly encountered than the inherited perforating disorders.

PATHOGENESIS

The precise pathogenesis underlying the perforating disorders is unknown. As it is unlikely that dermal connective tissue or hair shafts actively perforate into the epithelium, some have argued that "transepidermal elimination" is a more accurate term. The term "perforating" is embedded in the dermatologic lexicon, however, and is easier to say. Epithelium becomes hyperplastic and eventually surrounds the abnormal connective tissue, just as it appears to do with wood splinters or other foreign bodies. In acquired perforating dermatosis, pruritus probably leads to chronic scratching, which results in epithelial hyperplasia, as in prurigo nodularis. Indeed, prurigo nodules are often admixed with classic perforating lesions. The possibility has been raised that enlargement of a hyperkeratotic plug could lead to penetration through the base of the hyperplastic epidermis, i.e. the perforation is caused by the plug above rather than being due to the abnormal connective tissue below.

Primary perforating diseases may be due to either genetic or acquired abnormalities of collagen or elastic fibers. In EPS, as well as some cases of acquired perforating dermatosis in which perforation of elastic fibers is observed, enhanced expression of elastin receptors has been detected in the epidermis surrounding the elastic material[6]. It has been proposed that scratching exposes keratinocytes to *a*dvanced *g*lycation *e*nd product (AGE)-modified extracellular matrix proteins, in particular collagen types I and III. This would then lead to terminal differentiation of keratinocytes via the AGE receptor (CD36), followed by upward movement of keratinocytes along with glycated collagen[7]. Increased levels of AGEs have been detected in the skin of patients with acquired perforating dermatoses[8].

Plasma fibronectin levels are elevated in patients with diabetes mellitus and uremia, and fibronectin is also increased within the skin at sites of transepidermal elimination[9]. This may be significant, since fibronectin plays a role in epithelial cell signaling, locomotion, and differentiation. It binds to type IV collagen (the type found in basement membranes) and to keratinocytes and may incite epithelial proliferation and perforation. In one study of RPC, the investigators demonstrated that the collagen being transepidermally eliminated was type IV collagen[10]. Increased expression of transforming growth factor-β_3 (TGF-β_3), matrix metalloproteinase-1 (MMP-1), and tissue inhibitor of metalloproteinase-1 (TIMP-1) has been observed in lesional skin of acquired RPC[11], but this enhanced expression may be a reflection of concurrent wound healing (see Ch. 141).

MAJOR PERFORATING DISEASES					
Disease	**Incidence**	**Time of onset**	**Most common location**	**Perforating substance**	**Associations**
Familial reactive perforating collagenosis (RPC)	Very rare	Childhood	Arms, hands, sites of trauma	Collagen	None
Elastosis perforans serpiginosa (EPS)	Rare, M > F	Childhood, early adulthood; variable with penicillamine-induced EPS	Neck, face, arms, other flexural areas	Elastic tissue	Genetic diseases (see Fig. 96.13), penicillamine
Perforating folliculitis	Common	Early adulthood	Trunk, extremities	Necrotic material	May simply be ordinary folliculitis with follicular rupture, i.e. not a specific entity
Acquired perforating dermatosis, includes acquired RPC, Kyrle disease*, and rarely, acquired EPS	Common (10% of dialysis patients)	Adulthood	Legs or generalized	Necrotic material, collagen, or uncommonly, elastic tissue	Diabetes, chronic kidney disease (stages 4–5), pruritus, rarely liver disease; may be end stage of perforating folliculitis
Perforating calcific elastosis	Very rare, more common in Black women	Adulthood	Abdomen, periumbilical	Calcified elastic tissue	Multiparity, weight gain, obesity, hypertension

*In the opinion of some authors.

Table 96.1 Major perforating diseases. F, female; M, male.

SECONDARY PERFORATING DISEASES
Endogenous substances
Chondrodermatitis nodularis helicis Hematomas Perforating pseudoxanthoma elasticum Perforating calcinosis Osteoma cutis Gout (urate crystals) Papular mucinosis (mucin)
Granulomas
Perforating granuloma annulare (see Fig. 93.10) Necrobiosis lipoidica Sarcoidosis Rheumatoid nodule
Exogenous foreign material
Silica Wood splinters Tattoo Sutures Injectable soft tissue fillers
Infectious diseases
Chromoblastomycosis Leprosy Schistosomiasis
Tumor cells (more common examples)*
Melanoma Spitz nevus Pilomatricoma
*May be a nonspecific finding in a range of benign and malignant tumors due to "perforation" of the epidermis by complexes of neoplastic cells.

Table 96.2 Secondary perforating diseases. For a more extensive list, see reference 4.

Other proposed pathomechanisms include abnormal vitamin A or D metabolism, enzyme release from neutrophils[12], and microangiopathy related to diabetes. Deposition of uric acid, hydroxyapatite, or silicon[13] has also been implicated in the pathogenesis of perforating disorders.

CLINICAL FEATURES

Reactive Perforating Collagenosis

Familial RPC is a rare disorder that begins during childhood[1,14]. After superficial trauma, patients develop keratotic papules that reach a size of 5–8 mm over the following 3–4 weeks. The Koebner phenomenon may occur, in which injury to the skin results in the formation of new lesions, often in a linear distribution. Koebnerization is more commonly observed with RPC than with the other perforating disorders, but it has been reported with all of them. Arms and hands are the most common sites of involvement in RPC (Fig. 96.1). The papules tend to spontaneously resolve over 6–10 weeks. Verrucous perforating collagenoma (*collagenome perforant verruciformé*) is a very rare non-familial variant of RPC in which severe trauma to the skin results in verrucous papules with transepidermal elimination of collagen[15]. Acquired RPC that begins in adulthood usually occurs in association with diabetes mellitus and/or chronic kidney disease (stages 4–5), and these cases are best classified as acquired perforating dermatosis, even though the histopathology is identical to the inherited form of RPC.

Fig. 96.1 Reactive perforating collagenosis of the arm. Several erythematous papules with a central scale-crust core. *Courtesy Lorenzo Cerroni, MD.*

Elastosis Perforans Serpiginosa

EPS is a rare disorder whose onset is during childhood or early adulthood. About 40% of cases occur in association with other genetic disorders, including Down syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, Marfan syndrome (Fig. 96.2), pseudoxanthoma elasticum (PXE), Rothmund–Thomson syndrome, and acrogeria. In a survey of pediatric dermatologists, the majority performed a detailed history and careful physical examination but did not embark upon an extensive search for these genetic disorders in an otherwise healthy child or adolescent with EPS[16].

Fig. 96.2 Elastosis perforans serpiginosa in the setting of Marfan syndrome. Annular papules and plaques developed on the ear.

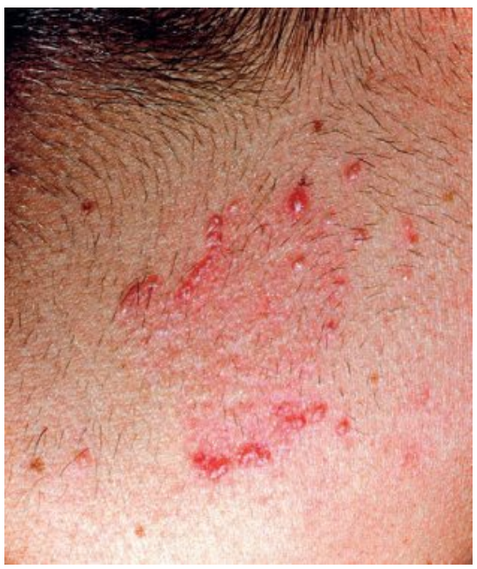

Fig. 96.3 Elastosis perforans serpiginosa. Papules arranged in an annular configuration on the neck.

Fig. 96.4 Penicillamine-induced elastosis perforans serpiginosa. A Multiple annular plaques favoring the antecubital fossae. **B** Closer view with foci of hyperkeratosis at sites of transepidermal elimination.

Very rarely, EPS has been associated with chronic kidney disease (more rarely encountered than the acquired form of RPC) and may overlap with acquired perforating dermatosis. EPS has also been reported following long-term use of penicillamine, usually for 10 or more years. This drug is known to disrupt desmosine cross-links within elastin (see Ch. 97)[17]. Because penicillamine is used to treat Wilson disease, the possibility that abnormal copper metabolism plays a pathogenic role in EPS has been raised. However, EPS has also been observed in patients with cystinuria or rheumatoid arthritis who have received penicillamine.

Lesions of EPS are keratotic, 2- to 5-mm papules that tend to be arranged in a serpiginous or annular pattern, most commonly on the lateral neck (Fig. 96.3), but also on the face, arms (Fig. 96.4), or other flexural areas. The rings of papules may reach several centimeters in diameter. Most patients experience no symptoms or only mild pruritus. Like RPC, the lesions may spontaneously resolve, but in general tend to persist, often for several years.

Acquired Perforating Dermatosis and Kyrle Disease

Acquired perforating dermatosis has been used as a catch-all term for those perforating diseases that arise in adults, usually in association with diabetes mellitus and/or the pruritus of chronic kidney disease (stages 4–5)[2]. The majority of affected patients with established renal failure are receiving dialysis, and most of those with diabetes mellitus have associated nephropathy[18]. In individuals requiring dialysis, predictors for the development of acquired perforating dermatosis include diabetes mellitus, reduced circulating levels of intact parathyroid hormone, hypoalbuminemia, and elevated serum levels of high-sensitivity C-reactive protein[19]. This disorder can also occur in conjunction with other causes of pruritus, from insect bites and scabies to lymphoma and hepatobiliary diseases, including primary biliary cholangitis and hepatocellular carcinoma.

Acquired perforating dermatosis can arise from other forms of trauma (not just scratching), including within sites of healing herpes zoster. In addition, acquired perforating dermatosis and perforating folliculitis may develop following exposure to several classes of drugs including TNF inhibitors, epidermal growth factor receptor inhibitors (e.g. gefitinib, panitumumab) and other kinase inhibitors (e.g. nilotinib), dipeptidyl peptidase-4 inhibitors, antivirals (e.g. telaprevir, indinavir), sirolimus, and several monoclonal antibodies (e.g. natalizumab, bevacizumab). Of note, some of these medications more commonly induce an acneiform eruption with disrupted pilosebaceous units rather than a perforating dermatosis. While an association with hypothyroidism and hyperparathyroidism has been reported, most of these patients also had established risk factors (e.g. diabetes, nephropathy). Lastly, in a series of 22 patients with acquired perforating dermatosis, three were healthy and had no known associated illnesses and two were renal transplant recipients[18].

Acquired perforating dermatosis occurs most commonly on the legs (Fig. 96.5), but generalized or widely scattered papules and nodules can be seen (Figs. 96.6 & 96.7). Extensor surfaces are favored over flexures and the mucous membranes are spared. A clue to the diagnosis is the presence of a central keratotic core, which is sometimes physically removed by the patient. Occasionally, a giant variant is observed,

Fig. 96.5 Acquired perforating dermatosis. **A** Numerous hyperpigmented papules and nodules on the legs in a patient with both chronic kidney disease and diabetes mellitus. **B** The central portion of these lesions can be keratotic or composed of scale-crust. **C** Larger nodules in a patient receiving hemodialysis for end-stage kidney disease. *B, Courtesy Lorenzo Cerroni, MD; C, Courtesy Frank Samarin, MD.*

Fig. 96.8 Perforating calcific elastosis. When a biopsy was performed from the elevated edge of this supraumbilical plaque in a multiparous African-American woman, resistance was felt, as well as a grinding sound.

Fig. 96.7 Acquired perforating dermatosis. Note the linear arrangement of the keratotic papules (Koebner phenomenon).

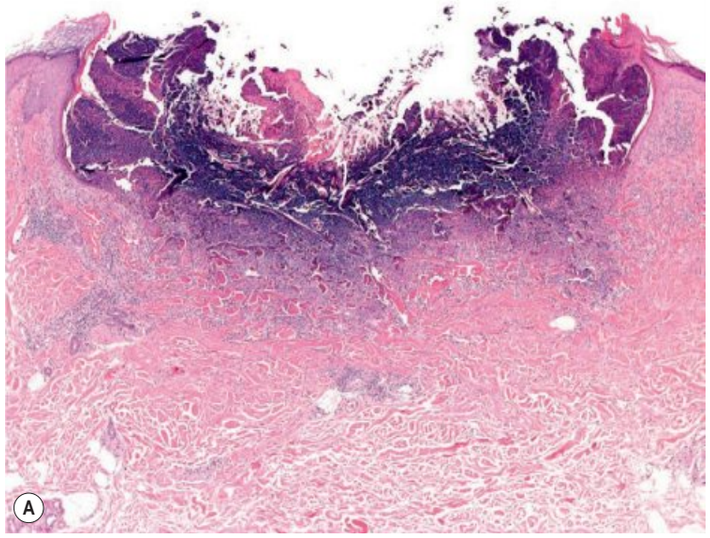
where lesions may reach 2 cm in diameter. Rarely, secondary infections due to bacteria (e.g. *Staphylococcus aureus*), atypical mycobacteria (e.g. *Mycobacterium abscessus*), or fungi (e.g. *Mucor* spp.) have been reported.

Largely on the basis of histologic findings, patients with acquired perforating dermatosis have been variably designated in the literature as having RPC, EPS[2], perforating folliculitis[14], or perforating PXE. However, not only do the pathologic findings vary from lesion to lesion in the same patient, but there are often overlapping features. In addition, since some, but not necessarily all, of these lesions appear to be follicular, and since manipulation of the lesions by patients frequently alters the histologic changes, the term "acquired perforating dermatosis" was proposed to encompass all of these cases. Furthermore, since Kyrle had used the phrase "follicularis et parafollicularis" to emphasize that not all lesions were centered on hair follicles, the eponym Kyrle disease has been used synonymously with acquired perforating dermatosis by some authorities[2]. However, others do not consider Kyrle disease to be an entity or prefer to define it as merely representing the presence of end-stage, excoriated, prurigo nodules of folliculitis[2].

Perforating Calcific Elastosis

This disorder is characterized by plaques that favor the abdomen, especially the periumbilical region of middle-aged, obese, hypertensive, multiparous Black women (Fig. 96.8)[20]. Involvement of the breast in patients with chronic kidney disease has also been observed. The plaques may be verrucous or have keratotic papules at their periphery.

In histologic sections stained with H&E or von Kossa or Verhoeff–van Gieson stains, calcified elastic fibers (identical to those in PXE) are seen undergoing transepidermal elimination. However, affected patients do not manifest other clinical findings of PXE. Similar transepidermal elimination has been observed in patients with dermatitis who applied a commercially available calcium salt water normally used for making bean curd or were exposed to calcium chloride contained in ice-melting salt.



PATHOLOGY

In all the perforating diseases, there is a plug of crusting or hyperkeratosis, with variable parakeratosis, depending upon the stage of the lesion (Fig. 96.9A). As the plug enlarges, epithelial hyperplasia develops, sometimes with dyskeratosis of keratinocytes. At the site of perforation, the epithelial hyperplasia often resembles an elephant snout or crab claw. However, sections from multiple levels through the tissue may need to be examined to find the site of perforation. Some lesions may have aggregates of neutrophils within the dermis, while older lesions, particularly those of EPS, tend to have lymphocytes, macrophages, or multinucleated giant cells in the dermis at the site of perforation.

In RPC, basophilic (degenerative) collagen fibers, some of which are vertically oriented, are seen within the plug or within the epidermis (Figs. 96.9B & 96.10), whereas in EPS, elastic fibers are seen instead (in the same location; Fig. 96.11A). It is important to note, however,

Fig. 96.10 Reactive perforating collagenosis. Transepidermal elimination of red collagen fibers through the spinous layer and into the stratum corneum (Verhoeff–van Gieson stain).

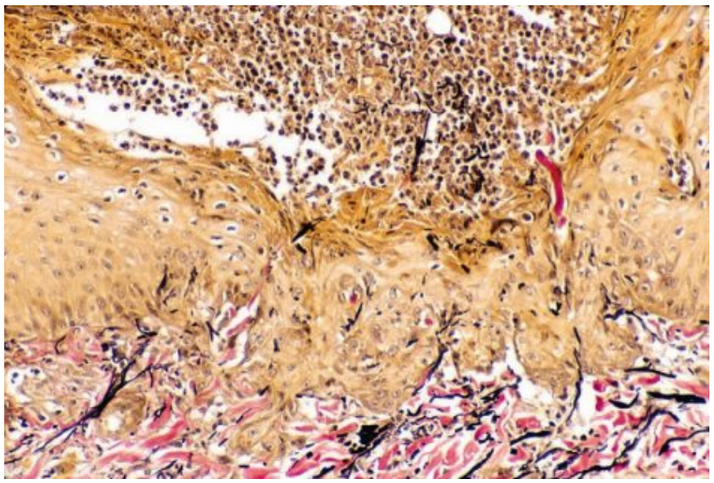

Fig. 96.12 Acquired perforating dermatosis. Transepidermal elimination of both collagen (red) and elastic fibers (black) into a crust with many neutrophils is seen (Verhoeff–van Gieson stain).

DIFFERENTIAL DIAGNOSIS OF PERFORATING DISEASES
Reactive perforating collagenosis and acquired perforating dermatosis
Excoriations from a variety of causes (prurigo simplex)
Prurigo nodularis
Folliculitis
Arthropod bites
Perforation of exogenous foreign material
Perforation of endogenous substances
Multiple keratoacanthomas
Verrucous lupus erythematosus or lichen planus
If Koebner phenomenon: psoriasis, lichen planus, verrucae (autoinoculation)
Elastosis perforans serpiginosa (resembles other annular diseases; see Ch. 19)
Granuloma annulare, Tinea, Sarcoidosis — Common annular diseases
Annular elastolytic giant cell granuloma (actinic granuloma)
Perforating pseudoxanthoma elasticum
Porokeratosis
Discoid lupus erythematosus

Table 96.3 Differential diagnosis of perforating diseases.

that intraepidermal elastic fibers can also be found in other disorders characterized by a hyperplastic epidermis (see below). In RPC, the dermal connective tissue adjacent to the plug appears unremarkable, while in EPS, an increased amount of brightly eosinophilic elastic tissue is often present in the superficial dermis (Fig. 96.11B). The Verhoeff–van Gieson stain is most helpful, because collagen fibers appear red and elastic fibers appear black (Fig. 96.12). However, in EPS, the elastic fibers higher up in the epidermis may lose their ability to stain black. In penicillamine-induced EPS, characteristic "lumpy-bumpy" elastic fibers with lateral buds resembling a "bramble bush" are seen in both lesional and non-lesional skin.

Biopsy findings in acquired perforating dermatosis vary according to the stage of evolution of the lesion. The histology may be identical to childhood RPC or EPS, or to perforating folliculitis. In other cases, it may be less specific, with amorphous degenerated material within the perforations. This material often cannot be clearly identified as collagen or elastic fibers, but sometimes both are present (see Fig. 96.12)[2]. A Japanese consensus group recently proposed classification criteria for perforating disorders based on histologic and clinical findings[21].

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes other disorders characterized by papules or nodules with central keratotic plugs or crusts, in particular prurigo simplex and prurigo nodularis (Table 96.3). Some authors, including the late A.B. Ackerman, have considered RPC to be a variant of excoriated prurigo. When the Koebner phenomenon occurs, other disorders that can also arise in a linear pattern should be considered, e.g. psoriasis, lichen planus. EPS may be confused with other disorders that are annular or serpiginous (see Ch. 19), but usually the individual keratotic plugs within the ring are distinctive. Histologically, elastic fibers may also be observed within the hyperplastic epidermis of healing wounds, keratoacanthomas, and occasionally hypertrophic lupus erythematosus and lichen simplex chronicus[22].

Since many patients with acquired perforating dermatosis have coexisting folliculitis and prurigo nodularis, there may be several different types of lesions at different stages of development and histologic findings in a single biopsy specimen may not be representative of the entire process.

Fig. 96.13 provides an algorithm for the approach to the patient with a primary perforating disorder.

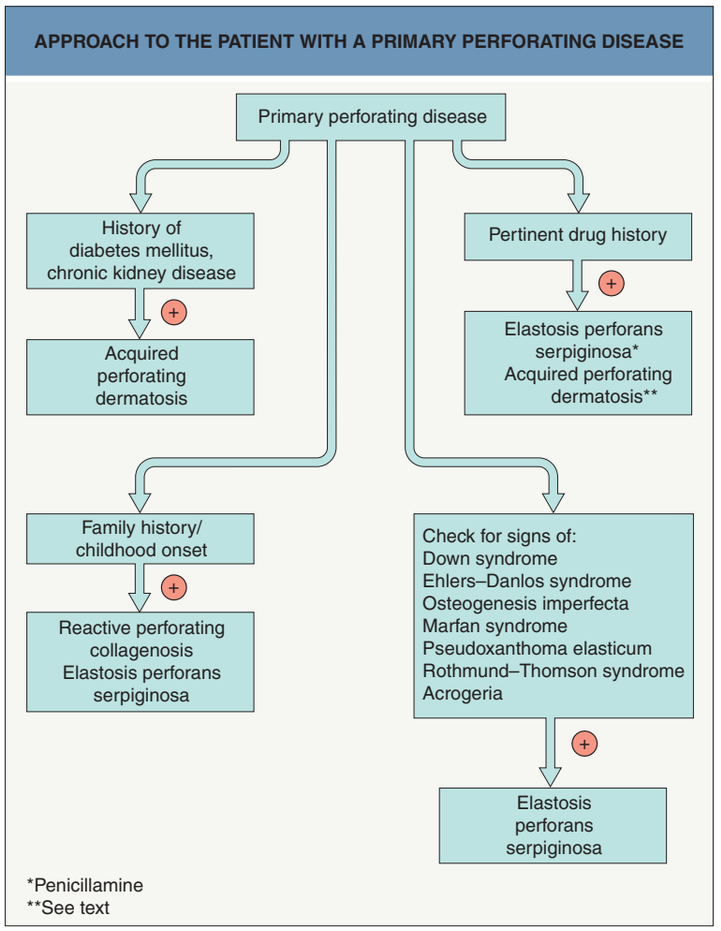

Fig. 96.13 Approach to the patient with a primary perforating disease.

TREATMENT

Table 96.4 summarizes the various treatments that have been reported, most of which are anecdotal or based upon small case series[23–29]. Well-designed, placebo-controlled studies of therapeutic interventions are needed. The inherited forms of RPC and EPS generally remain mild and localized. Sometimes local measures may be successful, but a number of authors have declared treatment to be largely ineffective. The patient with mild RPC may be counseled to simply avoid trauma and wait for lesions to resolve spontaneously.

TREATMENT OF PERFORATING DISEASES Rx
Address contributing factors
If end-stage chronic kidney disease, transplantation may lead to improvement
Discontinue culprit medication, if possible
Topical
Retinoids (e.g. tretinoin, tazarotene)[23] (3)
Corticosteroids (3)
Menthol (3)
Salicylic acid (3)
Sulfur (3)
Benzoyl peroxide (3)
Emollients (3)
Imiquimod (3)
Cantharidin (3)
Systemic
Antihistamines (e.g. doxepin) (3)*
Corticosteroids (intralesional, intramuscular, oral) (2)
Retinoids (vitamin A, acitretin, isotretinoin) (2)
Antibiotics (e.g. doxycycline, clindamycin, erythromycin, rifampin)[24,25] (3)
Dupilumab[26] (3)
Colchicine (3)
Methotrexate (3)
Charcoal (3)
Allopurinol (3)
Other
Avoid trauma and scratching (wearing gloves, trimming fingernails, behavior modification, transcutaneous nerve stimulator) (3)
Cellophane-tape stripping (for EPS) (3)
Phototherapy (broadband or narrowband UVB > UVA1, PUVA)[27,28] (2)
Cryotherapy[29] (3)
Photodynamic therapy (3)
Electrosurgical destruction (3)
Laser ablation (e.g. CO_2, Er:YAG, excimer, pulsed dye) (3)
Excision of larger bothersome lesions (3)
*See Ch. 6 for other anti-pruritic medications.

Table 96.4 Treatment of perforating diseases. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. EPS, elastosis perforans serpiginosa.

EPS may be treated with local cryotherapy, tangential excision, electrosurgical destruction, laser therapy (e.g. pulsed dye, Er:YAG), or cellophane tape stripping. However, aggressive treatment is more likely to result in scarring. As with RPC, spontaneous resolution of lesions makes it difficult to evaluate therapies.

Treatment of generalized acquired perforating dermatosis or extensive perforating folliculitis is often difficult. Sedating antihistamines and other typical "anti-itch" treatments (see Ch. 6) are often prescribed in an attempt to reduce the associated pruritus. Phototherapy (usually broadband or narrowband UVB) is a particularly good choice for patients with chronic kidney disease, since it often relieves coexisting pruritus. Other therapies that are sometimes helpful include intralesional corticosteroids and oral[15] or topical retinoids. Dupilumab was reported to significantly improve acquired RPC in the setting of adult atopic dermatitis[26]. Anecdotally, some patients have attributed rapid improvement to a change in the type of dialysis tubing or equipment employed, or even an alteration in the methods used during the actual dialysis procedure (personal observation). Occasional dialysis patients with acquired perforating dermatosis have been cured after renal transplantation[13].

97 Heritable Disorders of Connective Tissue

Nigel P. Burrows, Franziska Ringpfeil and Jouni Uitto†

Chapter Contents

Ehlers–Danlos Syndrome 1714
Pseudoxanthoma Elasticum. 1719
Cutis Laxa 1724

Key features

- Heritable connective tissue disorders with skin involvement comprise a phenotypically diverse group of conditions
- Recognition of characteristic skin findings is often critical to establishing the diagnosis and identifying associated internal involvement, which may include life-threatening cardiovascular disease as in vascular Ehlers–Danlos syndrome and pseudoxanthoma elasticum
- Heritable connective tissue disorders can result from mutations in genes encoding structural extracellular matrix (ECM) proteins (e.g. collagens, components of elastic fibers), enzymes that modify these structural proteins, and other proteins with effects on the ECM (e.g. via transport or regulatory functions)

INTRODUCTION

Heritable connective tissue diseases manifest with a broad range of phenotypic abnormalities, including variable degrees of cutaneous and extracutaneous involvement. At one end of the spectrum, the clinical findings are mild and may be limited to the skin, while in other patients the cutaneous manifestations are part of multi-organ pathology with considerable morbidity and even mortality[1,2]. There have been significant advances in understanding the molecular bases of heritable disorders of connective tissue. This has led to improved classification and prognostication, with better recognition of the phenotypic spectra and relationships among disorders.

Connective tissue is critical for organogenesis during embryonic development and homeostatic maintenance of tissues, with complex protein assembly and cell–matrix interactions. The principal fibrillar components of the extracellular matrix (ECM) of the skin are networks consisting of collagen and elastic fibers (see Ch. 95). The study of heritable disorders of connective tissue has demonstrated the considerable impact of disruption of various individual components of the ECM and related proteins.

Classic, "primary" heritable disorders of connective tissue caused by mutations (pathogenic variants) in the genes encoding collagen and structural components of elastic fibers include several forms of Ehlers–Danlos syndrome (EDS) and cutis laxa, respectively. In addition to defects in the genes that encode these structural proteins and enzymes that modify them, seemingly unrelated pathologic processes can perturb the ECM. Examples of the latter, which can be considered as "secondary" connective tissue disorders, include pseudoxanthoma elasticum (PXE) and homocystinuria.

This chapter provides a detailed review of EDS, PXE, and cutis laxa. In addition, Marfan syndrome, homocystinuria, osteogenesis imperfecta, and Buschke–Ollendorff syndrome are presented in Table 97.1. These and other genetic diseases that affect the ECM of the skin are also summarized in Table 95.5.

EHLERS–DANLOS SYNDROME

Synonym: ■ Cutis hyperelastica

Key features

- Clinically and genetically heterogeneous group of connective tissue disorders due to abnormalities in the synthesis and maintenance of collagens and other ECM components
- Autosomal dominant and autosomal recessive inheritance patterns
- Typical cutaneous features include hyperextensible and fragile skin, easy bruising, and poor wound healing
- Variable extracutaneous features include joint hypermobility, scoliosis, ocular changes, and, particularly in the vascular type, a significant risk of arterial, intestinal, or uterine rupture

History

Patients with features of Ehlers–Danlos syndrome (EDS) were described as early as the mid-1600s. The first comprehensive report of this condition was published in 1892 by Tschernogobow[3]. Drs Ehlers and Danlos, Danish and French dermatologists, respectively, contributed to a comprehensive clinical description in the early 1900s, and this constellation of findings became known as the Ehlers–Danlos syndrome in 1936. The genetic nature of EDS was noted in 1949, and soon thereafter it was suggested that the phenotype resulted from abnormal collagen. The genetic heterogeneity of EDS became evident in the 1960s, and molecular defects in collagen synthesis were first described in 1972[4].

In the past, EDS was divided into 11 subtypes (numbered I–XI) based primarily upon clinical features. In 1997, a consensus conference led to the revised "Villefranche nosology", which included only six subtypes[5]. Following determination of the molecular bases of other forms of EDS[6], an international classification recognizing 13 subtypes due to alterations in 19 genes was proposed in 2017[7], and an additional subtype was identified in 2018 (Table 97.2).

Epidemiology

Features suggestive of EDS (e.g. loose-jointedness) are present in a relatively large number of individuals in the general population. However, more stringent diagnostic criteria that include findings in the skin and joints, at a minimum, estimate the incidence of EDS to be ~1 in 5000.

Pathogenesis

EDS is a genetically as well as clinically heterogeneous group of connective tissue disorders that most often result from disruption of collagen fiber organization and function (Fig. 97.1). The collagen family includes 28 distinct proteins that differ in their tissue distributions and functions[8] (see Ch. 95). Approximately 90% of the collagen within the body is type I, which is expressed in almost all connective tissues and has especially important roles in the skin, tendons, and bones. Each collagen consists of three α-chain polypeptides, many of which are synthesized as precursor pro-α-chains. A trimeric collagen molecule may be either a homotrimer or heterotrimer consisting of the same versus two or three genetically different kinds of α-chains, respectively. There are 45 distinct α-chains, each encoded by a different gene[8].

The pathogenesis of EDS can involve mutations in genes for collagen-processing enzymes as well as those encoding collagen α-chains. The latter result in either dominant-negative effects, e.g. disruption of trimers and fibrils due to incorporation of mutant collagen α-chains, or haploinsufficiency. The precise phenotype depends upon the nature of the mutation(s) and the type of collagen or other protein that is affected.

ADDITIONAL HERITABLE DISORDERS OF CONNECTIVE TISSUE WITH CUTANEOUS FINDINGS				
Disease	**Cutaneous findings**	**Extracutaneous manifestations**	**Inheritance**	**Associated gene/protein product**
Marfan syndrome	Striae, elastosis perforans serpiginosa, decreased subcutaneous fat on extremities	Skeletal abnormalities (e.g. disproportionately long limbs, arachnodactyly, scoliosis), lens subluxations (upward), dilation/dissection of ascending aorta*	AD	*FBN1*/fibrillin 1 defects (the major component of microfibrils)†
Homocystinuria	Malar flush, livedo reticularis, diffuse pigmentary dilution, tissue paper-like scars	Marfanoid habitus, lens subluxations (downward), venous and arterial thrombosis‡, intellectual disability	AR	*CBS*/cystathionine synthase enzyme deficiency (resulting in increased plasma homocysteine¶); rarely, methylenetetrahydrofolate reductase, 5-methyltetrahydrofolate-homocysteine methyltransferase, or 5-methyltetrahydrofolate-homocysteine methyltransferase reductase deficiency (enzymes that convert homocysteine back to methionine)
Osteogenesis imperfecta	Thin skin	Bone fragility, blue sclerae, dentinogenesis imperfecta (in a subset of patients)	AD	*COL1A1*, *COL1A2*/type I collagen defects
Buschke–Ollendorff syndrome	Connective tissue nevi (dermatofibrosis lenticularis disseminata); occasionally cutaneous sclerosis associated with melorheostosis	Osteopoikilosis ("spotted" bones); occasionally melorheostosis (sclerotic bone resembling "dripping candle wax" on radiographs; reflects a postzygotic "second hit" in the *LEMD3* gene); rarely otosclerosis	AD	*LEMD3*/LEM domain-containing 3, an antagonist of bone morphogenic protein (BMP) and TGF-β signaling

*In addition to traditional treatment with β-blockers, angiotensin II receptor blockers (e.g. losartan), which antagonize pathogenic transforming growth factor (TGF)-β signaling, can prevent aortic root dilation in patients with Marfan syndrome; administration of doxycycline, which inhibits metalloproteinases-2 and -9, may also be of benefit.
†Mutations in the genes encoding TGF-β receptors 1 and 2 can lead to a phenotype that mimics Marfan syndrome.
‡Methionine-restricted, cysteine-supplemented diet plus pyridoxine recommended.
¶Elevated plasma homocystine and homocysteine can be detected in patients with homocystinuria, but only homocysteine is elevated in hyperhomocysteinemia.

Table 97.1 Additional heritable disorders of connective tissue with cutaneous findings. Other rare genetic diseases of the extracellular matrix are listed in Table 95.5. AD, autosomal dominant; AR, autosomal recessive.

Several forms of EDS are caused by *dominant-negative* mutations in the genes encoding α-chains of type I (*COL1A1, COL1A2*), type III (*COL3A1*), and type V (*COL5A1, COL5A2*) collagens. Characteristic examples include splice site mutations that can result in an in-frame deletion of a single exon and missense mutations that lead to a glycine substitution in the collagenous domain. The resultant polypeptides are incorporated into the polymeric collagen molecules and disrupt the formation, secretion, and/or thermal stability of triple helices. As a consequence, there may be a reduced amount of collagen as well as structurally and functionally abnormal fibrils.

Haploinsufficiency is caused by a heterozygous loss-of-function mutation, usually associated with a premature termination codon. These types of mutations often result in unstable mRNA that undergoes accelerated decay, leading to an absence of the corresponding polypeptide. Haploinsufficiency can also be caused by a missense mutation encoding a polypeptide that cannot be incorporated into collagen triple helices. Haploinsufficiency occurs when only 50% of the normal amount of collagen is present, which is not enough to form fully functional fibrils and thus results in a disease phenotype.

Vascular EDS can result from either dominant-negative mutations in *COL3A1* or haploinsufficiency of type III collagen, with the latter associated with a delayed onset of arterial complications and prolonged survival[9]. Collagen III is an important component of arterial and intestinal walls and a less abundant component of dermal connective tissue. However, a reduced amount of type III collagen leads to small or variably sized dermal collagen fibrils and thinning of the dermis, emphasizing the role of type III collagen in fibrillogenesis.

Classical EDS can be caused by dominant-negative mutations in *COL5A1* and *COL5A2* or (in 30%–50% of cases) haploinsufficiency of type V collagen (*COL5A1*). The role of type V collagen in collagen fibrillogenesis is to limit fibril diameter, explaining the ~25% increase in fibril diameter that is observed by electron microscopy in affected individuals.

Arthrochalasia EDS results from heterozygous *COL1A1* and *COL1A2* mutations that specifically affect the amino-terminal cleavage site of procollagen I N-peptidase and thereby disrupt processing of type I collagen pro-α-chains. Biallelic loss-of-function mutations in *ADAMTS2*, which encodes this procollagen I N-peptidase, are responsible for *dermatosparaxis* EDS. The latter disorder is characterized by irregular and thin collagen fibrils containing type I collagen with an intact N-propeptide, termed pN-collagen.

Kyphoscoliotic EDS is most often caused by biallelic mutations in *PLOD1*, which encodes another collagen-processing enzyme, lysyl hydroxylase; this leads to reduced hydroxylysine content in collagen polypeptides and altered cross-linking of collagen fibrils. Another form of kyphoscoliotic EDS results from biallelic mutations in *FKBP14*, which encodes an FK506-binding peptidyl-prolyl cis–trans isomerase that catalyzes collagen folding and acts as a chaperone for collagens within the endoplasmic reticulum[10].

Complete tenascin-X deficiency via biallelic null mutations underlies an autosomal recessive *classical-like EDS*[11]. Tenascin-X is an ECM protein that reinforces associations among collagen fibrils and may also regulate the structure and stability of elastic fibers. Another form of classical-like EDS is caused by mutations in *AEBP1*, which encodes an aortic carboxypeptidase-like protein (ACLP) that associates with collagens in the ECM and plays a role in both tissue repair and fibrosis[7].

Spondylodysplastic EDS can result from abnormal glycosaminoglycan processing due to mutations in genes encoding galactosyltransferases (*B4GALT6, B3GALT7*), as well as via disruption of intracellular zinc homeostasis (*SLC39A1*). In addition, defects in glycosaminoglycan biosynthesis due to mutations in dermatan-4-sulfotransferase 1 (*CHST14*) or dermatan sulfate epimerase (*DSE*) cause *musculocontractural EDS*[5]. Lastly, constitutive activation of complement 1 (*C1R, C1S*) in the classical complement pathway underlies *periodontal EDS*[12].

Clinical Features

The general features of EDS include hyperextensible fragile skin and joint hypermobility[4] (Fig. 97.2A,B). The Beighton scale can be utilized to assess the latter[13], and different subtypes of EDS have additional manifestations that facilitate their classification[5,7] (Fig. 97.3). Table 97.2 outlines the currently recognized variants of EDS.

Typical skin findings are present, to a varying degree, in all subtypes of EDS[14]. Skin hyperextensibility is defined as the ability to stretch ≥1.5 cm on the volar surface of the distal forearm or dorsum of the hand; ≥3 cm on the neck, elbow, or knee; and ≥1 cm on the palm[15]. The

2017 INTERNATIONAL CLASSIFICATION OF EHLERS–DANLOS SYNDROME			
EDS subtype	**Clinical features**	**Inheritance**	**Mutated gene/protein**
Classical*	Hyperextensible and soft/doughy skin, joint hypermobility, atrophic scars, easy bruising	AD	*COL5A1, COL5A2*/α_1- and α_2-chains of type V collagen Rarely, *COL1A1*/α_1-chain of type I collagen (associated with vascular fragility)
Classical-like, type 1	Similar to mild classical type but normal scarring; also variable muscle weakness, foot deformities	AR	*TNXB*, tenascin-X
Classical-like, type 2†	Similar to classical EDS; also foot deformities (pes planus, hallux valgus, hammer toes), osteopenia	AR	*AEBP1*/adipocyte enhancer-binding protein 1 (also known as aortic carboxypeptidase-like protein)
Cardiac valvular	Cardiac valve defects, otherwise similar to the classical type	AR	*COL1A2*/α_2-chain of type I collagen
Hypermobile*	Joint hypermobility, pain, and dislocations; less pronounced skin changes, e.g. soft/velvety, mildly hyperextensible; recurrent hernias, variable autonomic dysfunction	AD	Unknown
Vascular*	Thin, translucent skin with excessive bruising; arterial, gastrointestinal, and uterine rupture; small joint hypermobility, varicose veins, characteristic facies	AD	*COL3A1*/α_1-chain of type III collagen
Kyphoscoliotic*	Hyperextensible skin, easy bruising, joint hypermobility, kyphoscoliosis, congenital hypotonia, arterial rupture, blue sclerae, marfanoid habitus *PLOD1*: atrophic scarring, ocular fragility *FKBP14*: follicular hyperkeratosis, myopathy, impaired hearing	AR	*PLOD1*/lysyl hydroxylase‡ *FKBP14*/FK506-binding protein 14
Musculocontractural	Hyperextensible and fragile skin, wrinkled palms, congenital joint contractures, recurrent dislocations, scoliosis, ocular anomalies, craniofacial abnormalities	AR	*CHST14*/dermatan-4-sulfotransferase 1 (allelic with adducted thumb–clubfoot syndrome) *DSE*/dermatan sulfate epimerase
Arthrochalasia*	Hyperextensible and fragile skin, severe joint hypermobility with congenital bilateral hip dislocation, scoliosis	AD	*COL1A1*, *COL1A2*/α_1- and α_2-chains of type I collagen
Dermatosparaxis*	Severe skin fragility, sagging and redundant skin that is soft and doughy, easy bruising, joint hypermobility, short limbs, hernias, distinctive facies	AR	*ADAMTS2*/procollagen I N-peptidase
Periodontal	Mildly hyperextensible skin with prominent vessels, excessive bruising with pretibial plaques, small joint hypermobility, early-onset periodontitis with gingival recession, increased infections, marfanoid habitus	AD	*C1R, C1S*/complement C1r, C1s
Spondylodysplastic (includes former progeroid type)	Soft/doughy, translucent, and/or hyperextensible skin; variable joint hypermobility, hypotonia, limb bowing, short stature, variable tapered fingers, osteopenia, developmental delay *B4GALT6/7*: progeroid facies, joint contractures *SLC39A13*: wrinkled palms, platyspondyly, protuberant eyes	AR	*B4GALT7*/galactosyl transferase-1 *B3GALT6*/ galactosyltransferase-II *SLC39A13*/zinc transporter ZIP13
Brittle cornea syndrome	Soft, translucent skin with variable hyperextensibility and fragility, acral wrinkling, hypermobility of small joints, ocular fragility, keratoglobus/keratoconus, blue sclerae, impaired hearing, scoliosis	AR	*ZNF469*/ zinc finger protein 469 *PRDM5*/ PR domain-containing protein 5
Myopathic	Soft/doughy skin with atrophic scarring, proximal joint contractures and distal hypermobility, congenital myopathy with hypotonia that improves with age	AD or AR	*COL12A1*/α_1-chain of type XII collagen

*Six main types recognized by the 1997 Villefranche consensus classification[4].
†Described after the 2017 international classification.
‡Analysis of the urine for an increased deoxypyridinoline : pyridinoline ratio can be used as a screening test for kyphoscoliotic EDS.

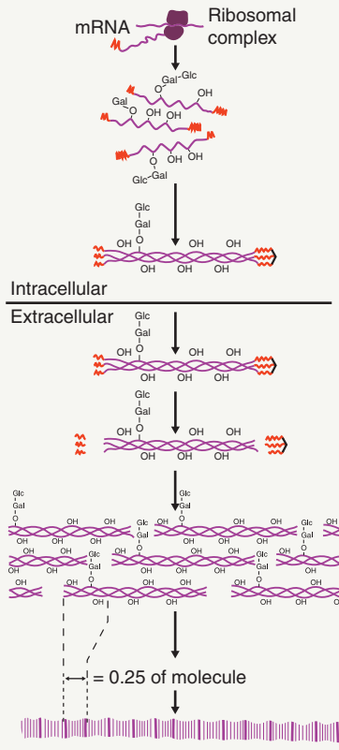
Table 97.2 2017 International classification of Ehlers–Danlos syndrome (EDS)[7]. See reference 7 for full diagnostic criteria. The historical X-linked and fibronectin subtypes have unknown molecular bases and are not included in the current nosology. Other previous EDS subtypes have been reclassified as occipital horn syndrome (see Table 97.7) and familial joint hypermobility syndrome. In addition to recognized forms of EDS, heterozygous mutation in the elastin microfibril interfacer 1 (*EMILIN1*) gene was identified in a patient with increased skin elasticity, aortic aneurysms, sensorimotor peripheral neuropathy, and arthropathy. AD, autosomal dominant; ADAMTS2, *a d*isintegrin-like *a*nd *m*etalloprotease domain with *t*hrombospondin type 1 motif 2; AR, autosomal recessive; COL, collagen; PLOD1, *p*rocollagen-*l*ysine 1, 2-*o*xoglutarate 5-*d*ioxygenase 1.

skin also tends to be fragile, splitting readily due to trauma, particularly on the knees, elbows, shins, and forehead. These wounds present with a gaping, "fish-mouth" appearance; healing may be delayed and dehiscence is common. The resulting scars are typically atrophic and widen over time (Fig. 97.2C), although some affected individuals develop hypertrophic scars. Easy bruising is commonly observed, reflecting the fragility of small blood vessels. Dermatologic disorders that are associated with, but not specific to, EDS include elastosis perforans serpiginosa and piezogenic papules (Fig. 97.2D).

Major subtypes

Classical EDS is inherited in an autosomal dominant fashion and presents with hypermobile joints as well as hyperextensible and fragile skin that is prone to bruising. Scars are typically widened and atrophic, often with a "cigarette paper" appearance. The skin also tends to be soft, with a slightly doughy or velvety texture. Sites of repeated trauma develop a variety of secondary lesions such as molluscoid pseudotumors, which are fleshy nodules composed of redundant skin and fibrous tissue that favor the knees and elbows. Multiple small, hard, mobile

COLLAGEN BIOSYNTHESIS, SECRETION, AND FIBRIL ASSEMBLY – RELATIONSHIP OF PATHOLOGY TO THE MAJOR SUBTYPES OF EHLERS–DANLOS SYNDROME



Physiology		Pathology	EDS subtype (mode of inheritance)
	Synthesis, hydroxylation and glycosylation of pro-α polypeptides of type I, III and V collagens	**Lysyl hydroxylase** deficiency results in reduced hydroxylysine content and altered cross-linking profile	Kyphoscoliotic (AR)
	Formation of interchain S-S bonds at the carboxyl ends followed by triple helix formation	Dominant-negative mutations or haploinsufficiency in ***COL3A1*** affect triple helix formation, thermal stability, and secretion of type III collagen molecules	Vascular type (AD)
	Secretion of procollagen	Dominant-negative mutations in the recognition sites for procollagen N-peptidase in ***COL1A1*** and ***COL1A2*** prevent cleavage of amino-terminal propeptides	Arthrochalasia (AD)
	Removal of propeptides by specific proteases	Loss-of-function mutations in **procollagen-N-peptidase** result in the formation of only thin collagen fibrils	Dermatosparaxis (AR)
	Fibril assembly	Dominant-negative mutations in ***COL5A1*** and ***COL5A2*** or haploinsufficiency in ***COL5A1*** result in abnormal or reduced amount of collagen fibrils	Classical type (AD)
		Absence of **tenascin-X** leads to reduced collagen fibril density	Classical type (AR)
	Stabilization of fibrils by intermolecular cross-linking

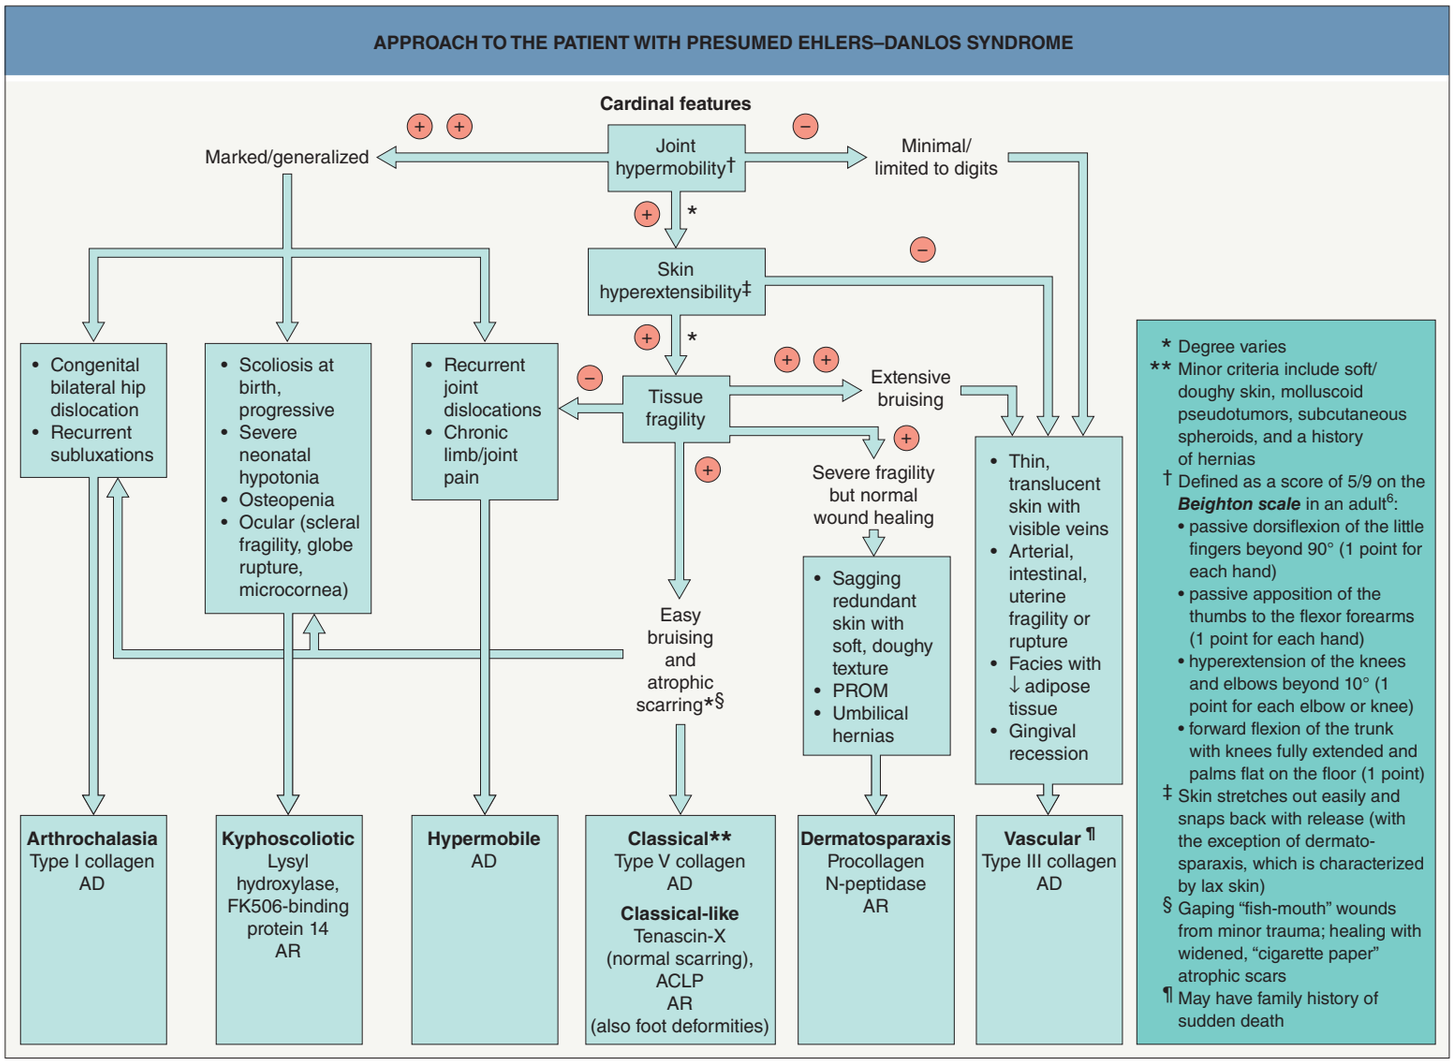

Fig. 97.3 Approach to the patient with presumed Ehlers–Danlos syndrome (EDS). See Table 97.2 for additional rare types of EDS. ACLP, aortic carboxypeptidase-like protein; AD, autosomal dominant; AR, autosomal recessive; PROM, premature rupture of fetal membranes.

papulonodules over bony prominences, such as the ulnar and tibial borders, are also a frequent finding. These subcutaneous spheroids are thought to represent calcified fat. At least half of affected individuals can touch the tip of their nose with their tongue (Gorlin sign), compared to 10% of the general population (Fig. 97.2E). Although classical EDS may be associated with mild aortic root dilation and mitral valve prolapse, each in ~5% of patients, these findings are rarely of clinical significance[16]. Other frequent musculoskeletal manifestations include pes planus, subluxations, and temporomandibular joint dysfunction.

Hypermobile EDS is the most common variant and has autosomal dominant inheritance. The most prominent clinical feature is generalized joint hypermobility, typically leading to recurrent joint dislocations that can cause chronic pain and susceptibility to osteoarthritic changes. Easy bruising is common, and the skin tends to be soft but with only mild hyperextensibility and atrophic scarring. Fatigue is common, and patients may have autonomic dysfunction presenting with orthostatic intolerance and gastrointestinal symptoms[17]; concomitant mast cell activation syndrome has also been described. The 2017 diagnostic criteria distinguish hypermobile EDS from other hypermobility spectrum disorders[18].

Vascular EDS is an autosomal dominant disorder characterized by thin translucent skin (Fig. 97.2F) with extensive bruising and a high risk of arterial, intestinal, and uterine ruptures[19]. Spontaneous arterial rupture has the highest incidence in the third and fourth decades of life but may occur earlier, especially in men, and median survival is ~50 years[9]. Affected individuals often have a characteristic facial appearance, with a "pinched" nose, thin lips, micrognathia, hollow cheeks, and prominent "staring" eyes due to decreased periorbital adipose tissue. Small earlobes and fine scalp hair are additional features.

Less common subtypes

Classical-like EDS, due to either tenascin-X or ACLP deficiency, has autosomal recessive inheritance and an overall phenotype similar to that of classical EDS. Tenascin-X deficiency is characterized by an *absence* of atrophic scarring as well as variable muscle weakness, risk of bowel rupture, and occasional association with congenital adrenal hyperplasia due to deletion of the contiguous gene encoding 21-hydroxylase[20]. Foot deformities are observed in both forms of classical-like EDS, while osteopenia is an additional feature of ACLP deficiency.

Kyphoscoliotic EDS is an autosomal recessive disorder that features skin hyperextensibility, generalized joint hypermobility, severe hypotonia at birth, delayed gross motor development, and progressive congenital scoliosis. Patients with *PLOD1* mutations have scleral fragility that can lead to rupture of the ocular globe, whereas individuals with *FKBP14* mutations present with congenital sensorineural deafness. Additional findings may include atrophic scars, easy bruising, fragility of other tissues (rarely arterial rupture), a marfanoid habitus, and osteopenia.

Arthrochalasia EDS is inherited in an autosomal dominant fashion. The major clinical features include severe generalized joint hypermobility with recurrent subluxations and congenital bilateral hip dislocation. Patients may also present with hyperextensible skin, atrophic scars, easy bruising, hypotonia, scoliosis, and mild osteopenia.

Dermatosparaxis EDS is an autosomal recessive disorder that, unlike other forms of EDS, presents with skin that is sagging and redundant as well as extremely fragile. The skin has a highly characteristic soft, doughy consistency, and it tears and bruises easily (Fig. 97.4). The clinical features of other rare forms of EDS are outlined in Table 97.2.

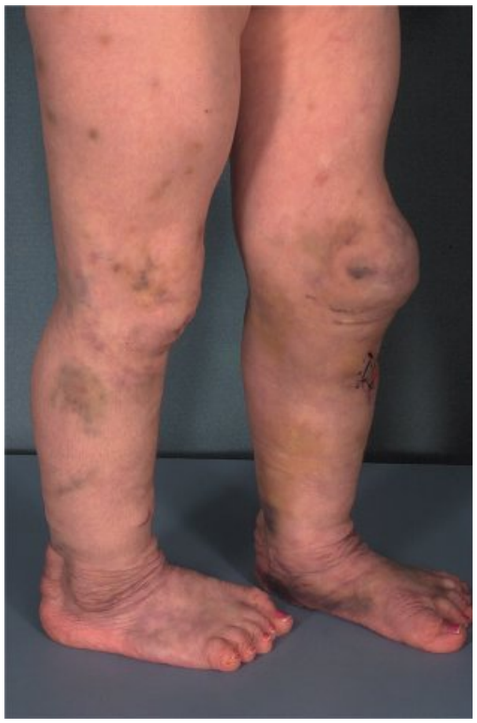

Fig. 97.4 Extensive bruising on the shins in a patient with the dermatosparaxis type of Ehlers–Danlos syndrome (EDS). Similar changes can be seen in vascular EDS. *Courtesy Julie V. Schaffer, MD.*

COMPARISON OF SELECTED CLINICAL FEATURES IN EHLERS–DANLOS SYNDROME AND MARFAN SYNDROME		
	Ehlers–Danlos syndrome	**Marfan syndrome**
Molluscoid pseudotumors	++	–
Skin	Hyperextensibility, "fish-mouth" atrophic scars	Striae

Myopia	+	++
Mitral valve abnormalities	+	++
Stature	Variable	Tall

Table 97.3 Comparison of selected clinical features in Ehlers–Danlos syndrome and Marfan syndrome. ++, common feature; +, occasional feature; –, not a feature.

Pathology and Laboratory Findings

Histopathologic examination of the skin does not usually yield diagnostic findings. Nonspecific increases in elastic fibers have been reported, particularly in areas of repeated trauma or molluscoid pseudotumors. However, in vascular EDS the dermis is often reduced to ~25% of its normal thickness, and immunohistochemical staining may show intracellular accumulation of type III collagen.

Although transmission electron microscopic findings in different EDS subtypes have some overlap, collagen fibrils with variable diameters and occasional large "cauliflower" fibrils with an irregular contour are characteristic of classical EDS[21]. Ultrastructurally, arthrochalasia and dermatosparaxis types of EDS feature angular and "hieroglyphic" appearances of collagen fibrils in cross-section, respectively.

Genetic testing is available for all the major forms of EDS except the hypermobile type[22]. Additional diagnostic methods include: (1) protein electrophoresis of collagens extracted from cultured dermal fibroblasts to assess for specific collagen defects in vascular, arthrochalasia, and dermatosparaxis types of EDS; (2) urine analysis for an increased deoxypyridinoline:pyridinoline ratio in kyphoscoliotic EDS; and (3) ELISA of serum for tenascin-X deficiency[11].

Differential Diagnosis

Several previously described rare forms of EDS, including X-linked and fibronectin subtypes, are no longer included in the EDS nosology due to a lack of clear descriptions of their clinical features and unknown molecular bases. Occipital horn syndrome is now considered to represent a form of cutis laxa (see Table 97.7) rather than EDS. In contrast to cutis laxa, which is characterized by loose and sagging skin with decreased resilience, the skin of patients with EDS (except the dermatosparaxis type) retains its elasticity and recoil. Although some patients with EDS, in particular the kyphoscoliotic type, have a marfanoid body habitus, they do not typically exhibit other findings of Marfan syndrome (Table 97.3), a distinct heritable connective tissue disorder due to mutations in the fibrillin 1 gene (*FBN1*) (see Table 97.1).

The phenotype of Loeys–Dietz syndrome (LDS; formerly known as LDS type II) can mimic that of vascular EDS, with overlapping features including translucent skin, easy bruising, atrophic scarring, joint hypermobility, and arterial rupture (see Table 95.5). However, some patients with LDS have additional features such as a bifid uvula, hypertelorism, and facial milia. Patients with vascular EDS and other types that result in extensive bruising are often suspected to have a bleeding disorder, and they may present to a dermatologist after a hematologic evaluation fails to reveal any abnormalities.

Treatment

Contact sports should be avoided and the use of padding or shin guards may help to decrease trauma to the skin. Delaying suture removal for up to twice as long as usual plus use of two layers of sutures with prolonged tensile strength may improve wound healing and the appearance of surgical scars.

In vascular EDS, affected individuals are at high risk of arterial and bowel ruptures. Use of celiprolol (currently not available in the US), a long-acting β_1-antagonist with partial β_2-agonist properties, may reduce the incidence of arterial dissection; the utility of other β-blockers in vascular EDS remains to be determined[23,24]. Approximately 5% of pregnancies in women with vascular EDS are complicated by fatal uterine or arterial rupture[22]; it is unclear whether elective caesarean section reduces these risks, and patients should be managed in a high-risk obstetric unit with multidisciplinary input. Total abdominal colectomy with end ileostomy or ileorectal anastomosis are considered the safest surgical procedures after colonic perforation, with higher risks of re-perforation and anastomotic leak associated with end colostomy or restoration of colonic continuity[25].

PSEUDOXANTHOMA ELASTICUM

Synonym: ■ Grönblad–Strandberg syndrome

Key features

- An autosomal recessive disorder characterized by clumped, distorted, and calcified elastic fibers
- Cutaneous features include yellowish papules, "cobblestoning," and redundant folds in flexural areas
- Calcification of elastic fibers in the walls of medium-sized arteries can lead to luminal narrowing and clinical sequelae such as intermittent claudication, renovascular hypertension, angina, and less commonly stroke or myocardial infarction
- Angioid streaks reflect breaks in the calcified elastic lamina of Bruch's membrane; choroidal neovascularization and hemorrhage can result in loss of visual acuity
- Gastrointestinal hemorrhage is an occasional complication

History

The French dermatologist Balzer first described the skin manifestations of PXE and associated elastic degeneration in the skin and heart in 1884, which was followed 5 years later by a similar case report by Chauffard. Based on these two cases, Darier coined the name "pseudo-xanthome élastique" in 1896 to differentiate this condition from xanthomas[26]. In the late 1920s, Grönblad[27] and Strandberg[28] recognized the association of the characteristic skin manifestations with angioid streaks, and the cardiovascular manifestations were better defined two decades later. More recently, the molecular defects that underlie PXE were identified, clarifying the mode of inheritance, which had previously been debated[29,30].

Epidemiology

PXE is an autosomal recessive disease, with a prevalence estimated to be from 1 in 25 000 to 1 in 100 000. There is no racial predilection but a slight female preponderance[31]. Skin changes of PXE usually appear during childhood or early adolescence, but the diagnosis is occasionally not made until serious arterial or ocular complications develop in the third or fourth decade of life. Mild cutaneous and ocular findings have also been observed in heterozygous carriers[24].

Pathogenesis

Loss-of-function mutations in both copies of *ABCC6* can be identified in ~90% of patients with PXE. *ABCC6* encodes an ATP-binding cassette (ABC) transporter with a high degree of homology to multidrug resistance-associated proteins. ABCC6 is predominantly expressed in the basolateral plasma membrane of hepatocytes, where it serves as an efflux pump. The absence of functional ABCC6 in PXE patients results in reduced ATP release from hepatocytes[32]. The ectonucleotide pyrophosphatase/phosphodiesterase 1 enzyme (ENPP1) converts extracellular ATP to AMP + inorganic pyrophosphate (PPi), which acts as a physiologic inhibitor of mineralization. Reduced PPi levels in PXE patients result in ectopic calcification of elastic structures in various tissues. PPi is converted to inorganic phosphate (Pi) by tissue nonspecific alkaline phosphatase (TNAP), and inhibition of this enzyme was found to increase PPi levels in a mouse model of PXE[33].

Biallelic mutations in *ENPP1* can cause *generalized arterial calcification of infancy* (GACI), a rare autosomal recessive disorder that is usually lethal during the first six months of life[34]. Occasionally, biallelic *ENPP1* mutations also cause PXE, and *ABCC6* mutations underlie a subset of GACI (GACI-2), thus demonstrating pathogenic and clinical overlap between these two conditions[34–36]. *Arterial calcification due to CD73 deficiency* (ACDC) represents a rare, milder ectopic calcification disorder caused by mutations in *NT5E*, which encodes an ecto-5′-nucleotidase that converts AMP to Pi and adenosine. The latter functions as an inhibitor of TNAP, and lower adenosine levels in ACDC lead to increased TNAP activity that then results in reduced plasma PPi levels. Clinical features of ACDC include calcification of arteries in the lower extremities and calcium hydroxyapatite deposition in juxtaarticular tissues of the hands and vertebrae[37,38].

Biallelic mutations in the γ-glutamyl carboxylase gene (*GGCX*) cause PXE-like skin changes plus deficiency in vitamin K-dependent coagulation factors[39]. A combination of heterozygous mutations in *GGCX* and *ABCC6* has also been identified in patients with cutaneous findings of PXE[40]. The GGCX enzyme catalyzes the vitamin K-dependent γ-glutamyl carboxylation that is necessary for activation of coagulation factors in the liver as well as the matrix gla protein in peripheral connective tissues. When carboxylated (activated), matrix gla protein prevents ectopic mineralization.

In general, the pathogenesis of PXE and related ectopic calcification disorders is related to decreased anti-mineralization activity due to reduced plasma PPi levels. Collectively, this group has been designated as PPi deficiency syndromes[41]. Calcification of elastic fibers in the mid and deep dermis, media and intima of mid-sized arteries, and Bruch's membrane of the eye produces the characteristic clinical and histopathologic changes of PXE (Fig. 97.5).

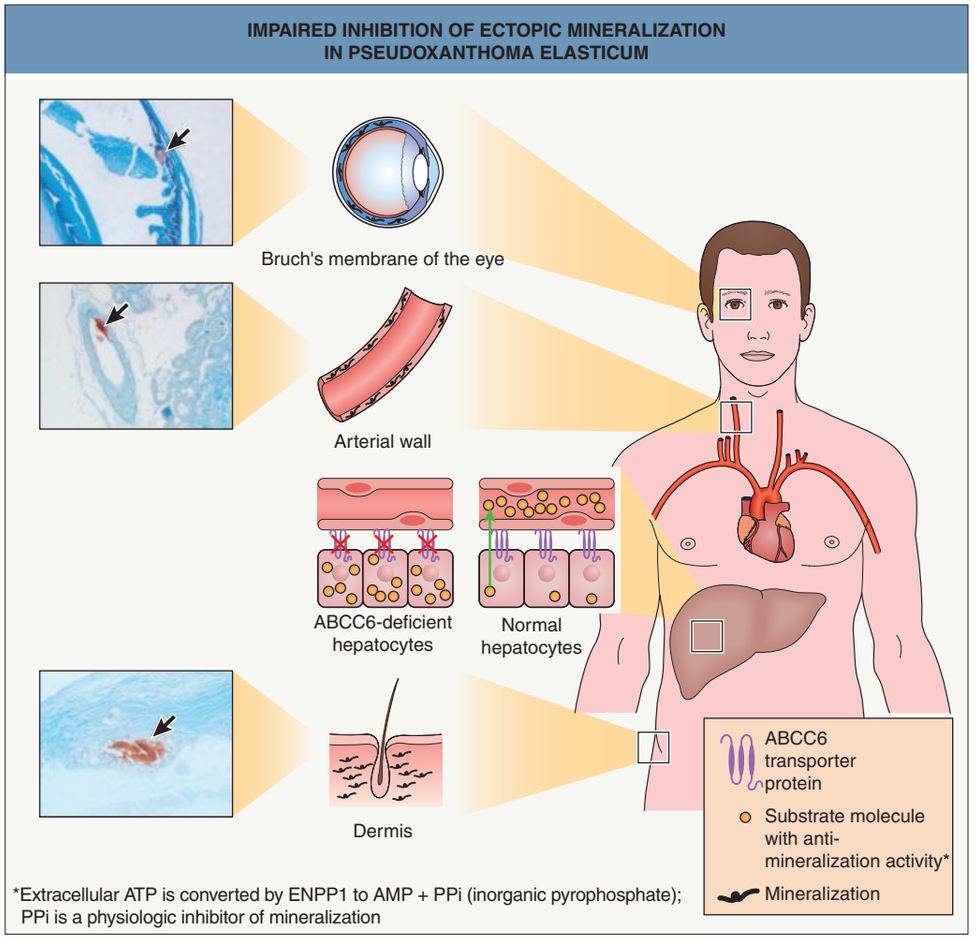

Fig. 97.5 Impaired inhibition of ectopic mineralization in pseudoxanthoma elasticum. The normal liver expresses high levels of the ABC-binding cassette subfamily C member 6 (ABCC6) protein, which serves as an efflux pump on the basolateral surface of hepatocytes, transporting molecules such as ATP from inside these cells to the extracellular space. ATP is rapidly converted to AMP and inorganic pyrophosphate (PPi), with the latter representing a physiologic anti-mineralization factor. In patients with pseudoxanthoma elasticum (PXE), an absence of ABCC6 transporter activity in the liver results in reduced circulating concentrations of PPi, which allows ectopic calcification of connective tissues in the eye, arterial walls (media and intima), and dermis. The presence of calcium is evident on histopathological examination of these tissues (alizarin red staining; see arrows in left panels) in *Abcc6*$^{-/-}$ mice, which recapitulate the features of human PXE. *Adapted from Uitto J, Li Q, Jiang Q. Pseudoxanthoma elasticum: molecular genetics and putative pathomechanisms. J Invest Dermatol 2010;130:661–70.*

Clinical Features

PXE primarily affects the elastic fiber networks of the skin, eyes, and cardiovascular system. There is tremendous variability in severity even among siblings, and sometimes only one or two of these organ systems show signs of the disease.

PXE owes its name to the characteristic cutaneous findings, which bear some resemblance to xanthomas and represent the most frequent manifestation of the condition. Thin, yellowish papules typically begin to appear in flexural areas during the first or second decade of life. Over time, the papules coalesce to form cobblestone-like plaques, giving rise to a "plucked chicken skin" or "cobblestone" appearance (Fig. 97.6). The lateral aspect of the neck is often affected first, with the antecubital and popliteal fossae, wrists, axillae, and groin being additional sites of possible involvement. The periumbilical area may be affected in multiparous women, which should not be confused with *perforating calcific elastosis*, a localized, acquired, purely cutaneous PXE-like condition (Table 97.4; see Ch. 96). Involvement of non-flexural sites can occur in patients with more extensive disease.

Fig. 97.6 Clinical features of pseudoxanthoma elasticum. A–C Yellowish papules and "cobblestoned" plaques on the neck (**A, B**) and in the antecubital fossa (**C**). **D** Pebbling of the skin as well as thickened folds on the neck. **E** Thickened, yellowish, sagging skin in the axilla (**D**). *A, C, Courtesy Addenbrooke's Hospital, Cambridge, UK; D, E, Courtesy Julie V. DIFFERENTIAL DIAGNOSIS OF PSEUDOXANTHOMA ELASTICUM

Disorder	Patient characteristics	Clinical features	Histologic features
Actinic elastosis	History of chronic sun exposure; lightly pigmented skin; middle-aged and older adults	Yellow to gray, thickened, lax, finely to coarsely wrinkled skin; photodistribution on the lateral forehead, neck, dorsal aspect of the forearms	Masses of basophilic, amorphous, degenerated elastic fibers in the papillary and upper reticular dermis
Late-onset focal dermal elastosis	7th–9th decades	Multiple 1- to 3-mm yellow papules; may coalesce; neck, axillae, groin, antecubital and popliteal fossae	*Increased* normal-appearing elastic fibers in the mid and deep reticular dermis
PXE-like papillary dermal elastolysis*	6th–9th decades; primarily women	Multiple 2- to 3-mm yellow or skin-colored papules coalescing to form plaques with a cobblestone appearance; neck, flexor forearms, axillae, lower abdomen, inframammary folds	*Decreased* elastic tissue in a band-like distribution in the papillary dermis, with fragmentation and clumping of elastic fibers
White fibrous papulosis of the neck*	5th–9th decades; Japanese men, White women	Multiple 2- to 3-mm whitish papules; lateral and posterior neck > upper trunk	*Decreased* elastic fibers in the papillary and mid reticular dermis; thickened collagen bundles
Elastoderma	3rd–4th decades	Localized areas of lax, pendulous skin; neck, trunk, arm	*Increased* normal- and abnormal-appearing elastic fibers throughout the dermis, extending into the subcutis
Perforating calcific elastosis†	Multiparous Black women; 5th–8th decades‡	Plaque composed of coalescing keratotic papules (most apparent at the periphery); periumbilical area¶	Transepidermal elimination of calcified, distorted elastic fibers

*Within the spectrum of fibroelastolytic diseases of the skin.
†Also referred to as periumbilical perforating PXE.
‡Occasionally associated with an increased calcium–phosphate product in the setting of chronic kidney disease.
¶Similar lesions have been reported on the breasts.

Table 97.4 Differential diagnosis of pseudoxanthoma elasticum (PXE). The differential diagnosis also includes PXE-like skin lesions in patients receiving D-penicillamine, after local exposure to saltpeter, and in chronic kidney disease. In addition, the possibility of underlying β-thalassemia, sickle cell anemia, or primary systemic amyloidosis needs to be considered.

Fig. 97.7 Mucosal lesions in pseudoxanthoma elasticum. Yellow papules on the inner aspect of the lower lip. *Courtesy Addenbrooke's Hospital, Cambridge, UK.*

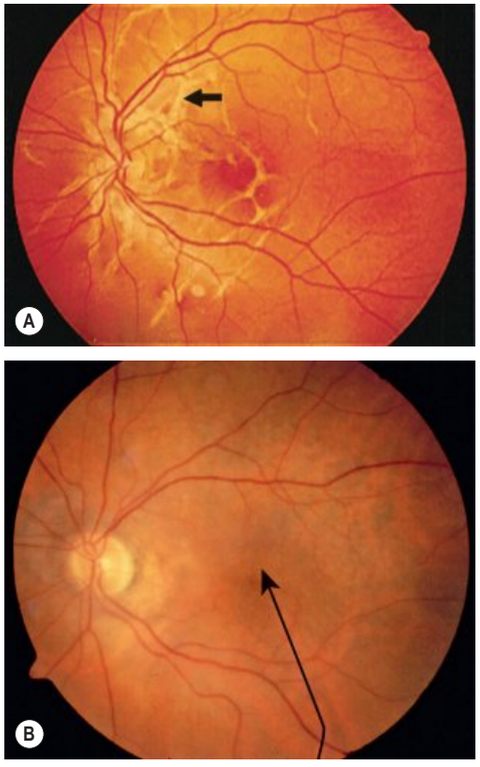

Fig. 97.8 Funduscopic findings in pseudoxanthoma elasticum (PXE). **A** Broad, lightly colored streaks (arrow) represent angioid streaks. **B** Mottling with "peau d'orange" color changes (arrow) over the entire retinal pigment epithelium, which may precede the onset of angioid streaks and represents the most common ophthalmologic finding in PXE.

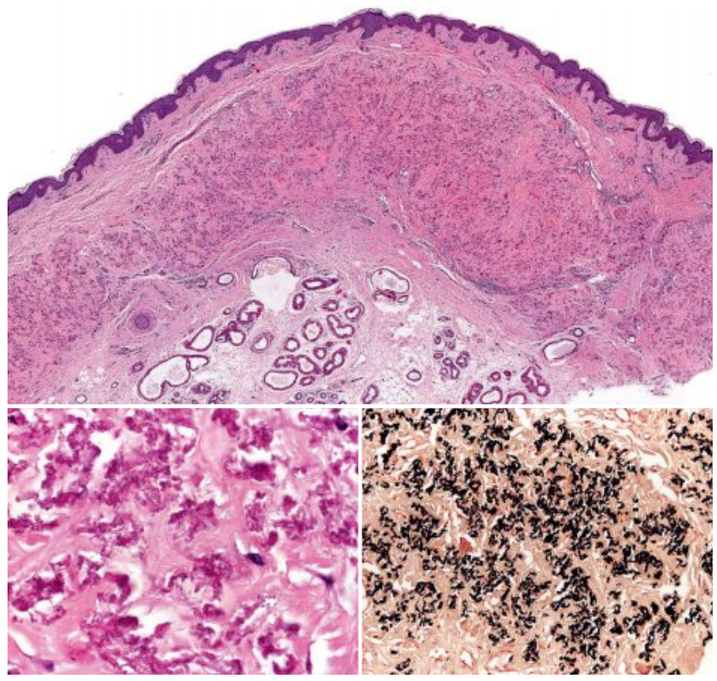

Fig. 97.9 Histopathology of pseudoxanthoma elasticum (PXE). Purple clumps in the mid and deep reticular dermis in H&E-stained sections represent calcium deposits on elastic fibers in advanced PXE (see left inset). An orcein stain highlights the clumped elastic fibers (see right inset). *Courtesy Lorenzo Cerroni, MD.*

With advanced disease, firm papules or plaques may develop due to increased dermal calcium deposition, and extrusion of this yellowish material through the epidermis as "perforating PXE" occasionally occurs. Loss of recoil due to impaired function of the elastic fiber network often leads to sagging of the skin (secondary cutis laxa), which is most notable in the axillae and groin (Fig. 97.6E). Mucosal involvement presents as yellow papules, which are most often apparent on the lower lip (Fig. 97.7). Prominent creases develop on the chin in two-thirds of affected individuals <30 years of age and the vast majority of older patients, contributing to a prematurely aged appearance[42].

The classic ocular finding in PXE is angioid streaks (Fig. 97.8A), which may be evident as early as the first decade of life and can be found in virtually all PXE patients by 30 years of age[31]. Angioid streaks are usually asymptomatic and reflect breaks in the calcified elastic lamina of Bruch's membrane, which is derived from the retina and choroid plexus. These fractures allow choroidal neovascularization, and the newly formed vessels are prone to hemorrhage with subsequent scarring. This process ultimately results in progressive loss of vision, especially within central fields, which usually becomes apparent after 40 years of age and occasionally leads to legal blindness.

Angioid streaks are highly characteristic but not pathognomonic of PXE. They can be encountered, albeit rarely, in a variety of other metabolic and heritable disorders, including Paget disease of the bone, sickle cell anemia, thalassemia, EDS and lead poisoning, as well as in the setting of age-related degeneration of Bruch's membrane. Mottling of the retinal pigment epithelium ("peau d'orange" changes; Fig. 97.8B) due to subconfluent calcification of Bruch's membrane is actually the most prevalent ophthalmologic finding in PXE and may precede the development of angioid streaks. "Coquille d'oeuf" areas reflecting more confluent calcification and "comet" lesions appearing as white bodies in the midperiphery of the fundus represent additional ocular findings that are characteristic of, but not specific to, PXE. Less commonly, macular degeneration, optic drusen, and "owl's eyes" (paired hyperpigmented spots) may be detected.

Cardiovascular manifestations of PXE often cause significant morbidity and occasionally result in premature death. PXE affects primarily mid-sized arteries, especially of the extremities, and progressive calcification of the elastic media and intima leads to the formation of atheromatous plaques. Sequelae may include intermittent claudication, loss of peripheral pulses, renovascular hypertension, angina pectoris, and less often myocardial infarction and stroke; all may occur at a younger age than in the general population. Calcified blood vessels of the gastric and intestinal mucosa have an increased propensity for hemorrhage, and even younger patients may present with gastrointestinal bleeding, particularly from the stomach[31]. Patients with PXE also have an increased prevalence of mitral valve prolapse.

Individuals with *GGCX* mutations have cutaneous, ocular, and cardiovascular findings similar to those of classic PXE. The skin manifestations tend to be more extensive and severe, with involvement of non-flexural areas of the trunk and extremities as well as redundant folds of skin that resemble cutis laxa. Loss of visual acuity secondary to ocular involvement is not typical. Additional hemorrhagic complications may occur secondary to the associated coagulation factor deficiency, including epistaxis, gingival bleeding, menorrhagia, and intracranial hemorrhage.

GACI is typically diagnosed at birth or even prenatally via ultrasound examination. Severe arterial calcification and endothelial proliferation lead to death in the first six months of life due to myocardial ischemia, hypertension, and heart failure. However, surviving children with *ENPP1* mutations may develop skin changes of PXE and angioid streaks as well as hypophosphatemic rickets due to elevated fibroblast growth factor 23 levels[34,43]. Of note, *heterozygous ENPP1* mutations underlie Cole disease, which features punctate palmoplantar keratoderma, guttate hypopigmentation, and variable ectopic calcification (see Ch. 58).

Pathology

Characteristic light microscopic changes in the skin consist of distorted, pleomorphic elastic fibers in the mid and deep reticular dermis. In advanced cases, calcium deposits on these altered elastic fibers are visible in routinely stained sections as purple clumps (Fig. 97.9). Similar changes are observed in the media of mid-sized arteries. In early disease, stains for elastin (orcein and Verhoeff–van Gieson) and calcium (alizarin red and von Kossa) are sometimes necessary to visualize the characteristic alterations in the elastic fibers. In some patients without skin manifestations who are suspected to have PXE because of other findings, such as angioid streaks, biopsy of a preexisting scar can support the diagnosis[44].

Differential Diagnosis

Diagnosis of PXE can be challenging and is often delayed for years after the initial appearance of cutaneous findings. Proposed diagnostic criteria for PXE are presented in Table 97.5[46,47]. Genetic testing of *ABCC6* can be helpful, especially in younger patients and individuals with affected family members. Considering the clinical overlap with other ectopic calcification disorders (see Pathogenesis above), additional genes such as *ENPP1* and *GGCX* should be assessed when pathogenic variants in *ABCC6* are not identified, and use of multigene panels or whole exome sequencing can increase the diagnostic yield[36].

Although characteristic skin lesions are highly suggestive of PXE in younger patients, actinic damage within chronically sun-exposed sites in older individuals may clinically mimic the yellowish plaques of lax skin in PXE. However, the latter findings involve the neck but not the axillae or groin. The differential diagnosis may also include late-onset focal dermal elastosis, PXE-like papillary dermal elastolysis, white fibrous papulosis of the neck, elastoderma, and perforating calcific elastosis (see Table 97.4).

Skin lesions with the same morphology and distribution as PXE and similar histologic features have been observed in patients receiving D-penicillamine (which interferes with desmosine cross-linking in elastin; see below)[48], after local exposure to saltpeter[49], in chronic kidney disease[50], and (historically) in L-tryptophan-induced eosinophilia myalgia syndrome[51]. There is no calcification of the abnormal fibers in D-penicillamine-induced PXE-like skin changes, whereas calcification does occur with saltpeter exposure and chronic kidney disease. Ophthalmologic and cardiovascular findings are absent and the skin lesions may resolve after cessation of the causative exposure or, in patients with renal disease, normalization of the serum calcium–phosphate product.

A PXE-like phenotype is present in up to 20% of the patients with β-thalassemia (Mediterranean populations) or sickle cell anemia[52]. Affected individuals may have characteristic cutaneous involvement as well as angioid streaks and vascular findings, but none of their siblings without a hematologic disorder have signs of PXE, and mutations in *ABCC6* have not been detected. Interestingly, downregulation of ABCC6 expression in the liver has been observed in a mouse model of β-thalassemia, suggesting a possible pathogenic mechanism[53]. PXE-like skin lesions have also been encountered in amyloid elastosis, which typically occurs in the setting of primary systemic amyloidosis; histologic examination reveals amyloid deposits that encase dermal elastic fibers, which may be short and fragmented[54].

Treatment

An approach to the multidisciplinary management of PXE is presented in Table 97.6[55–63]. Several therapies with the goal of preventing progressive mineralization are under investigation[55]. A randomized controlled clinical trial found that etidronate, a PPi analogue, may halt the progression of ectopic arterial calcification in PXE patients[64–66]. Administration of PPi orally, recombinant ENPP1, and TNAP inhibitors represent additional strategies to increase plasma PPi levels[55,67]. Other potential treatments include agents such as inositol that block calcium–phosphate deposition, sodium thiosulfate to chelate calcium,

PROPOSED DIAGNOSTIC CRITERIA FOR PSEUDOXANTHOMA ELASTICUM (PXE; 2014)
Major criteria
Skin findings
• Characteristic pseudoxanthomatous papules and plaques on the neck and/or other flexural sites • Histopathologic evidence of calcified elastic fibers in the mid and lower dermis of affected skin
Eye findings
• Angioid streak(s) >1 disc diameter in length • "Peau d'orange" changes*
Genetic testing
• Biallelic pathogenic variants in *ABCC6*
Minor criteria
• Definite PXE diagnosed in a first-degree relative (especially a sibling) • Pathogenic variant identified in one allele of *ABCC6* • Histopathologic findings of PXE in non-lesional skin
Definite PXE diagnosis* requires either**: Both major skin criteria plus one major eye criterion ***-or- Major genetic criterion ***Probable PXE diagnosis in an individual with an affected first-degree relative* requires either**: Both major skin criteria ***-or-*** One major eye criterion ***Minor criteria can be helpful in suggesting a possible PXE diagnosis***
*In an individual <20 years of age.

Table 97.5 Proposed diagnostic criteria for pseudoxanthoma elasticum (PXE; 2014)[46,47].

A MULTIDISCIPLINARY APPROACH TO MANAGEMENT OF PSEUDOXANTHOMA ELASTICUM
Skin
• No specific treatment is available • Surgical intervention for excessive skin folds[58]
Eyes
Prevention and early detection
• Annual funduscopic examination • Regular use of an Amsler grid to assess for central visual field defects • Use of sunglasses • Diet/vitamins rich in antioxidants • Avoidance of head trauma, heavy straining, and smoking; limited participation in contact and racket sports
Treatment
• Intravitreal injections of VEGF antagonists (e.g. bevacizumab, ranibizumab, aflibercept) to prevent retinal neovascularization (but not mineralization); may stabilize or improve visual acuity[56,57,59,60]
Cardiovascular system
Prevention and early detection
• Baseline electrocardiogram and echocardiogram • Annual cardiovascular examination • Healthy lifestyle with balanced diet, regular exercise, weight control, and avoidance of smoking and excessive alcohol intake • Magnesium supplementation* (e.g. magnesium oxide or citrate)[61–63] • Moderate calcium intake (as appropriate for age) • Low-dose therapy with acetylsalicylic acid if not contraindicated
Treatment
• Correction of hyperlipidemia and hypertension • Low-dose acetylsalicylic acid, pentoxifylline, cilostazol, or clopidogrel for intermittent claudication
*A diet high in magnesium was shown to reduce connective tissue mineralization in a mouse model of PXE[62], and a non-significant trend toward reduced calcification of skin elastic fibers was observed in PXE patients who received magnesium oxide in a small randomized placebo-controlled trial[63].

Table 97.6 A multidisciplinary approach to management of pseudoxanthoma elasticum. VEGF, vascular endothelial growth factor.

and phenylbutyrate to promote maturation of mutant ABCC6[55,68,69]. Overactivation of the DNA damage response/PARP1 pathway has been implicated in aberrant mineralization, and minocycline was recently found to attenuate this signaling and reduce ectopic calcification in PXE fibroblasts as well as *Abcc6*$^{-/-}$ mice and zebrafish[70,71].

Resources for patients and families include PXE International (www.pxe.org), which provides information on ectopic calcification disorders and their management[72].

CUTIS LAXA

Synonyms: ■ Dermatochalasia ■ Dermatomegaly ■ Generalized elastolysis ■ Generalized elastorrhexis

Key features

- Group of conditions characterized by sparse and fragmented elastic fibers
- Both heritable (autosomal dominant, autosomal recessive, and X-linked recessive) and acquired forms
- Features loose, sagging skin with reduced resilience and recoil
- Extracutaneous manifestations include emphysema, arterial and cardiac valvular abnormalities, hernias, diverticula, and craniofacial anomalies

History

The clinical differences between cutis laxa (CL) and EDS were delineated in 1923 by F. Parkes Weber[3], and the generalized nature of the elastolysis and potential for internal involvement were recognized by Goltz and co-workers in 1965[73].

Epidemiology

The heritable forms of CL are rare and no precise estimate of their prevalence is available. There appears to be no racial or ethnic predilection, and inheritance can be autosomal dominant, autosomal recessive, or X-linked recessive. Heritable CL is typically apparent at birth or during early childhood, but the development of lax skin is occasionally delayed until early adulthood in autosomal dominant forms. Acquired CL frequently has a later onset.

Pathogenesis

CL represents a disorder of the elastic fiber network and can involve multiple tissues, including internal organs as well as the skin. Insights into the molecular bases of inherited forms of CL have refined their classification[74,75] (Table 97.7). Mutations in the elastin gene (*ELN*) that lead to qualitative as well as quantitative abnormalities in this protein have been identified as the cause of an autosomal dominant form of CL[76]. Defects in several genes can underlie autosomal recessive CL (ARCL), which tends to be more severe and is divided into groups with different patterns of extracutaneous involvement. ARCL type 1 features potentially fatal involvement of the lungs, vascular abnormalities, and gastrointestinal/genitourinary diverticula, whereas ARCL types 2 and 3 (de Barsy syndrome) are characterized by craniofacial anomalies and delayed growth and development (see Table 97.7).

Fibulins are calcium-dependent glycoproteins that stabilize ECM networks and provide support for elastic fiber assembly. Biallelic mutations in the genes that encode fibulin 5 and fibulin 4 (EGF-containing fibulin-like extracellular matrix protein 2) cause ARCL types 1A and 1B, respectively; a heterozygous duplication within the fibulin 5 gene was also found to underlie CL in one patient[77–79]. Mutations in the latent TGF-β binding protein-4 gene (*LTBP4*) result in ARCL type 1C, which is characterized by severe pulmonary, gastrointestinal, and genitourinary involvement[80]. LTBP4 is an ECM protein that binds to fibrillin and controls the bioavailability of TGF-β, and LTBP4 deficiency leads to aberrant TGF-β activity and defective elastic fiber assembly in many tissues (see Fig. 95.6).

Defects in several intracellular proteins that play a role in metabolic pathways underlie other forms of ARCL. Variable glycosylation abnormalities result from biallelic mutations in *ATP6V0A2*, *ATP6V1E1*, and *ATP6V1A*, which encode subunits of the vacuolar H^+-ATPase, with a phenotypic spectrum that includes ARCL types 2A, 2C, and 2D and features facial dysmorphism, microcephaly, joint hypermobility, and delayed growth and development[75,81]. Mutations in the genes encoding the mitochondrial enzymes pyrroline-5-carboxylate reductase 1 (*PYCR1*) and pyrroline-5-carboxylate synthetase (*P5CS/ALDH18A1*) cause ARCL types 2B/3B and 3A, respectively, with prominent progeroid features and neurodevelopmental manifestations thought to be related to mitochondrial dysfunction[82] (see Table 97.7). *PYCR1* mutations may also lead to features of EDS (e.g. joint hypermobility) and osteogenesis imperfecta[83]. These enzymes are critical for the biosynthesis of proline, which is a major amino acid in collagen and plays a role in an oxidative cycle important to cellular metabolism. In PYCR1 deficiency, there is increased apoptosis of fibroblasts following oxidative stress.

An alternate pathogenic mechanism for CL, in particular acquired variants, is enhanced degradation of elastic fibers. Sagging of the skin, usually with little or no associated internal organ involvement, can develop in the weeks to months following the onset of an inflammatory skin condition such as a drug reaction, chronic urticaria, or Sweet syndrome (Table 97.8). In these cases, release of elastases into the extracellular milieu by inflammatory cells (e.g. neutrophils, monocytes/macrophages) leads to proteolytic degradation of elastic fibers[84]. Generalized or localized CL can develop following a Sweet syndrome-like neutrophilic dermatosis (referred to as Marshall syndrome) and some of these patients may have increased susceptibility to proteolysis due to α_1-antitrypsin deficiency. Immunopathogenic mechanisms may play a role in some cases of acquired CL, as evidenced by the occurrence of acral or generalized CL in association with monoclonal gammopathies and observation of IgG, IgA, or amyloid deposition on elastic fibers in lesional skin[85,86]. In addition, there may be an underlying genetic susceptibility for the development of CL, e.g. polymorphisms or "mild" mutations in the elastin and/or fibulin 5 genes[87].

CL-like cutaneous changes as well as elastosis perforans serpiginosa and PXE-like findings have been observed in patients treated for a prolonged period with high-dose D-penicillamine for conditions such as Wilson disease or cystinuria. D-penicillamine can interfere with elastin cross-linking by two mechanisms. First, D-penicillamine is a copper chelator and can lower serum copper levels, which reduces the activity of lysyl oxidase, an enzyme required for elastin cross-linking (see Ch. 95)[88]. Second, D-penicillamine can chemically block the allysine and lysine residues that come together to form desmosine cross-links. Because of these actions, newly synthesized elastin molecules do not become stably cross-linked. Instead, they are subject to rapid proteolysis, thus precluding the synthesis of functional elastic fibers.

Clinical Features

All forms of CL are characterized by loose, sagging skin with reduced elasticity and resilience. This often gives the affected patient an "aged" facial appearance with down-slanting palpebral fissures and a long philtrum (Fig. 97.10). Cutaneous findings are present at birth in most heritable forms of CL but may develop later in life in autosomal dominant as well as acquired variants. The laxity and wrinkling usually progress over time, although improvement of the skin with age has been noted in ARCL type 2A. Skin involvement is frequently generalized; however, it can be primarily acral, especially in ARCL type 2B or acquired CL.

In some patients with CL, clinical manifestations are limited to the skin, and the phenotype is primarily of cosmetic concern. In other patients, the cutaneous findings are associated with prominent extracutaneous features, which can include emphysema, umbilical and inguinal hernias, gastrointestinal and vesicourinary tract diverticula, arterial and cardiac valvular abnormalities, skeletal or joint involvement, and delayed growth and development. The extracutaneous manifestations, particularly pulmonary complications, can cause considerable morbidity and mortality[89]. Cutaneous and extracutaneous features of specific types of heritable CL are summarized in Table 97.7.

Generalized acquired CL without an identifiable trigger may be clinically indistinguishable from milder heritable forms of CL, e.g.

HERITABLE FORMS OF CUTIS LAXA AND RELATED CONDITIONS					
Disorder	**Inheritance**	**Gene**	**Protein**	**Distribution of cutis laxa**	**Additional features**
Heritable forms of cutis laxa					
ADCL	AD*	*ELN*	Elastin	Generalized	• Cardiac valve abnormalities, aortic dilatation (variable) • Emphysema (uncommon) • Hernias†
		FBLN5 (single patient reported)	Fibulin 5		
ARCL type 1A	AR	*FBLN5*	Fibulin 5	Generalized; large ears with prominent lobes	• Pulmonary emphysema • Stenoses of the supravalvular aorta and pulmonary arteries • Gastrointestinal and vesicourinary diverticula, hernias† • Micrognathia
ARCL type 1B	AR	*FBLN4/EFEMP2*	Fibulin 4	Generalized but less pronounced; may favor skin folds	• Arterial or aortic tortuosity/ aneurysms; aortic isthmus stenosis • Joint hypermobility, arachnodactyly, fractures, high arched palate, micrognathia
ARCL type 1C (Urban–Rifkin–Davis syndrome)	AR	*LTBP4*	Latent TGF-β binding protein-4	Generalized	• Emphysema (severe, often fatal) • Pulmonary arterial stenosis, valvular defects • GI and GU malformations (diverticula, rupture risk) • Micrognathia, large fontanelles • Joint hypermobility, hypotonia • Bitemporal hypotrichosis
ARCL type 2A (Debré type; allelic to wrinkly skin syndrome)	AR	*ATP6V0A2*	Vacuolar H^+-ATPase V0, subunit A2	Generalized; may favor abdomen and dorsal hands; improves over time	• Translucent skin with prominent veins • High myopia (2A); corneal opacities & cataracts (3A/B, PADCL) • Facial dysmorphism‡; triangular face with more progeroid appearance (2B, 3A/B); large fontanelles • Microcephaly, partial pachygyria (2A), absent corpus callosum (2B) • Intellectual disability; seizures, neurologic degeneration (2A); dystonia/ athetosis (3A/B) • Congenital hip dysplasia, joint hypermobility, hypotonia, scoliosis, short stature; osteopenia (2B, 3A/B) • Cranial arterial tortuosity (3A, PADCL) • O- and N-glycosylation defect (2A¶)
ARCL type 2B and 3B (de Barsy syndrome B)	AR	*PYCR1*	Pyrroline-5-carboxylate reductase 1	Generalized; may favor dorsal hands/feet or improve over time; occasionally fat pads (e.g. on buttocks; 3A)	
ARCL type 3A (de Barsy syndrome A) and Progeroid ADCL (PADCL)	AR (3A) AD (PADCL)	*P5CS/ALDH18A1*	Pyrroline-5-carboxylate synthetase		
ARCL types 2C and 2D	AR	*ATP6V1E1* (2C) *ATP6V1A* (2D)	Vacuolar H^+-ATPase V1, subunits E1 and A	Generalized with sparse or subcutaneous fat; large skin folds on extremities, fat pads on buttocks; may improve over time (2D)	• Pneumothorax • Cardiac abnormalities, aortic dilation • "Mask-like" triangular face, hypotonia; variable hip dysplasia, marfanoid habitus • Neurodevelopmental abnormalities (2D)
Gerodermia osteodysplastica (geroderma osteodysplasticum)	AR	*GORAB*	Golgin, RAB6-interacting	Primarily on dorsal hands/ feet	• Malar hypoplasia, prognathism, oblique furrow lateral to eyebrows • Joint hypermobility • Osteoporosis, fractures, dwarfism
Occipital horn syndrome	X-R	*ATP7A*	ATPase, Cu^{2+}-transporting, α-polypeptide	Generalized, most pronounced on face and neck	• Easy bruising, coarse hair (variable) • Arterial tortuosity • Chronic diarrhea; bladder diverticula • Long face, high forehead, hooked nose • Developmental delay • Wedge-shaped occipital calcifications • Joint hypermobility
Macrocephaly, alopecia, CL, and scoliosis (MACS)	AR	*RIN2*	RAS and RAB interactor 2	Generalized, most pronounced on face	• Sparse scalp hair • Gingival hypertrophy, facial dysmorphism • Macrocephaly • Scoliosis, joint hypermobility

Table 97.7 Heritable forms of cutis laxa (CL) and related conditions.

Continued

HERITABLE FORMS OF CUTIS LAXA AND RELATED CONDITIONS					
Disorder	**Inheritance**	**Gene**	**Protein**	**Distribution of cutis laxa**	**Additional features**
Other heritable conditions that feature lax and/or redundant skin					
Arterial tortuosity syndrome	AR	*SLC2A10 (GLUT10)*	Solute carrier family 2, member 10 (a glucose transporter)	Generalized; soft, hyperextensible skin has also been described	• Telangiectasias on cheeks (variable) • Arterial tortuosity • Long face, micrognathia, high-arched palate • Joint hypermobility and contractures
Larsen-like syndrome	AR	*B3GAT3*	Glucuronosyltransferase I	Wrinkled acral skin	• Joint dislocations, craniofacial dysmorphism, short stature • Congenital heart defects
Costello syndrome	AR	*HRAS*	HRAS	Variable, especially on hands and feet	• Deep palmoplantar creases, acanthosis nigricans, periorificial papillomas • Curly or sparse hair, coarse facies • Cardiac malformations • Intellectual disability, short stature • Risk of malignancies, e.g. rhabdomyosarcoma
Donohue syndrome ("leprechaunism"; see Ch. 101)	AR	*INSR*	Insulin receptor	Variable	• Generalized lipodystrophy, hypertrichosis, acanthosis nigricans • Insulin resistance • Distinctive "elfin" facies • Severe growth delay
Finnish-type amyloidosis	AD	*GSN*	Gelsolin	Generalized	• Corneal dystrophy • Polyneuropathy
Cranioectodermal dysplasia (Sensenbrenner syndrome)	AR	*IFT122* *IFT43*	Intraflagellar transport proteins 122 and 43	Generalized; redundant skin folds at neck, ankles, and wrists	• Sparse, fine hair; short, broad nails • Narrow thorax, short proximal limbs, joint hypermobility, brachydactyly, dolichocephaly, dysmorphic facies, dental anomalies • Nephronophthisis, hepatic fibrosis, retinal dystrophy
		WDR35 *WDR19*	WD repeat domain 35 and 19		
Circumferential skin creases, Kunze type	AD, AR	*MAPRE2*	Microtubule-associated protein RP/EB family member 2	Multiple circumferential creases/folds of skin on the extremities (see Fig. 97.13) > neck > trunk (excess rather than lax skin); may resolve over time	• Cleft palate, short stature, dysmorphic facies (e.g. epicanthal folds, small eyes), overfolded helices • Intellectual disability
	AD	*TUBB*	Tubulin-β class I		
Nonsyndromic "Michelin tire baby"	AD	?	?		• Affected skin may have excess fat or smooth muscle, and the latter is often associated with hypertrichosis; elastic fibers are usually normal (fragmentation noted in only one report)

*An AR form of cutis laxa due to a homozygous elastin mutation has been reported in two related families.
†E.g. inguinal, umbilical, diaphragmatic.
‡Features may include a broad forehead and midfacial hypoplasia as well as findings related to the lax skin (e.g. down-slanting palpebral fissures, long philtrum).
¶Can be assessed via analysis of the glycosylation of serum sialotransferrin ± apolipoprotein C-III via isoelectric focusing.

Table 97.7 Heritable forms of cutis laxa (CL) and related conditions. CL can also occur in Williams–Beuren syndrome, which results from deletion of multiple contiguous genes that include *ELN*. In addition to ARCL types 2A and 2C, CL can occur in other congenital disorders of glycosylation, e.g. due to mutations in a component of oligomeric Golgi complex 7 (*COG7*; multiple-system malformations) or steroid 5-α-reductase 3 (*SRD5A3*; also ichthyosis, ocular colobomas, and midline brain malformations). Transaldolase deficiency can present with neonatal CL (generalized or of the forehead) that improves over time as well as hypertrichosis, hepatosplenomegaly, hemolytic anemia, and GU malformations. Features of cutis laxa have also been reported in PURA syndrome. "Neonatal CL with a marfanoid phenotype" was described in an infant who lacked immunohistochemical evidence of laminin-β1 in the skin. AD, autosomal dominant; *ALDH18A1*, aldehyde dehydrogenase 18 family, member A1; AR, autosomal recessive; *EFEMP2*, EGF-containing fibulin-like extracellular matrix protein 2; GI, gastrointestinal; GU, genitourinary; TGF, transforming growth factor; X-R, X-linked recessive.

late-onset autosomal dominant CL. Generalized or localized forms of acquired CL can also occur in association with a plasma cell dyscrasia (see Fig. 97.10B), as a consequence of drug intake (particularly penicillamine), and subsequent to a systemic or cutaneous inflammatory disorder (see Table 97.8). In the latter situation, the inflammatory reaction is followed by progressive sagging of the skin, which can become extensive and lead to a prematurely aged appearance. Acquired CL most commonly develops in adults and when it presents with generalized skin involvement, often beginning on the face and neck, there can be associated internal manifestations such as emphysema and diverticula (e.g. gastrointestinal, vesicourinary). Occasionally, localized CL is found predominantly around the eyes (blepharochalasis) or on the distal extremities, particularly the palms and soles (Fig. 97.11). Marshall syndrome refers to CL in association with a Sweet syndrome-like neutrophilic dermatosis, and it occurs primarily in infants and young children[90].

Pathology

In the skin of patients with CL, the characteristic histopathologic feature is sparse and/or fragmented elastic fibers (Fig. 97.12). This ranges from virtual absence of elastic fibers in a newborn with severe CL (e.g. ARCL type 1) to fragmentation but normal density of fibers in late-onset autosomal dominant CL. Electron microscopy shows irregular

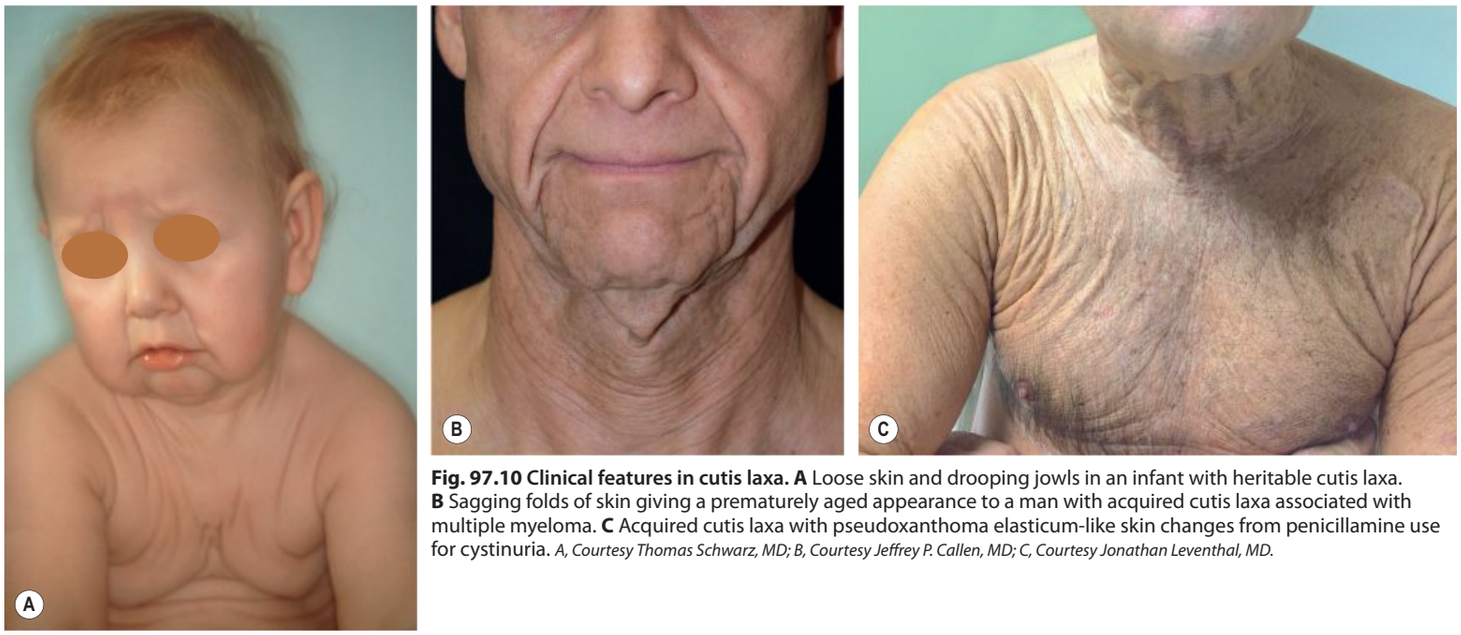

Fig. 97.10 Clinical features in cutis laxa. A Loose skin and drooping jowls in an infant with heritable cutis laxa. **B** Sagging folds of skin giving a prematurely aged appearance to a man with acquired cutis laxa associated with multiple myeloma. **C** Acquired cutis laxa with pseudoxanthoma elasticum-like skin changes from penicillamine use for cystinuria. *A, Courtesy Thomas Schwarz, MD; B, Courtesy Jeffrey P. Callen, MD; C, Courtesy Jonathan Leventhal, MD.*

ACQUIRED CUTIS LAXA: ASSOCIATED CONDITIONS
Skin disorders
• Urticaria and/or angioedema • Drug eruptions (e.g. due to penicillin or an SSRI) • Sweet syndrome-like eruptions (Marshall syndrome*) • Urticarial vasculitis • Arthropod bite reactions • Erythema multiforme • Dermatitis herpetiformis • Lupus panniculitis • Interstitial granulomatous dermatitis • Cutaneous mastocytosis • Cutaneous lymphoma
Extracutaneous inflammatory disorders
• Rheumatoid arthritis • Systemic lupus erythematosus • Nephrotic syndrome • Celiac disease • Sarcoidosis
Hematologic disorders
• Monoclonal gammopathy (especially acral CL; underlying plasma cell dyscrasia)† • Congenital hemolytic anemia
Infectious diseases
• Febrile viral syndrome • *Borrelia burgdorferi* infection • Syphilis • Leprosy
Drug intake (also see drug eruptions above)
• Penicillamine • Isoniazid
*Occurs primarily in infants and young children and is referred to as type II acquired CL, with other forms of acquired CL classified as type I. †Commonly associated with systemic amyloidosis in setting of multiple myeloma.

Table 97.8 Acquired cutis laxa (CL): associated conditions. Generalized or localized CL (including Marshall syndrome) can occur in the setting of α_1-antitrypsin deficiency. SSRI, selective serotonin reuptake inhibitor.

Fig. 97.11 Idiopathic acral localized acquired cutis laxa. The pulp of the digits has loose redundant skin (**A**) and pressure can produce a depression (**B**). The only abnormal finding was an elevated ANA titer. *Courtesy Luis Requena, MD.*

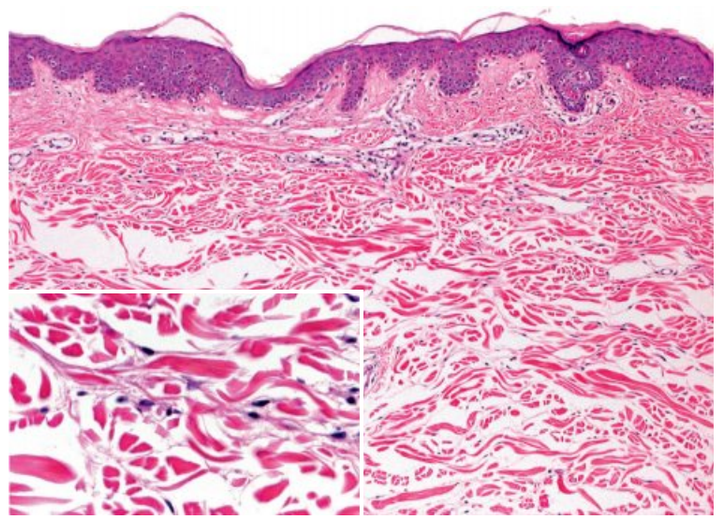

Fig. 97.12 Histologic features of cutis laxa. Dermal elastic fibers are sparse and fragmented. *Courtesy Lorenzo Cerroni, MD.*

fragmentation of the elastic fiber structure. In some patients, elastic fiber abnormalities are accompanied by alterations in collagen fibers, which likely reflect a general perturbation of the ECM and mechanical properties of the skin due to the primary elastic fiber defect.

Differential Diagnosis

Clinical findings similar to CL can develop as a consequence of the normal skin aging. In contrast to CL, the hyperextensible skin of patients with EDS retains elasticity and recoil, with the exception of

the rare dermatosparaxis type. Skin fragility and bruising represent additional features of EDS but not CL. In PXE and the related PXE-like disorder with multiple coagulation factor deficiency, the skin can be loose and sagging without recoil; however, the primary papular lesions at the predilection sites distinguish these conditions from CL.

Mid-dermal elastolysis is an acquired disorder with a predilection for young and middle-aged women that is characterized by circumscribed or diffuse areas of fine wrinkling, most often in sun-exposed sites on the upper trunk, lateral neck, and upper arms (see Ch. 99)[91]. It features the pathognomonic histopathologic finding of a band-like loss of elastic fibers in the mid dermis. Anetoderma presents as focal areas of flaccid skin (typically 1 to 2 cm in diameter) with loss of elastic tissue and may have an antecedent inflammatory process. It is histologically and ultrastructurally identical to CL and may be regarded as a variant of acquired localized CL with smaller, circumscribed lesions.

Additional rare syndromes that can present with lax skin and elastic fiber abnormalities are outlined in Table 97.7[92]. Of note, the "Michelin tire baby" phenotype of congenital circumferential skin creases on the extremities may be reminiscent of CL, but the folds reflect excess tissue rather than cutaneous laxity (Fig. 97.13).

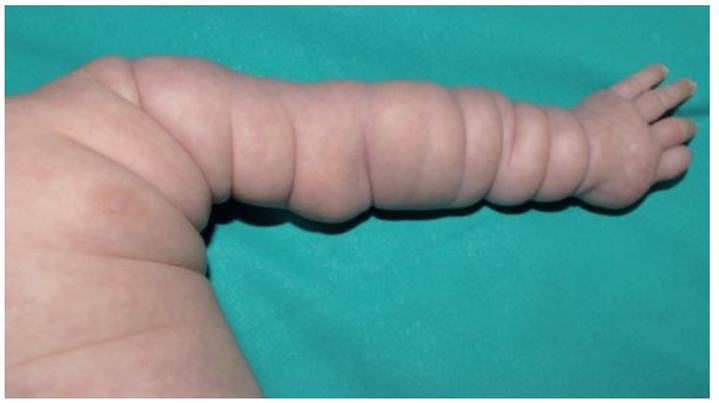

Fig. 97.13 "Michelin tire baby" phenotype. Note the circumferential skin creases on the extremities. *Courtesy Antonio Torrelo, MD.*

Treatment

The redundant and sagging skin may be of major cosmetic concern to patients with CL, and reconstructive surgery can provide improvement with significant psychosocial benefit. Surgical wounds heal with scars that have a normal appearance and tensile strength. However, sagging may reoccur, necessitating additional surgical procedures.

The associated internal organ involvement requires appropriate care through a multidisciplinary approach. All patients should have a baseline echocardiogram and pulmonary assessment, with further investigations such as urinary tract ultrasound (ARCL type 1) and neurologic evaluation (ARCL types 2/3) depending on the subtype and clinical findings[75].

Additional figures and table, Five-point joint hypermobility questionnaire, available in our eBook (see inside front cover for access code).

FIVE-POINT JOINT HYPERMOBILITY QUESTIONNAIRE
1. Can you now (or could you ever) place your hands flat on the floor without bending your knees?
2. Can you now (or could you ever) bend your thumb to touch your forearm?
3. As a child, did you amuse your friends by contorting your body into strange shapes or could you do the splits?
4. As a child or teenager, did your shoulder or kneecap dislocate on more than one occasion?
5. Do you consider yourself "double-jointed"?
A "yes" answer to ≥2 questions suggests joint hypermobility, with 80%–85% sensitivity and 80%–90% specificity.

Hypertrophic Scars and Keloids 1730
Dupuytren Disease 1733
Cutis Verticis Gyrata 1735
Hyaline Fibromatosis Syndrome 1736
Elastic Tissue-Related Disorders 1738

This chapter will discuss disorders in which there are increased amounts of collagen within the skin, followed by those with increased elastin.

HYPERTROPHIC SCARS AND KELOIDS

Key features

- Conventional scars are preceded by injury, form within weeks, remain flat or minimally elevated, and are asymptomatic
- Hypertrophic scars are raised, firm, and confined to the wound margin. Sometimes they improve spontaneously and tend to have a good response to treatment
- Keloids extend beyond the wound margin and are delayed in onset. They seldom resolve spontaneously and response to treatment is often poor

Introduction

All wounds heal with some degree of scar formation, but the mechanisms that govern whether the result will be a fine thin scar, a prominent hypertrophic scar, or a tumor-like keloid remain unclear. The latter represent two forms of abnormal wound healing characterized by local fibroblast proliferation and excessive collagen production in response to cutaneous injury. However, their clinical and histopathologic features differ, as well as proposed pathogeneses.

Epidemiology

Hypertrophic scars develop more often than keloids, and keloids have a higher prevalence in individuals with more darkly pigmented skin including Africans, African-Americans, Hispanics, and Asians[1]. In these populations, an incidence ranging from 4%–16% has been reported[2]. Neither hypertrophic scars nor keloids have a sex predilection, and both entities occur most frequently in those 10 to 30 years of age[3]. Individuals in this age group are more often subjected to trauma and their rate of collagen synthesis is higher. Younger skin also possesses greater tension, as compared to older skin which has less elasticity and is more redundant[2].

Etiology

Proposed etiologic factors include: genetic predisposition; depth, type, and location of the skin injury or wound; degree of tension; local infection or inflammation; and hormonal influences[2,3]. Possible autosomal dominant inheritance with incomplete clinical penetrance and variable expression has been suggested[3]. A range of skin injuries can lead to abnormal scarring, from lacerations, burns, surgical excisions, and skin piercings to injections (vaccines, tattoo inks) and cutaneous inflammation (e.g. acne vulgaris, insect bites)[4]. Moreover, tension is constantly transmitted to the skin from the underlying cartilaginous and bony skeleton, and skin tension can be aggravated by loss of tissue, as occurs with surgical excisions[5]. In addition, hormonal influences have been proposed as an explanation for the appearance of keloids at or after puberty and their resolution following menopause, as well as reports of the onset or enlargement of keloids during pregnancy[2]. Lastly, spontaneous keloids may occur in the absence of any obvious trauma or inflammation, although there is the possibility of unrecognized skin disease (e.g. acne).

Future insights into etiology may come from the genetic disorders in which keloids are an associated feature, including Bethlem myopathy, Rubinstein–Taybi, Warburg–Cinotti and Goeminne syndromes, fronto-metaphyseal dysplasia, and other filamin A-related disorders (see Table 95.5)[6,7]. Patients with polyfibromatosis (see below) can also develop keloids.

Pathogenesis

The ability to heal wounds created by injuries, in particular trauma, offers an evolutionary advantage, with associated scarring being less of an issue. However, cutaneous scarring resulting from surgical procedures is viewed as an unwanted consequence. A regenerative response would be preferred, thereby conceivably providing a superior cosmetic result and avoiding the formation of hypertrophic scars and keloids[8]. Notably, in regenerative healing, there is an absence of inflammation in addition to a lack of scarring. In fetuses, cutaneous wounding during the first and second trimesters of gestation does not lead to scarring, and this is thought to reflect a healing process that is occurring via tissue regenerative pathways in a sterile environment and in the absence of inflammation[9].

Excess scar formation is thought to result from dysregulation during at least one of the three phases of wound healing – inflammatory, proliferative, and remodeling/maturation (see Fig. 141.2)[8–12]. Proinflammatory cytokines such as interleukin-6 (IL-6) and IL-8 have been associated with increased scar formation while the anti-inflammatory cytokine IL-10 can lead to a reduction in scar tissue[8]. Several additional factors have been shown to play a role in enhancing fibroblast-related scar formation, including transforming growth factor (TGF)-β, platelet-derived growth factor (PDGF), the transcription factor homeobox B13, and components of the Wnt signaling pathway[8]. Greater insights into regulation of crucial components of the remodeling phase, e.g. cessation of granulation tissue formation, will hopefully provide targets for preventative or therapeutic interventions for hypertrophic scarring.

Because keloid formation only occurs naturally in humans, the ability to use animal models is limited[9]. In studies utilizing biopsy specimens of keloids, collagen synthesis by fibroblasts is markedly increased as is the production of TGF-β, a key regulatory factor during the proliferative phase of wound healing. However, different TGF-β isoforms may play distinct and even competing roles in wound healing. Expression of TGF-β1 or TGF-β2 may lead to an increase in scarring, whereas expression of TGF-β3 has been associated with a reduction in scarring[13]. This has led to the introduction of therapies that specifically address these different forms of TGF-β (see Table 98.4).

Clinical Features

Distinguishing clinically between a hypertrophic scar and a keloid is usually straightforward, but sometimes it can be difficult if the lesion is small or of recent onset. The characteristic features of hypertrophic scars and keloids are outlined in Table 98.1. Both have a smooth surface, are firm to palpation, and may be pruritic or painful. Occasionally, they can restrict normal movement of adjacent soft tissues. The color can

vary from pink–purple (early lesions) to skin-colored to hypo- or hyperpigmented. While keloids may be more elevated above the skin surface than hypertrophic scars, the key difference is that keloids extend beyond the boundary of the original wound into adjacent normal skin, often with claw-like extensions resembling the pincers of a crab (in Greek, chelè means claw) (Figs. 98.1 & 98.2). In contrast, hypertrophic scars remain confined to the site of the original injury (Fig. 98.3).

Hypertrophic scars usually develop within a few weeks to months after wounding, and they may flatten spontaneously within 1 to 2 years. Most keloids appear within one year of an injury, although the intervening interval may be up to two decades[5]. Of note, keloids do not regress over time. Both hypertrophic scars and keloids favor sites of increased wound tension such as the upper trunk, shoulder, and upper outer arm. However, keloids can also develop in sites such as the earlobe, where there is minimal tension. In addition, keloids can form spontaneously, most often in the midchest region but there is the possibility of unrecognized skin disease (e.g. acne).

CLINICAL FEATURES OF CONVENTIONAL SCARS, HYPERTROPHIC SCARS, AND KELOIDS

	Conventional scar	Hypertrophic scar	Keloid
Preceded by injury	Yes	Yes	Not always
Onset	Within weeks	Few weeks to months	Delayed
Erythema	Temporary	Prominent	Varies
Profile	Flat	Raised	Raised
Symptomatic	No	Yes	Yes
Confined to wound margin	Yes	Yes	No
Spontaneous resolution	N/A	Possible, gradual	Rare
Treatment response	N/A	Good	Poor

Table 98.1 Clinical features of conventional scars, hypertrophic scars, and keloids. N/A, not applicable.

Scar assessment

Scar evaluation ranges from simple scales to technologically advanced devices (e.g. optical coherence tomography) that analyze one or more variables in a reproducible manner[14]. The Vancouver Scar Scale (Table 98.2) and the Patient & Observer Scar Assessment Scale (POSAS) are the most commonly employed assessment tools[14,15]. These scales have significant inter-patient variation because they score subjective features from color to degree of pain and pruritus. More recently, the Japan Scar Workshop (JSW) published the JSW Scar Scale (JSS), a simple and easy tool for objectively diagnosing keloids and hypertrophic scars

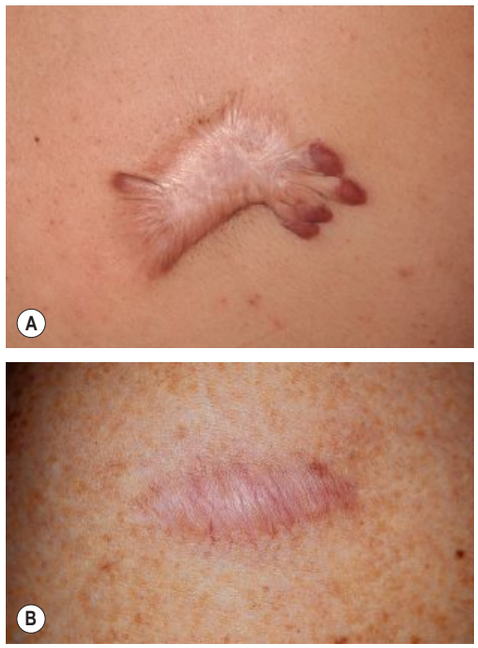

Fig. 98.2 Comparison of a keloid and a hypertrophic scar. A The keloid has claw-like extensions that extend beyond the original wound margin into adjacent normal skin. **B** The hypertrophic scar remains confined to the site of the original surgical wound. *A, Courtesy Edward Cowen, MD; B, Courtesy Jean L. Bolognia, MD.*

Fig. 98.1 Keloids. Common sites include the upper trunk (**A–C**), neck (**D**), and shoulder (**E**). There is a higher prevalence of keloids in patients with darkly pigmented skin, but they can occur in individuals with any skin phototype. Note the extension of the keloids into the normal surrounding skin in a claw-like manner. *C, Courtesy Lorenzo Cerrroni, MD; E, Courtesy Julie V. Schaffer, MD.*

based on risk factors of individual patients and sites of involvement[16]. Non-invasive techniques can also be used to more objectively measure scar color, blood flow, transcutaneous oxygen tension, skin hardness, elasticity, and hydration[17].

Pathology

Distinguishing between a keloid and a hypertrophic scar is important when contemplating treatment, especially more aggressive therapies such as radiation. In some patients, histologic examination is required to make this distinction (Table 98.3). Hypertrophic scars are characterized by an increase in the number of fibroblasts and the density of collagen fibers within the dermis, both of which are oriented parallel to the skin surface. This is accompanied by multiple vertically oriented dermal blood vessels (Fig. 98.4). In keloids, there are whorls and nodules of strikingly thick, glassy, homogeneous collagen bundles that are composed of densely packed fibrils and are oriented haphazardly throughout the dermis (keloidal collagen) (Fig. 98.5). Early on, there are abundant deposits of fibrillary collagen within the reticular dermis of keloids, while mature lesions often have the characteristic thick sclerotic collagen. In longstanding keloids, there may be a return to the earlier fibrillary pattern.

It is noteworthy that keloidal collagen may be absent in up to 45% of keloids[18]. In scars with no detectable keloidal collagen, histologic features that favor a keloid include: no flattening of the epidermis; a lack of fibrosis within the papillary dermis; a tongue-like advancing edge as the scar tissue extends through the reticular dermis; a horizontal cellular fibrous band within the upper reticular dermis with a sharp demarcation from the normal-appearing papillary and reticular dermis; and prominent fascia-like fibrous bands in the deeper portion of the scar[18].

Attempts to differentiate hypertrophic scars from keloids via immunohistochemistry has led to conflicting results[18,19]. In one study, nodules of α-smooth muscle actin (α-SMA)-positive cells (myofibroblasts) were only observed in hypertrophic scars, whereas another investigation found α-SMA expression in both hypertrophic scars (70%) and keloids (45%)[18]. Expression of cyclooxygenase (COX)-1 was observed in 100% of keloids, but it was also expressed in ~50% of hypertrophic scars[19]; thus COX-1 expression favored, but did not specifically identify, keloids. Lastly, *in vitro* differences in fibroblast phenotype, production of extracellular matrix, and CCL5 secretion have been observed[18].

Fig. 98.3 Hypertrophic scar at the site of a knife injury.

Differential Diagnosis

The clinical differential diagnosis of keloids includes the sclerotic form of xanthoma disseminatum, lobomycosis (keloidal blastomycosis; lacaziosis), and the keloidal forms of scleroderma and morphea. Rarely, carcinoma en cuirasse can present as keloidal nodules. Patients with the vascular type of Ehlers–Danlos syndrome may occasionally develop keloidal plaques on their lower extremities, and spontaneous formation of keloids can be a clinical clue to other rare inherited syndromes such as Bethlem myopathy, Rubenstein–Taybi syndrome, and Goeminne syndrome (see above).

Histologically, keloids and hypertrophic scars need to be differentiated from spindle cell tumors, primarily dermatofibroma (DF)[20], dermatofibrosarcoma protuberans (DFSP), dermal fibromatoses, desmoplastic melanoma, and the scar-like variant of squamous cell carcinoma (SCC). Immunostaining for CD34 and factor XIIIa, which is usually positive in DFSP and DF, respectively, is negative in keloids and hypertrophic scars[21]. While there is minimal or no immunostaining for S100 protein in scars, desmoplastic melanomas usually demonstrate strong expression of this marker[22]. Finally, the unusual scar-like variant of SCC may only have focal keratin expression, and a complete panel of keratin stains (to increase sensitivity) may be required for its detection[23].

Treatment

The management of keloids and hypertrophic scars continues to challenge clinicians, and there is no universally accepted treatment algorithm. Potential evidence-based treatments are outlined in Table 98.4[24-33]. Prevention remains the best strategy in predisposed patients, including avoidance of nonessential surgery in high-risk anatomic sites and attention to postsurgical wound care[24]. International guidelines recommend use of silicone gels and sheets in the treatment of both hypertrophic scars and keloids[28]. While potent topical corticosteroids

HISTOPATHOLOGIC FEATURES OF HYPERTROPHIC SCARS AND KELOIDS		
	Hypertrophic scar	**Keloid**
Epidermis	Flattened	Not involved
Papillary dermis	Fibrotic	Not involved
Fibroblasts	Increased	Not increased within keloidal collagen
Collagen bundles	Fine, wavy; orientation is parallel to the epidermis	Large, thick, closely packed; orientation is random relative to the epidermis
Elastic fibers	Diminished or absent	Increased within the deep dermis
Dermal blood vessels	Increased; oriented vertically, perpendicular to the epidermis	Not increased; few, if any, vertically oriented vessels
Inflammatory infiltrate	Sparse, perivascular	Sparse, perivascular
Mast cells	Increased	Increased
Dermal mucin	Increased	Increased
Myofibroblasts	+++	++

Table 98.3 Histopathologic features of hypertrophic scars and keloids. Shading indicates differences.

VANCOUVER SCAR SCALE						
Score for each clinical feature	**0**	**1**	**2**	**3**	**4**	**5**
Pliability	Normal	Supple	Yielding	Firm, solid unit	Banding/"ropes"	Contracture
Height	Flat	<2 mm	2–5 mm	>5 mm	–	–
Vascularity	Normal	Pink	Red	Purple	–	–
Pigmentation	Normal	Hypopigmentation	Hyperpigmentation	–	–	–

Table 98.2 Vancouver Scar Scale. *Adapted from Sullivan T, Smith J, Kermode J, et al. Rating the burn scar. J Burn Care Rehabil 1990;11:256–60.*

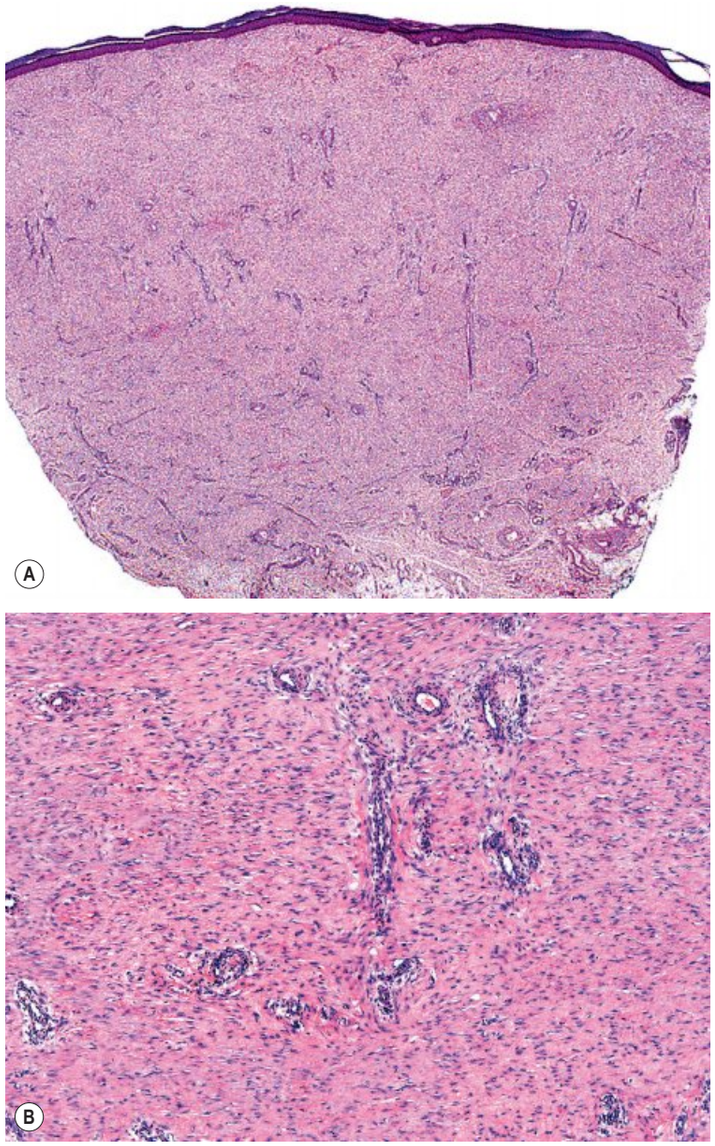

Fig. 98.4 Hypertrophic scar – histopathologic features. A Increased density of collagen fibers within the dermis and vertically oriented blood vessels. **B** Increase in the number of fibroblasts and density of collagen fibers, both of which are oriented horizontally (parallel to the epidermis). The central blood vessel is oriented vertically and there is a sparse perivascular inflammatory infiltrate.

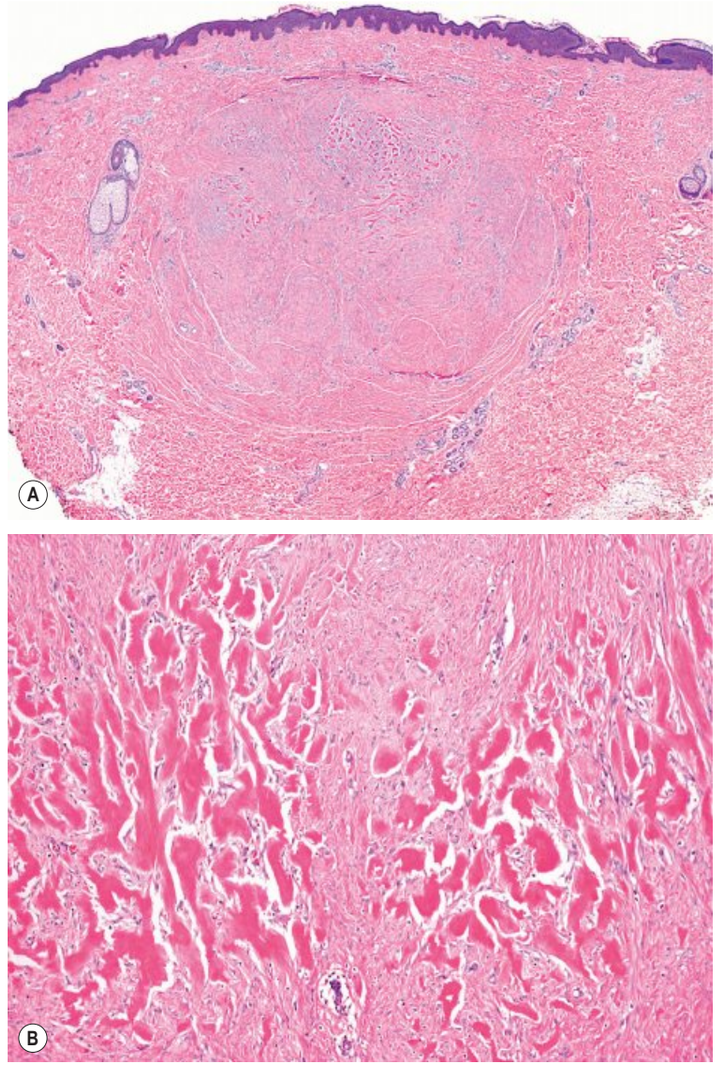

Fig. 98.5 Keloid – histopathologic features. A Nodules of thick collagen bundles are oriented haphazardly within the dermis (keloidal collagen). There is neither flattening of the epidermis nor involvement of the papillary dermis, and a sharp demarcation is seen between the normal-appearing papillary and reticular dermis and the nodules. **B** Strikingly thick, glassy, homogeneous collagen bundles composed of multiple, densely packed fibrils.

are sometimes used to address pruritus, intralesional triamcinolone remains a commonly employed first-line therapy[34]. Incremental increases in triamcinolone concentration may be used to balance flattening effects against the risk of atrophy[29]. An alternative, especially for needle-averse individuals, is clobetasol propionate 0.05% cream under silicone dressing occlusion[30].

Intralesional or topical corticosteroids may be combined with intralesional 5-fluorouracil[31]. For hypertrophic scars and keloids in patients with darker skin color who are at risk for steroid-induced hypopigmentation, intralesional bleomycin and intralesional triamcinolone have been shown to lead to comparable improvement[32]. By reducing muscle tension during wound healing, intralesional botulinum toxin type A can minimize scar formation and reduce associated symptoms[33]; possible explanations include pausing of the fibroblast cell cycle and changes in TGF-β1 expression. Based upon case reports, dupilumab can reduce associated pruritus and may lead to an improvement in appearance[34a].

Surgical revision of hypertrophic scars and keloids can quickly relieve symptoms, but the recurrence rate is quite high. Cryosurgery has been used successfully[24] and is often combined with intralesional triamcinolone. Shave excision followed by contact cryosurgery has also been employed. Pulsed dye laser therapy has become popular as a modality for postsurgical scar reduction and is associated with few side effects. The use of lower cumulative doses has improved the safety of adjuvant postoperative radiation therapy while still maintaining efficacy[25,26] (see Table 98.4 & Ch. 139).

DUPUYTREN DISEASE

Synonyms: ■ Dupuytren's contracture ■ Palmar fibromatosis ■ Dupuytren's diathesis

Key features

- Thickening of palmar and digital fascia
- Progressive flexion contracture of affected digits
- Myofibroblast proliferation followed by excess collagen synthesis
- Treatment includes injections of collagenase, percutaneous needle fasciotomy, and surgical fasciotomy/fasciectomy

History

Henry Cline described thickening of the palmar fascia in 1777 and proposed palmar fasciotomy as a cure. In 1831, Guillaume Dupuytren characterized and popularized this entity.

TREATMENT OPTIONS FOR HYPERTROPHIC SCARS AND KELOIDS		
Treatment	**Mechanism(s) of action**	**Level of evidence**
Silicone sheeting	Reduction in collagen deposition due to an increase in temperature, hydration (reduces water vapor loss), and perhaps oxygen tension	2
Pressure therapy	Pressure-induced hypoxic effects lead to collagen and fibroblast degeneration	2
Onion extract (topical)	Decrease in inflammation and fibroblast proliferation rate	1
Vitamin E (topical)	Antioxidant properties	2
Triamcinolone (intralesional; 10–40 mg/ml)*	Inhibits fibroblast proliferation and collagen synthesis; vasoconstriction; decreases in TGF-β1 and TGF-β2	1
5-Fluorouracil (intralesional; 50 mg/ml not to exceed 100 mg/session; administered weekly)	Inhibits fibroblast proliferation	2
Bleomycin (1.5 IU/ml – multiple puncture technique; maximum 2 ml/cm^2 and 10 IU per session; once monthly)	Direct or indirect, TGF-β-mediated, inhibitory effects on collagen	2
Botulinum toxin (intralesional)	Reduces muscle tension during wound healing, leading to reduction in symptoms, volume and vascularity, presumably due to pausing of the fibroblast cell cycle and changes in TGF-β1 expression	1
Surgical scar revision	Reorientation and construction of multiple tension vectors	2
Cryosurgery (contact and needles more effective than spray; monthly × 3–10 months)*	Direct cellular freezing effects; post-thaw vascular stasis	2
Radiation therapy (postoperative [usually within 72 hours]; 8–10 Gy in a single dose; 6–15 Gy in 3–5 fractions)	Induction of fibroblast apoptosis; restoration of balance between synthesis and degradation of collagen within scar; damage to connective tissue stem cells	2
Laser therapy (pulsed dye laser [PDL] – can begin day of suture removal then every 3–4 weeks; CO_2 fractional laser*; Nd:YAG [1064 nm])	Induces wound contraction and collagen remodeling following thermal necrosis; decreased levels of TGF-β from heat shock response	1 (PDL)
Avotermin (intralesional)†	Recombinant TGF-β3 (form of TGF associated with a reduction in scarring)	1 (phase II trial; no difference in phase III trial)
Human recombinant interleukin-10 (intralesional)†	Anti-inflammatory activity	1‡,¶
Mannose-6-phosphate (intralesional)†	Inhibition of TGF-β1 and TGF-β2 signaling (two forms of TGF associated with an increase in scarring)	1‡
Insulin (intralesional)	Inhibitor of myofibroblasts	1

*Cryotherapy or CO_2 laser sometimes administered prior to intralesional injections of corticosteroids.
†Not commercially available.
‡Based upon phase II trial.
¶In lightly, but not darkly, pigmented individuals.

Table 98.4 Treatment options for hypertrophic scars and keloids. There are also reports of the use of topical retinoic acid, calcineurin inhibitors, imiquimod (deemed ineffective in controlled trials), and tamoxifen; mitomycin C (topical or intralesional); and systemic methotrexate, dupilumab, and calcium channel blockers[75]. Treatments reserved for the treatment of keloids are shaded mid-blue and experimental treatments are shaded dark blue. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports. TGF, transforming growth factor. *Adapted from Tziotzios C, et al. J Am Acad Dermatol 2012;66:13–24.*

Epidemiology

Dupuytren disease is common in White people of northern European ancestry, with a prevalence in Western countries that ranges from 1%–30%; it is rarer in patients with darker skin phototypes. The incidence of Dupuytren disease increases with age and it is most common in middle-aged and older men. Familial associations suggest an autosomal dominant inheritance, but sporadic cases are common. The lesion is associated with other fibromatoses (e.g. plantar fibromatosis, polyfibromatosis; see Ch. 116) as well as diabetes mellitus, liver disease including alcoholic cirrhosis[35], and perhaps epilepsy[35], manual labor[36,37], and cigarette smoking.

Vemurafenib has been linked to new-onset or worsening of Dupuytren disease and plantar fascial fibromatosis. To date, there has been one report of the association of topical timolol with the development of Dupuytren disease and penile fibromatosis[38].

Pathogenesis

Fibrogenic cytokines (e.g. TGF-β1, TGF-β2) are thought to play a role due to their ability to induce collagen production, proliferation of fibroblasts, and the differentiation of fibroblasts into myofibroblasts. Production of tumor necrosis factor (TNF) by M2 macrophages and mast cells in early-stage Dupuytren disease is also thought to activate myofibroblasts, leading to and/or sustaining fibrosis[39]. In genome-wide assays of fibroblasts from Dupuytren disease, the differential expression patterns included genes that encode proteins involved in the extracellular matrix (e.g. collagen), fibrosis (e.g. follistatin), tissue remodeling (e.g. collagenases, matrix metalloproteinases), cellular movement (e.g. kinesins), and signaling pathways (e.g. STAT1, Wnt2), as well as growth factors (e.g. fibroblast growth factor 9)[40]. Activation of the Wnt signaling pathway appears to play a key role as it does in scar formation (see above)[41].

Clinical Features

Patients often present late in the course of their disease with flexion contractures of the affected digits. Lesions usually have an ulnar distribution, and the ring finger is most commonly affected (Fig. 98.6). The disorder begins with a nodule in the fascia of the palm, which grows to produce a cord which then contracts, producing a flexion contracture of the metacarpophalangeal and proximal interphalangeal joints. Complications of Dupuytren disease include nerve injury, loss of joint mobility, and development of complex regional pain syndrome (also referred to as reflex sympathetic dystrophy)[42].

Fig. 98.6 Dupuytren disease. Fibrotic nodule at the base of the fourth finger with an obvious cord extending proximally. In addition to palpation, fibrotic cords can be accentuated by extension of the digit. Eventually, flexion contractures develop.

Fig. 98.7 Cutis verticis gyrata. Cerebriform folding of the skin of the scalp.

Pathology

Histologically, the nodular lesion consists of a proliferation of myofibroblasts, which align along lines of tension. The initial stages are more cellular and there are some mitotic figures; the cells may express α-SMA, indicative of myofibroblastic differentiation. Thicker collagen, fewer myofibroblasts, and scarce to absent mitotic figures characterize later stages[43].

Differential Diagnosis

Although usually the diagnosis is straightforward, one must consider a ganglion cyst, giant cell tumor of the tendon sheath, soft tissue sarcoma (e.g. epithelioid sarcoma), callus, and tenosynovitis. An ultrasonographic hypoechoic mass superficial to a flexor tendon of the third, fourth, or fifth digits at the level of the distal metacarpal, where the length of the lesion is greater than its width, is typical for palmar fibromatosis and helps to exclude other diagnoses[44].

A rare case of lung cancer metastasis simulating Dupuytren disease has been reported[45], and in injection drug users, flexion digital contractures (camptodactyly) due to repeated vascular injury and infection of the digits may mimic Dupuytren disease. Flexion contractures of the hand, along with multiple tender nodules, can develop in the rare paraneoplastic palmar fasciitis and polyarthritis syndrome.

Treatment

Although surgical fasciotomy/fasciectomy to release the joint contracture is the mainstay of treatment, minimally invasive procedures such as percutaneous needle fasciotomy and enzymatic fasciotomy with injectable collagenase (from *Clostridium histolyticum*) are increasingly utilized despite higher recurrence rates[46–51]. Patients receive up to three monthly injections of collagenase per cord, followed by passive finger extension 1–3 days later. Complications include bruising, tendon rupture, ligament or nerve injury, and anaphylaxis. Although some authors have advocated the use of radiotherapy during the early stage of Dupuytren disease, a systematic review found limited evidence to support this approach[52].

A risk score determined by whole genome sequencing may predict postsurgical recurrence[53], while ultrasound findings (e.g. mixed echogenicity, nodular structure) may predict recurrence after minimally invasive treatments[54]. Additional possible treatments include intralesional triamcinolone[55], blue light irradiation (to prevent relapse)[56], correction of vitamin D deficiency[57], and use of inhibitors of TGF-β1[58,59], TGF-β2, TNF[60] and one of its receptors TNFR2, or IL-33[39]. New enzymatic approaches are also in development[61].

CUTIS VERTICIS GYRATA

Key features

- Hypertrophy and folding of the scalp
- Primary (idiopathic) form occurs almost exclusively in males, with an onset at puberty and without facial involvement
- Underlying disorders in the secondary form include endocrinopathies (e.g. acromegaly, myxedema) and genetic disorders (e.g. Turner syndrome)

Clinical Features

Primary cutis verticis gyrata (CVG) consists of overgrowth of the scalp that progresses to produce symmetric gyrate or cerebriform folding of the skin (Fig. 98.7). The folds are usually aligned in an anterior–posterior direction on the crown and vertex and are soft to spongy on palpation. Typically, terminal hair density is reduced on the folds, but not in the furrows. Primary CVG can be subdivided into: (1) isolated CVG; and (2) CVG associated with neurologic and/or ophthalmologic abnormalities. Both subtypes have a male predominance and usually develop around puberty. Secondary CVG is less common and its onset varies from birth to adulthood. In secondary CVG, there is a more equal sex distribution and it may be asymmetric, depending on the underlying etiology (Table 98.5).

Pathology

Biopsy specimens typically show normal skin or diffuse dermal thickening with packed hyalinized collagen and an increased number of fibroblasts. Prominent adnexal structures may be present.

Differential Diagnosis

A cerebriform congenital melanocytic nevus of the scalp may simulate CVG. One must also differentiate the latter from pachydermoperiostosis (primary hypertrophic osteoarthropathy), which is associated with facial involvement, thickening of the skin on the hands and feet, and clubbing of the digits. Patients with pachydermoperiostosis have underlying homozygous or compound heterozygous mutations in *SLCO2A1* or *HPGD*, which encode a prostaglandin transporter and 15-hydroxyprostaglandin dehydrogenase, respectively. Pachydermia is observed in both groups, but exaggerated CVG-like skin changes are associated with mutations in *SLCO2A1* (Fig. 98.8)[62].

Furrowed skin on the scalp, forehead, preauricular areas, neck, trunk, palms, and soles in association with acanthosis nigricans, craniosynostosis, and a prominent umbilical stump characterizes Beare–Stevenson

CUTIS VERTICIS GYRATA – DISEASE ASSOCIATIONS
Primary isolated
• None
Primary with associated anomalies
• Neurologic (e.g. intellectual disability, seizures) • Ophthalmologic (e.g. cataracts, optic atrophy)
Secondary
• Acromegaly, pseudoacromegaly • Myxedema (including cretinism)* • Insulin resistance† and HIV-related lipodystrophy with insulin resistance[76] • Graves disease* • Turner and Noonan syndromes (following resolution of intrauterine lymphedema)* • Fragile X syndrome • Klinefelter syndrome • Hereditary neuralgic amyotrophy • Tuberous sclerosis complex • Hyper-IgE syndrome, autosomal dominant • Rosenthal–Kloepfer syndrome (acromegaloid changes, corneal leukoma) • Vemurafenib (selective BRAF inhibitor) + radiotherapy‡[77] • Paraneoplastic due to metastatic carcinoma
*Increased dermal mucin may also be observed. †May also have acanthosis nigricans. ‡Due to multiple follicular cysts and milia.

Table 98.5 Cutis verticis gyrata – disease associations.

CLINICAL FEATURES OF HYALINE FIBROMATOSIS SYNDROME	
Good prognosis (classic juvenile hyaline fibromatosis)	**Poor prognosis (classic infantile systemic hyalinosis)**
Onset during childhood (<5 years old) and survival into adulthood	Onset during infancy
Firm, pearly papules (favoring the perinasal area and ears)	
Verrucous perianal nodules	
Firm nodules/tumors favoring the scalp, neck, hands, and trunk	Reddish-blue to brown plaques overlying extensor surfaces of joints
	Diffusely thickened skin
Gingival hypertrophy	
Joint contractures	
Osteopenia and osteolytic lesions due to hyaline deposits	
No visceral involvement	Persistent diarrhea
	Recurrent infections
	Visceral involvement
Normal mental development	

Table 98.6 Clinical features of hyaline fibromatosis syndrome.

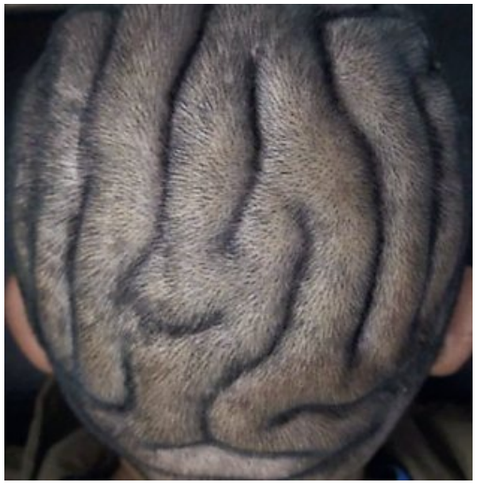

Fig. 98.8 Pachydermoperiostosis (primary hypertrophic osteoarthropathy). There is exaggerated cutis verticis gyrata-like folding of the scalp skin. *Courtesy Dr D. Timaná and Dr J. Valverde, Hospital Docente de Trujillo.*

cutis gyrata syndrome, an autosomal dominant condition caused by mutations in *FGFR2*. Patients with Goeminne syndrome may also have CVG-like folding of the scalp in conjunction with congenital torticollis, multiple keloids, cryptorchidism, and renal dysplasia (TKCR syndrome).

Other potential simulators of CVG include dissecting cellulitis of the scalp, benign hamartomas or tumors (e.g. plexiform neurofibroma, cutaneous neurocristic hamartoma[63], connective tissue nevus, nevus lipomatosus, aggregated cylindromas), primary systemic amyloidosis, leukemia cutis, and malignancies such as folliculotropic mycosis fungoides and angiosarcoma[64]. Based upon patient history, trauma has preceded the development of CVG and there are isolated reports of CVG-like presentations of pemphigus vegetans, Darier disease, scleromyxedema[65], and chronic actinic dermatitis[66] but clinical differentiation is more straightforward.

Treatment

CVG is generally asymptomatic and requires no treatment. Occasionally, surgical excision is performed. Improvement has been reported following injection of hyaluronidase[67].

HYALINE FIBROMATOSIS SYNDROME (JUVENILE HYALINE FIBROMATOSIS AND INFANTILE SYSTEMIC HYALINOSIS)

Synonyms: ■ Murray–Puretic–Drescher syndrome ■ Fibromatosis hyalinica multiplex juvenilis ■ (Juvenile) systemic hyalinosis

Key features

- Rare autosomal recessive disorder with variable phenotypic expression
- Usually presents during infancy or early childhood
- Papulonodules that favor the ears, scalp, neck, hands, and periorificial areas plus gingival hypertrophy and flexion contractures of large joints
- Mutations in the gene that encodes anthrax toxin receptor 2 (*ANTXR2*)
- Treatment consists of excision of nodules and gingivae as needed, but lesions often recur

Introduction

Hyaline fibromatosis syndrome (HFS) is a rare autosomal recessive genodermatosis characterized by hyaline accumulation within the dermis. HFS encompasses both juvenile hyaline fibromatosis (JHF) and infantile systemic hyalinosis (ISH). These two disorders are allelic, i.e. they are due to mutations in the same gene, but differ in severity and visceral involvement[68] (Table 98.6).

History

In 1873, Murray described a condition which he termed "molluscum fibrosum". In 1972, Kitano and colleagues renamed the disorder "juvenile hyaline fibromatosis".

Epidemiology

HFS is a rare disorder that presents during infancy or early childhood.

Fig. 98.9 Juvenile hyaline fibromatosis. Firm pearly papules favor the ears.

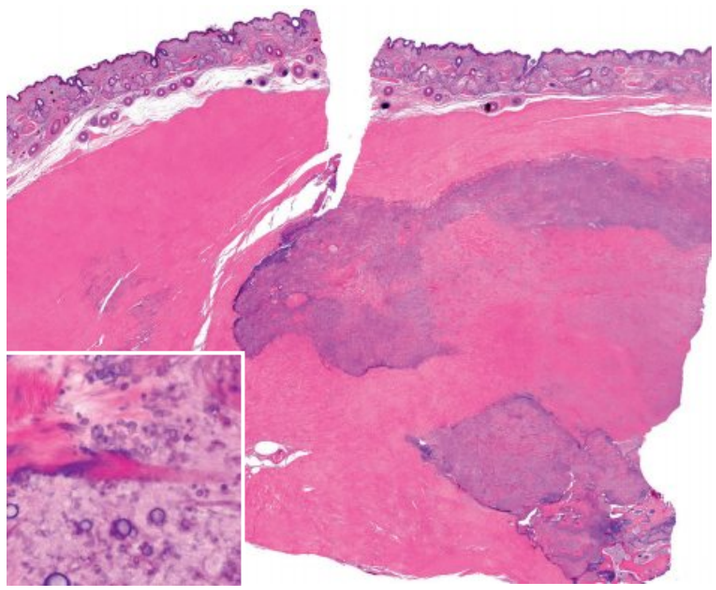

Fig. 98.10 Juvenile hyaline fibromatosis – histopathologic features. Abundant, dense, homogeneous, hyaline (PAS-positive) collagen within the lower dermis and subcutis. Round basophilic calcospherites are also present (inset).

Pathogenesis

Mutations are present in the gene that encodes anthrax toxin receptor 2 (ANTXR2), also referred to as capillary morphogenesis protein-2 (CMG2). ANTXR2 is a transmembrane protein that binds to laminins and types IV and VI collagen (as well as the anthrax toxin). In the skin it is thought to play a role in cell–matrix interactions and basement membrane integrity. Because ANTXR2/CMG2 is thought to target collagen VI for degradation, its dysfunction leads to an accumulation of collagen VI and a subsequent sequestration of inactive matrix metalloproteinases by excess collagen VI, thus leading to fibrosis[69]. As noted previously, mutations in *ANTXR2* can lead to either mild or severe forms of HFS[70]. Missense and other in-frame mutations of the cytoplasmic domain tend to cause a phenotype with a better prognosis (JHF), whereas truncating and missense mutations of the extracellular protein-binding domain lead to a more severe phenotype (ISH). Because ANTXR2 is not expressed in the brain, mental development is not impaired.

Clinical Features

Initially, firm papules and nodules develop on the scalp, ears, neck, and face (particularly perinasal and perioral regions) as well as the perianal area (Fig. 98.9); papulonodules also favor the hands. Patients often suffer severe physical limitations from joint contractures and tumors. Additional clinical features are outlined in Table 98.6. Milder phenotype and later onset has been observed in females[71].

Pathology

Ill-defined nodules composed of dense, homogeneous, hyaline (PAS-positive) collagen are seen within the dermis and, in larger lesions, the subcutaneous tissue (Fig. 98.10). Mononuclear cells and $CD68^+$, osteoclast-like giant cells may be present in a perivascular location in addition to perivascular calcification and eosinophilic globules. Over time, the lesions tend to become more paucicellular, and calcospherites or larger areas of calcification are frequently seen (Fig. 98.10, inset).

Differential Diagnosis

HFS needs to be distinguished from the autosomal recessive disorders MONA (multicentric osteolysis, nodulosis, and arthropathy) and Winchester syndrome which are due to mutations in genes that encode matrix metalloproteinases. Both can have joint contractures, coarse facies, thickened skin and gingival hypertrophy, with painful nodules, especially of the soles, in the former. Histologically, both disorders feature a proliferation of fibroblasts and thickened collagen bundles

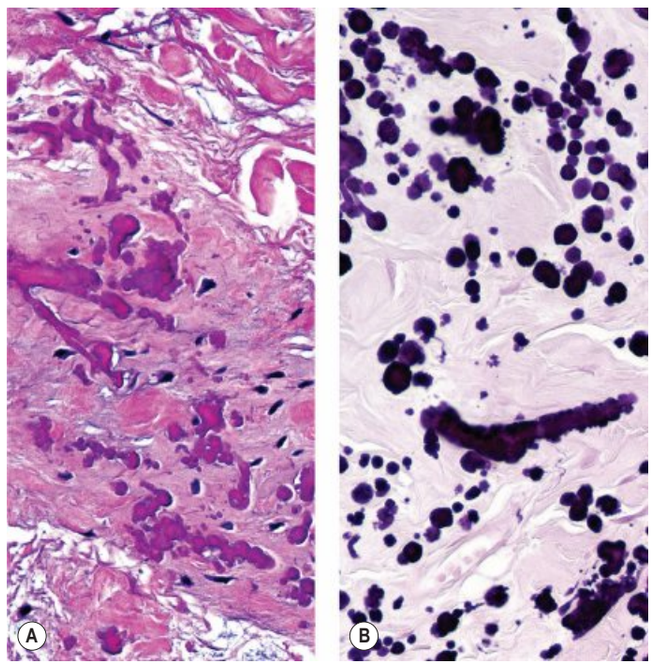

Fig. 98.11 Elastofibroma dorsi – histopathologic features. A Irregular, partially fragmented elastic fibers admixed with swollen collagen bundles. **B** An elastic tissue stain accentuates the fragmented fibers.

extending from the deep dermis to the hypodermis. Other genodermatoses to consider include Farber lipogranulomatosis, lipoid proteinosis, infantile myofibromatosis, terminal osseous dysplasia, and the rarer diffuse variant of stiff skin syndrome that is due to fibrillin-1 mutations and inherited in an autosomal dominant pattern.

Treatment

Treatment options are limited. Surgical excision of nodules and gingival hypertrophy and release of contractures can be performed, but lesions often recur. Diode laser therapy improved skin and mucosal lesions in one patient, but these recurred[72]. Physiotherapy may slow the progression of joint contractures. Injections of corticosteroids into fibromas have met with limited success. Subcutaneous interferon-α-2b therapy improved the skin lesions, gingival hypertrophy, and joint mobility in a patient

DISORDERS CHARACTERIZED BY INCREASED ELASTIC TISSUE FIBERS			
Disorder	**Clinical features**	**Histopathologic features**	**Comments**
Idiopathic or inherited			
Late-onset focal dermal elastosis (focal dermal elastosis)[78]	Multiple 1–3 mm yellow papules that may coalesce Favors the neck and other flexural areas	Increased normal-appearing elastic fibers in the mid and deep reticular dermis	Lacks the systemic features of PXE (see Ch. 97)
Linear focal elastosis (elastotic striae)	Multiple yellow, palpable, striae-like bands Favors the lumbosacral region	Focal increase in number of elongated or fragmented elastic fibers (thickened > thinned) within the mid dermis; the ends of the elastic fibers may be split with a "paintbrush" appearance Early lesions may have inflammation and elastolysis	May represent an excessive regenerative process of elastic fibers, perhaps to repair striae distensae (see Ch. 99)
Elastoderma	Localized areas of lax, pendulous skin with reduced elasticity; neck, trunk, arm	Increased normal- and abnormal-appearing elastic fibers throughout the dermis and subcutis	Lacks the systemic features of PXE (see Ch. 97) Overlaps with cutaneous aging, but earlier onset
Elastofibroma dorsi	Large mass in the deep subcutaneous tissue of the infrascapular area Rarely develops at thoracotomy sites, perhaps related to widened intercostal spaces	Arises within the fascia Increased elastic fibers with a globular and beaded morphology admixed with plump collagen bundles, fibroblasts, and mature fat cells (Fig. 98.11)	Favors older women > men and Japanese Possibly related to chronic mechanical stress Upregulation of TGF-β1 and basic fibroblast growth factor
Elastoma (nevus elasticus)	Firm, skin-colored to yellowish papule(s) which may be clustered Favors the trunk	Accumulation of thick, tortuous, branching elastic fibers within the reticular dermis	Type of connective tissue nevus (see Ch. 116) Associated with Buschke–Ollendorf syndrome (dermatofibrosis lenticularis disseminata)
Elastosis perforans serpiginosa	Annular and polycyclic plaques composed of keratotic papules Favors the neck, face, antecubital fossae, and other flexural areas	Transepidermal or perifollicular channels that contain fragments of elastotic material Increased number of coarse elastic fibers in the superficial dermis No secondary calcium deposition on elastic fibers	Associated with penicillamine (lumpy-bumpy fibers*), Down syndrome and connective tissue disorders (e.g. Ehlers–Danlos syndrome, Marfan syndrome; see Ch. 96)
Pseudoxanthoma elasticum (PXE)	Yellowish skin papules and "cobble-stoned" plaques; redundant folds Favors flexural sites, especially the neck and axillae, and periumbilical region	Distorted and fragmented elastic fibers (elastorrhexis) in mid and deep reticular dermis Calcium deposition on altered elastic fibers	Angioid streaks (Bruch membrane of eye), GI hemorrhage, atherosclerotic cardiovascular disease (see Ch. 97)
Related to cumulative actinic damage (see Fig. 87.24)			
Actinic or solar elastosis (including cutis rhomboidalis nuchae, solar elastotic bands, elastotic nodules of the ear)	Yellow to yellow–white, thickened, coarsely wrinkled skin that favors the lateral forehead, malar region, posterolateral neck, mid extensor arms Bands – forearms Nodules – antihelix > helix	Bluish-grey elastotic material composed of degenerated elastic fibers within the upper and mid dermis In more advanced phases, the elastotic material may aggregate into dense amorphous masses ("actinic elastoma")	Photodamage may be accelerated by medications, e.g. voriconazole (see Ch. 87)
Favré-Racouchot syndrome (nodular elastosis with cysts and comedones)	Bilateral, clustered, open > closed comedones within thickened skin Favors malar prominence and lateral periorbital region	Severe solar elastosis with follicular distention and cystic structures filled with compact keratin	See Ch. 87
Acrokeratoelastoidosis	Bands of waxy or translucent papules and plaques Favors ulnar side of thumb and radial side of forefinger	Shallow depression of the epidermis Usually a decrease in thin and partially fragmented elastic fibers in the mid and deep reticular dermis In some cases, elastic fibers are increased, coarse, and aggregated	May be exacerbated by trauma Also an inherited form that can involve non-sun-exposed sites of the hands and/or feet (see Ch. 58)
Elastoma of Dubreuilh	Yellow to yellow–brown papules or plaques Favor forehead, cheeks, lateral neck	Amorphous masses composed of aggregated elastotic material in the upper dermis	See Ch. 87

*By electron microscopy.

Table 98.7 Disorders characterized by increased elastic tissue fibers. Special stains for elastic fibers include Verhoeff–van Gieson and orcein (acid orcein–Giemsa; see Ch. 0). GI, gastrointestinal.

with JHF. Based on *in vitro* results, proteasome inhibitors may represent a future therapy for HFS patients with ectodomain-related mutations in *ANTXR2*[73].

ELASTIC TISSUE-RELATED DISORDERS

In general, mechanisms which lead to increased dermal elastic tissue are unknown, and the nosology of the elastic tissue-related disorders can be confusing[74]. There are several acquired disorders whose clinical appearance can overlap. Their clinical and histopathologic features are outlined in Table 98.7.

Additional figures and tables on Differences in adult versus fetal wound healing, Treatment options for Dupytren disease, and Differential diagnosis of hyaline fibromatosis syndrome, available in our eBook (see inside front cover for access code).

DIFFERENCES IN ADULT VERSUS FETAL WOUND HEALING		
	Adult	**Fetal**
Fluid environment	No	Yes
Sterile environment	No	Yes
Inflammation	Yes	No
Scar formation	Yes	No
pO_2 (mmHg)	>60	20

eTable 98.1 Differences in adult versus fetal wound healing.

TREATMENT OPTIONS FOR DUPUYTREN DISEASE		
Procedure	**Advantages**	**Disadvantages**
Dermofasci*ectomy* (removes diseased fascia including skin)	Addresses severe disease Lower rate of recurrence	Moderate perioperative morbidity Higher rate of complications* Prolonged rehabilitation High cost
Limited fasci*ectomy* (removes diseased fascia)	Addresses moderate to severe disease Low recurrence rate	Moderate perioperative morbidity Increased risk of scarring Prolonged rehabilitation High cost
Open fasci*otomy* (cord incised; diseased tissue is not excised)	Moderately invasive Good visualization Low complication rate*	Recurrence rate higher than with fasciectomy
Needle fasci*otomy* or percutaneous needle aponeurotomy (PNA) with or without lipofilling (cord fragmented by needle then released by manual force; diseased tissue is not excised)	Minimally invasive Outpatient procedure with local anesthesia Rapid recovery Low cost	Steep learning curve Skin tears Less effective for severe disease High rate of recurrences long-term
Enzymatic fasciotomy with collagenase from *Clostridium histolyticum* (Xiaflex® [USA]; Xiaplex® [Europe])	Minimally invasive Rapid Low risk of complications† First-line therapy or second-line therapy after failure of PNA or fasciectomy	Can only perform on a single cord or two thin cords May require multiple procedures High cost
Intralesional corticosteroids	Minimally invasive Softening of nodules after repeated injections Can improve outcome after PNA Low cost	High recurrence rate – at least 50%

*Complications include digital nerve injury or postoperative neurapraxia, flexor tendon injury/rupture, delayed wound healing or skin necrosis, dysvascular digit/arterial injury, hematoma, infection, and complex regional pain syndrome.
†Complications include bruising, tendon rupture, ligament or nerve injury, and anaphylaxis.

DIFFERENTIAL DIAGNOSIS OF HYALINE FIBROMATOSIS SYNDROME			
Disease (mode of inheritance)	**Gene**	**Cutaneous manifestations**	**Extracutaneous manifestations**
MONA (multicentric osteolysis, nodulosis, and arthropathy) (AR)	*MMP2*	Painful nodules on the palms and soles, hypertrichosis, gingival hypertrophy	Osteolysis of hand and foot bones, joint contractures, short stature, corneal opacities, coarse facies
Winchester syndrome	*MMP14*	Thickened hyperpigmented skin, hypertrichosis, gingival hypertrophy	
Farber lipogranulomatosis (AR)	*ASAH1*	Subcutaneous nodules, especially periarticular and at sites of trauma	Arthritis, contractures, progressive hoarseness, variable CNS involvement, hepatosplenomegaly
Lipoid proteinosis (AR) (see Ch. 48)	*ECM1*	Vesicles and hemorrhagic crusts followed by pitted scars, yellow papules and nodules favor the face, verrucous lesions on extensor surfaces	Hoarseness, infiltrated tongue with restricted motion, parotitis, loss of teeth, learning difficulties, seizures
Stiff skin syndrome (AD) (see Ch. 43)	*FBN1*	Induration and thickening of the skin – most often of the buttocks and thighs but more widespread than regional/segmental form, hypertrichosis of affected areas	Restricted joint mobility including hip contractures, short stature, internal organs spared
Mucolipidosis II (AR)	*GNPTAB*	Thickened waxy skin especially around the earlobes, gingival hypertrophy, dermal melanocytosis	Short stature, dysostosis multiplex, skeletal abnormalities, cardiac valve disease, developmental delay, coarse facies
Infantile myofibromatosis (see Ch. 116)	*PDGFRB*	Skin-colored to purple nodules – favor the head and neck region and trunk	Lytic metaphyseal lesions, internal organ involvement, e.g. GI tract, kidneys, lung, heart

Atrophies of Connective Tissue 99

Catherine Maari and Julie Powell

Chapter Contents

Mid-dermal Elastolysis 1741
Anetoderma. 1742
Striae 1745
Atrophoderma of Pasini and Pierini 1746
Follicular Atrophoderma 1748
Atrophia Maculosa Varioliformis Cutis 1749
Piezogenic Pedal Papules (Piezogenic Papules) 1749
Other Atrophies of the Connective Tissue 1750

Atrophies of the skin that are due to a diminution or loss of collagen and/or elastic fibers are discussed in this chapter. The areas of involvement can be quite large, as in mid-dermal elastolysis, or punctate, as in follicular atrophoderma. In most disorders, the underlying pathogenesis remains to be discovered.

MID-DERMAL ELASTOLYSIS

Key features

- Uncommon disorder with areas of fine wrinkling
- Usually affects White middle-aged women
- Selective loss of elastic tissue in the mid dermis

Introduction

Mid-dermal elastolysis (MDE) is a rare, acquired disorder of elastic tissue. Clinically, it is usually characterized by diffuse fine wrinkling, most often located on the trunk, shoulders, neck, and arms. Histologically, a clear band of elastolysis with loss of elastic fibers is present in the mid dermis.

History

In 1977, Shelley and Wood reported the first case of "wrinkles due to idiopathic loss of mid-dermal elastic tissue". Their patient, a 42-year-old woman, had circumscribed areas of fine wrinkles that gave her an inappropriately aged appearance[1].

Epidemiology

To date, around 100 cases have been reported in the literature. The vast majority of patients are White women between the ages of 30 and 50 years[2,3].

Pathogenesis

The cause of the acquired elastic tissue degeneration in MDE has yet to be determined. Exposure to UV light, including natural sunlight, UVA (tanning salon), and narrowband UVB phototherapy[4,5], was thought to be a contributing factor in MDE, but this remains unclear[3]. Other hypotheses include defects in the synthesis of elastic fibers, autoimmunity against elastic fibers, and damage to elastic fibers via the release of elastase by inflammatory cells or fibroblasts. Of note, MDE has been observed in the setting of immune reconstitution inflammatory syndrome (IRIS). An imbalance between matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) may also be playing a role, in addition to $CD34^+$ dendritic fibroblasts[6].

A decrease in lysyl oxidase-like 2 (LOXL2) expression, potentially affecting elastin renewal, has been observed in MDE[7]. There is also a decrease in dermal fibulin-4 and -5, pointing to altered re-assembly of elastic fibers in MDE, and not simply enhanced elastolysis[8]. In sum, the pathogenesis of MDE is likely multifactorial, with genetic predisposition, chronic inflammation, UV irradiation, and/or (auto)immune processes as contributing factors[3].

Clinical Features

Patients can have well-circumscribed to large diffuse areas of fine wrinkling (Fig. 99.1), usually in a symmetric distribution (type I). The wrinkles themselves tend to follow cleavage lines. Discrete perifollicular papules are seen in some patients (type II), with the site of the central hair follicle being indented. Occasionally, erythematous patches, telangiectasias, and reticulated erythema may be present (type III)[3]. Although in the majority of patients there is no history of a prior inflammatory dermatosis, some patients report previous mild to moderate erythema and, rarely, elastolysis is preceded by urticarial lesions or granuloma annulare.

Sites of predilection are the trunk, lateral neck, and upper extremities. Once the patches of wrinkling have appeared, they usually remain stationary. They are asymptomatic and give the skin a prematurely aged appearance. The affected areas usually have normal pigmentation and no associated scaling, induration, or herniation. There is typically no family history of similar lesions and unless linked to an autoimmune disorder, no systemic involvement[2,3]. MDE can lead to significant cosmetic concern.

While diagnosis is usually confirmed via histologic examination of involved skin, non-invasive imaging techniques such as optical coherence microscopy or high-frequency ultrasound may also prove helpful[9].

Pathology

The epidermis is normal in appearance and, occasionally, a mild perivascular infiltrate is noted in the dermis. Elastic tissue stains, such as Verhoeff–van Gieson or Weigert's stain, reveal a selective loss of elastic fibers in the mid dermis (Fig. 99.2). There is preservation of normal elastic tissue in the superficial papillary dermis above, in the reticular dermis below, and along adjacent hair follicles. The preservation of elastic tissue around the hair follicles explains the perifollicular papules observed in some patients.

By electron microscopy, phagocytosis of normal as well as degenerated elastic fiber tissue by macrophages has been described[3]. Elastophagocytosis by macrophages can also be observed by routine histology.

Differential Diagnosis

MDE must be differentiated from other disorders of elastic tissue such as anetoderma, pseudoxanthoma elasticum (PXE), PXE-like papillary dermal elastolysis, elastoderma, and cutis laxa, especially the acquired form (Table 99.1).

Clinically, anetoderma is characterized by soft macules and papules that herniate upon palpation, as opposed to diffuse wrinkling. Histologically, elastolysis can occur in the papillary and/or mid-reticular dermis in anetoderma (see below). Patients with heritable forms of generalized cutis laxa have loose, redundant skin, hanging in folds, and histologic examination shows reduced and fragmented elastic fibers, usually within the entire dermis. Acquired cutis laxa, both generalized and acral, can be a manifestation of an underlying paraproteinemia, with binding of immunoglobulins to elastic fibers (see Table 97.8).

Less often, MDE is confused with solar elastosis or the perifollicular elastolysis that is usually seen on the trunk in association with acne

Fig. 99.1 Mid-dermal elastolysis. A, B Type I – large diffuse patch as well as reticulated areas of fine wrinkling on the upper trunk and proximal arm. The junction of involved and uninvolved skin is marked with an arrow. **C** Types I and II – both circumscribed areas of wrinkling and follicular papules are present. **D** Type II – multiple skin-colored follicular papules. **E** Type III – primarily reticulated erythema. *A, Courtesy Judit Stenn, MD; B, Courtesy Carlo F. Tomasini, MD; C–E, Courtesy Lorenzo Cerroni, MD.*

vulgaris. Solar elastosis differs clinically by its onset in an older age group, restriction to only sun-exposed areas, yellow color, and coarser wrinkling and differs histologically by hyperplasia of abnormal elastic fibers and basophilic degeneration of the collagen in the papillary dermis. Perifollicular elastolysis leads to a selective and almost complete loss of the elastic fibers that surround hair follicles, compared with preservation of elastic fibers around follicles in MDE.

Treatment

Currently, there is no effective treatment for MDE. Sunscreens, colchicine, chloroquine, vitamin E, and topical agents (retinoic acid, corticosteroids) have been tried without success[2]. Topical soybean extract and eicosapentanoic acid are potential future therapies and oral mycophenolate mofetil may be beneficial[2,10].

ANETODERMA

Synonyms: ■ Macular atrophy ■ Anetoderma maculosa ■ Anetoderma maculosa cutis ■ Atrophia maculosa cutis

Key features

- Circumscribed 1–2 cm areas of flaccid skin, which may be elevated, macular, or depressed
- *Primary* anetoderma has classically been divided into inflammatory and non-inflammatory
- *Secondary* anetoderma is associated with infectious and inflammatory cutaneous disorders as well as tumors and autoimmune disorders (e.g. antiphospholipid antibody syndrome)
- Histologically, focal absence of dermal elastic tissue is seen

DISORDERS OF ELASTIC TISSUE			
Condition	**Clinical findings**	**Site of predilection**	**Pathology**
Anetoderma	• Multiple circumscribed areas of flaccid skin • Lesions are often elevated (protruding), but can be macular or depressed	Usually on trunk	Focal or complete loss of elastic tissue in the papillary and/or reticular dermis
Cutis laxa (see Ch. 97)	• Loose, sagging skin folds resulting in prematurely aged appearance • Hereditary or acquired • Internal organ involvement, e.g. pulmonary, in hereditary form and generalized acquired form	Eyelids, cheeks, neck, shoulder girdle and abdomen; distal digits in acquired acral form	Diminished and fragmented elastic fibers usually throughout the dermis
Mid-dermal elastolysis	• Diffuse areas of fine wrinkling (type I), perifollicular papules (type II), and/or reticulated erythema (type III) in middle-aged women	Trunk, arms, and lateral neck	Selective loss of elastic fibers within the mid dermis in a band-like pattern
Pseudoxanthoma elasticum (PXE; see Ch. 97)	• Yellowish coalescing skin papules, "cobblestoning", and redundant folds in flexural sites • Associated ocular and cardiovascular involvement	Lateral neck, axillae, and groin; scars	Clumped and calcified elastic fibers in the mid dermis
PXE-like papillary dermal elastolysis	• Multiple, 2–3 mm, yellow or skin-colored papules that can coalesce into cobblestoned plaques	Neck, flexor forearms, axillae, lower abdomen, inframammary folds	Decreased elastic tissue in the papillary dermis (band-like pattern); clumping and fragmentation of elastic fibers; no calcification of elastic fibers

Table 99.1 Disorders of elastic tissue. For additional entities, see Tables 95.5, 97.4 and 97.7.

Introduction

The term "anetoderma" is derived from *anetos*, the Greek word for slack, and *derma* for skin. Anetoderma is an elastolytic disorder characterized by localized areas of flaccid skin, which may be depressed, macular or papular; the latter can reflect herniation of the subcutaneous tissue. Anetoderma may be idiopathic or associated with an inflammatory disorder of the skin.

History

The first case of primary inflammatory anetoderma was reported by Jadassohn in 1892[11]. A year previously, Schweninger and Buzzi described a 29-year-old woman with multiple, non-inflammatory, sac-like tumors on the trunk and upper extremities[12].

CLASSIFICATION OF ANETODERMA	
Primary anetoderma	• Jadassohn–Pellizzari type: preceding inflammatory lesionsSchweninger–Buzzi type: no preceding inflammatory lesions
Secondary anetoderma	• Associated with a primary dermatosis or cutaneous tumorAssociated with a systemic disease (autoimmune, antiphospholipid syndrome, infectious) or drug
Familial anetoderma	• Both autosomal dominant and autosomal recessive formsUsually develops in first decade of life
Anetoderma of prematurity	• Occurs in extremely premature infants • At sites of monitoring leads or adhesives

Table 99.2 Classification of anetoderma.

Epidemiology

Several hundred cases of anetoderma have been reported in the world literature. Primary anetoderma favors young adults between 15 and 25 years of age and occurs more frequently in women than men. The epidemiology of secondary anetoderma reflects that of the underlying etiologies (see Table 99.3).

Pathogenesis

The pathogenesis of anetoderma is not known. These lesions could be considered unusual scars, since scars also have decreased elastic tissue. The loss of dermal elastin may reflect an impaired turnover of elastin, caused by either increased destruction or decreased synthesis of elastic fibers. There are a number of proposed explanations for the focal elastin destruction, e.g. the release of elastase from inflammatory cells, the release of cytokines such as interleukin-6, an increased production of progelatinases A and B[13], and the phagocytosis of elastic fibers by macrophages. More recently, a decrease in fibulin protein expression was observed, suggesting defective elastic fiber reassembly[6]. Immunologic mechanisms may also play a role, providing an explanation for associated findings such as antiphospholipid antibodies (see below). Based upon a few isolated patients, a link may exist between anetoderma and mutations in genes that encode enzymes in the citric acid cycle[14].

In *primary* anetoderma, there is no underlying associated disorder and lesions arise within clinically normal skin. It has classically been subdivided into two major forms: those with preceding inflammatory lesions (the Jadassohn–Pellizzari type) and those without preceding inflammatory lesions (the Schweninger–Buzzi type) (Table 99.2). This clinical classification is primarily of historical interest, since the two types of lesions can coexist in the same patient and their histopathology is often the same; the presence or absence of clinical inflammation at the onset of the disease is not related to prognosis[15].

Secondary anetoderma can arise in the setting of a primary inflammatory dermatosis, skin infection or cutaneous tumor, as well as in patients with systemic disorders (e.g. autoimmune). Over the past decade, an association with antiphospholipid antibody syndrome has been highlighted. Although the vast majority of cases are sporadic, familial anetoderma has been described and is usually not associated with pre-existing lesions[16].

Clinical Features

The characteristic lesions are flaccid, circumscribed areas of slack skin that are a reflection of a marked reduction or absence of dermal elastic fibers; they can appear as depressions, wrinkling, or sac-like protrusions (Fig. 99.3). These atrophic lesions vary in number from a few to hundreds, and they typically measure 1–2 cm in diameter and are skin-colored to bluish–white in color. The skin surface can be normal in appearance or wrinkled, and a central depression may be seen. Coalescence of smaller lesions can give rise to larger herniations.

The examining finger sinks into a distinct pit with sharp borders as if into a hernia ring. The bulge reappears when the pressure from the finger is released. This clinical finding is referred to as the "buttonhole" sign and is similar to that observed in neurofibromas.

Predilection sites for these asymptomatic lesions are the chest, back, neck, and upper extremities. Primary anetoderma usually develops in young adults, and new lesions often continue to form for many years as the older lesions fail to resolve.

True secondary anetoderma implies that the characteristic atrophic lesion has appeared in the same site as a previous specific skin lesion, e.g. from varicella or leprosy. Some authors also consider lesions associated

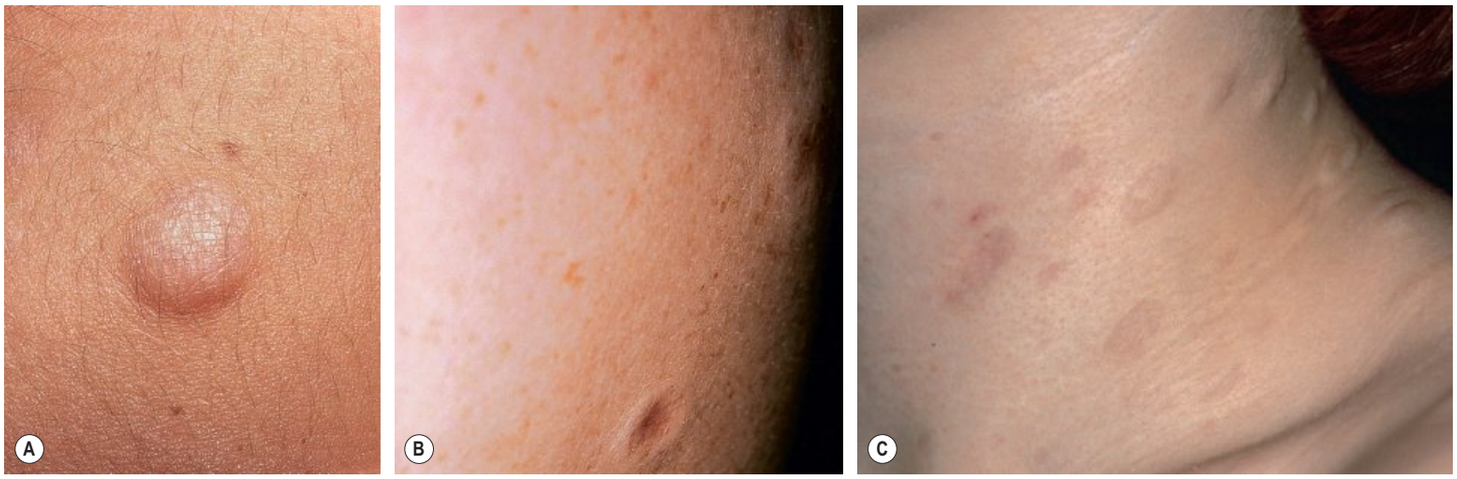

Fig. 99.3 Primary anetoderma. Lesions can range from soft, skin-colored papules that herniate upon palpation (**A**) to flaccid papules that have a central depression (**B**). The upper trunk and neck is a common location for primary anetoderma (**C**). *A, Courtesy Ronald P. Rapini, MD; C, Courtesy Thomas Schwarz, MD.*

with an underlying disease (e.g. HIV infection, antiphospholipid antibody syndrome, autoimmune thyroiditis) as secondary anetoderma; however, in this instance, the atrophic areas do not necessarily develop within areas of known inflammation. Evaluation for the presence of antiphospholipid antibodies should be performed before patients with idiopathic anetoderma are labeled as having primary anetoderma[17]. The range of heterogeneous conditions associated with secondary anetoderma are outlined in Table 99.3. With the exception of distribution (and perhaps size), the clinical features are the same as those of primary anetoderma.

Anetoderma has increasingly been reported in premature infants. In most neonates, it appears to be related to the use of cutaneous monitoring leads or adhesives[18], as well as extreme prematurity[18].

In patients with anetoderma, a variety of systemic abnormalities have been reported, including ocular, endocrinologic, skeletal, cardiac, pulmonary, and gastrointestinal disease. Because there has been no consistency with regard to these associated abnormalities, they are probably coincidental, although the possibility exists that they may reflect a more generalized elastolytic disorder that has yet to be defined.

Pathology

In routinely stained sections, the collagen within the dermis of affected skin appears normal. Perivascular lymphocytes, primarily T helper cells, are often present but do not correlate with clinical findings of inflammation.

The predominant abnormality, revealed by elastic tissue stains, is a focal, more or less complete loss of elastic tissue in the papillary and/or reticular dermis. There are usually some residual abnormal, irregular, and fragmented elastic fibers (Fig. 99.4)[19]. In addition to plasma cells and histiocytes with phagocyted elastic fibers, occasional granuloma formation can be seen.

Direct immunofluorescence sometimes shows linear or granular deposits of immunoglobulins and complement along the dermal–epidermal junction or around the dermal blood vessels in affected skin[20]. However, these findings are not helpful diagnostically.

By electron microscopy, the elastic fibers are fragmented and irregular in shape and occasionally they are engulfed by macrophages.

Differential diagnosis

Anetoderma must be differentiated from other disorders of elastic tissue such as MDE (see Table 99.1) as well as atrophodermas (see below). However, the major differential diagnosis consists of post-traumatic scars and papular elastorrhexis[21]. The latter is an acquired disorder characterized by firm, white, non-follicular papules that measure 2–5 mm in diameter and are evenly scattered on the trunk. The lesions usually appear during adolescence or early adulthood. Histology demonstrates focal degeneration of elastic fibers and normal collagen. There are no associated extracutaneous abnormalities. This disorder is believed by some authors to be a variant of connective tissue nevi or an abortive form of the Buschke–Ollendorff syndrome, while others think that these lesions represent papular acne scars. In contrast to anetoderma, lesions of papular elastorrhexis are firm and non-compressible.

Less often, anetoderma is confused with perifollicular elastolysis (see above), nevus lipomatosus, or focal dermal hypoplasia (Goltz

SECONDARY ANETODERMA – ASSOCIATED CONDITIONS	
Infectious	• Varicella • Folliculitis* • Lepromatous leprosy • Syphilis (cutaneous) • Molluscum contagiosum • Tuberculosis (cutaneous) • HIV infection • Acrodermatitis chronica atrophicans • Post-hepatitis B immunization
Drugs	• Penicillamine • Cabiralizumab (CSF1 receptor antagonist) plus nivolumab**
Inflammatory	• Acne vulgaris • Lichen planus • Neutrophilic dermatoses (Sweet syndrome, pyoderma gangrenosum) • Granuloma annulare • Cutaneous sarcoidosis • Juvenile xanthogranuloma • Cutaneous lymphoid hyperplasia (lymphocytoma cutis) • Insect bites • Prurigo nodularis
Autoimmune	• Cutaneous (e.g. discoid, panniculitis) and systemic lupus erythematosus • Antiphospholipid syndrome • Primary Sjögren syndrome • Addison disease • Graves disease
Tumors and depositions	• Involuted infantile hemangioma • Pilomatricoma • Melanocytic nevus • Schwannoma • Dermatofibroma • Dermatofibrosarcoma protuberans • Primary cutaneous marginal zone B cell lymphoproliferative disorder (formerly primary cutaneous plasmacytoma or immunocytoma) • Mycosis fungoides • Mastocytosis • Nodular amyloidosis • Xanthoma

*May overlap with perifollicular elastolysis.
**Preceding granulomatous inflammation with elastolysis.

Table 99.3 Secondary anetoderma – associated conditions.

syndrome). Nevus lipomatosus superficialis of Hoffman and Zurhelle presents as a clustered group of soft, skin-colored to yellow nodules, usually located on the lower trunk and present since birth (see Ch. 117). Histology shows ectopic mature lipocytes located within the dermis. The lesions of Goltz syndrome (including telangiectasias, vermiculate dermal atrophy, hypopigmentation, hyperpigmentation, and fatty herniations/hamartomas) are in a linear array along the lines of Blaschko (see Ch. 62). Histologically, a decrease in dermal content is seen as well as extension or deposition of subcutaneous fat into the dermis.

Treatment

Various therapeutic modalities have been tried, but have not resulted in improvement of existing atrophic lesions; these include intralesional triamcinolone and systemic administration of aspirin, dapsone, phenytoin, penicillin G, vitamin E, and inositol niacinate. Some authors have reported improvement with hydroxychloroquine. Surgical excision of limited lesions may be helpful, with informed consent from the patient regarding the risk of scar formation. The utility of soft tissue fillers is inconclusive. Based upon case reports, fractionated ablative and non-ablative lasers may be beneficial[22,23].

STRIAE

Synonyms: ■ Striae distensae ■ Striae atrophicans ■ "Stretch marks" ■ Striae gravidarum

Introduction

Striae are a very common condition in most age groups. They are linear atrophic depressions of the skin that form in areas of dermal damage produced by stretching of the skin. They are associated with various physiologic states, including puberty, pregnancy, rapid growth, weight gain or loss, obesity[24], and disorders that lead to hypercortisolism. Striae also develop at sites of potent topical corticosteroid application, in particular, occluded intertriginous zones.

History

Striae were first described by Roederer in 1773, and the first histologic descriptions were made by Troisier and Menetrier in 1889.

Epidemiology

Striae are very common and usually develop between the ages of 5 and 50 years. They are seen more commonly in White individuals and occur about twice as frequently in women as in men. They commonly develop during puberty, with a prevalence ranging from 5% to 85%[25], or during pregnancy, with an incidence of up to 90%[26].

Pathogenesis

Factors leading to the development of striae have not been fully elucidated. They are a reflection of "breaks" in the connective tissue that lead to dermal atrophy. A number of factors, including hormones (particularly corticosteroids), mechanical stress and genetic predisposition, appear to play a role. Bevacizumab, an anti-VEGF antibody well known for its negative effect on wound healing, has also been associated with severe ulcerations of corticosteroid-induced striae[27].

Clinical Features

Striae are usually multiple, symmetric, well-defined, linear atrophic lesions that often follow the lines of cleavage. They are usually more of a cosmetic concern, but rarely can ulcerate. Initially, striae appear as red-to-violaceous elevated lines that can be mildly pruritic and are called striae rubrae (Fig. 99.5). Over time, the color gradually fades, and the lesions become atrophic, exhibiting a fine wrinkled appearance. These striae albae are usually permanent, but they may fade somewhat over time[25]. The striae can measure several centimeters in length and a few millimeters to a few centimeters in width.

During puberty, striae appear in areas where there is a rapid increase in size. In girls, the most common sites are the thighs, hips, buttocks and breasts, whereas in boys, they are seen on the shoulders, thighs, buttocks, and lumbosacral region[25] (Fig. 99.6). Other less common sites include the abdomen, upper arms, neck, and axillae.

Striae distensae are a common finding on the abdomen, and less so on the breasts and thighs, of pregnant women, especially during the last trimester. They are more common in younger primigravidas than in older pregnant women, in those who gained more weight during pregnancy, and/or those who had babies with a higher birth weight[26]. The development of striae gravidarum has been associated with an increased risk of laceration during vaginal delivery as well as subsequent pelvic relaxation and clinical prolapse[28,29].

The striae associated with systemic corticosteroid therapy and Cushing syndrome can be larger and more widely distributed (see Ch. 53). Flexural and intertriginous areas are particularly at risk for developing striae from the use of potent topical corticosteroids.

Atrophic striae may become elevated and "worm-like" in the setting of severe edema, including lymphedema. In polymorphic eruption of pregnancy, initial lesions often arise within striae gravidarum.

Pathology

Histologic findings are similar to those of scars and depend upon the stage of evolution of the striae at the time the biopsy is performed. The epidermis can be normal during the early stages, but eventually becomes atrophic with blunted rete ridges. The dermal thickness is decreased, as is the collagen in the upper dermis. The collagen bundles lie parallel to the epidermis. Alterations in elastic fibers are variable, but they can be fragmented, and specific elastin staining can demonstrate a marked reduction compared with adjacent normal dermis[30]. There is an absence of both hair follicles and other adnexal structures.

Differential Diagnosis

The diagnosis of striae distensae is usually straightforward, but the differential diagnosis does include linear focal elastosis (elastotic striae), an entity first described by Burket et al.[31] in 1989. Linear focal elastosis is characterized by rows of yellow, palpable, striae-like bands on the lower back. Unlike striae, the lesions are raised and yellow rather than depressed and white. Elderly men are most commonly affected. Histologically, there is a focal increase in the number of elongated or fragmented elastic fibers as well as a thickened dermis. It is postulated that linear focal elastosis may represent an excessive regenerative process of elastic fibers and could be viewed as a keloidal repair of striae distensae[32].

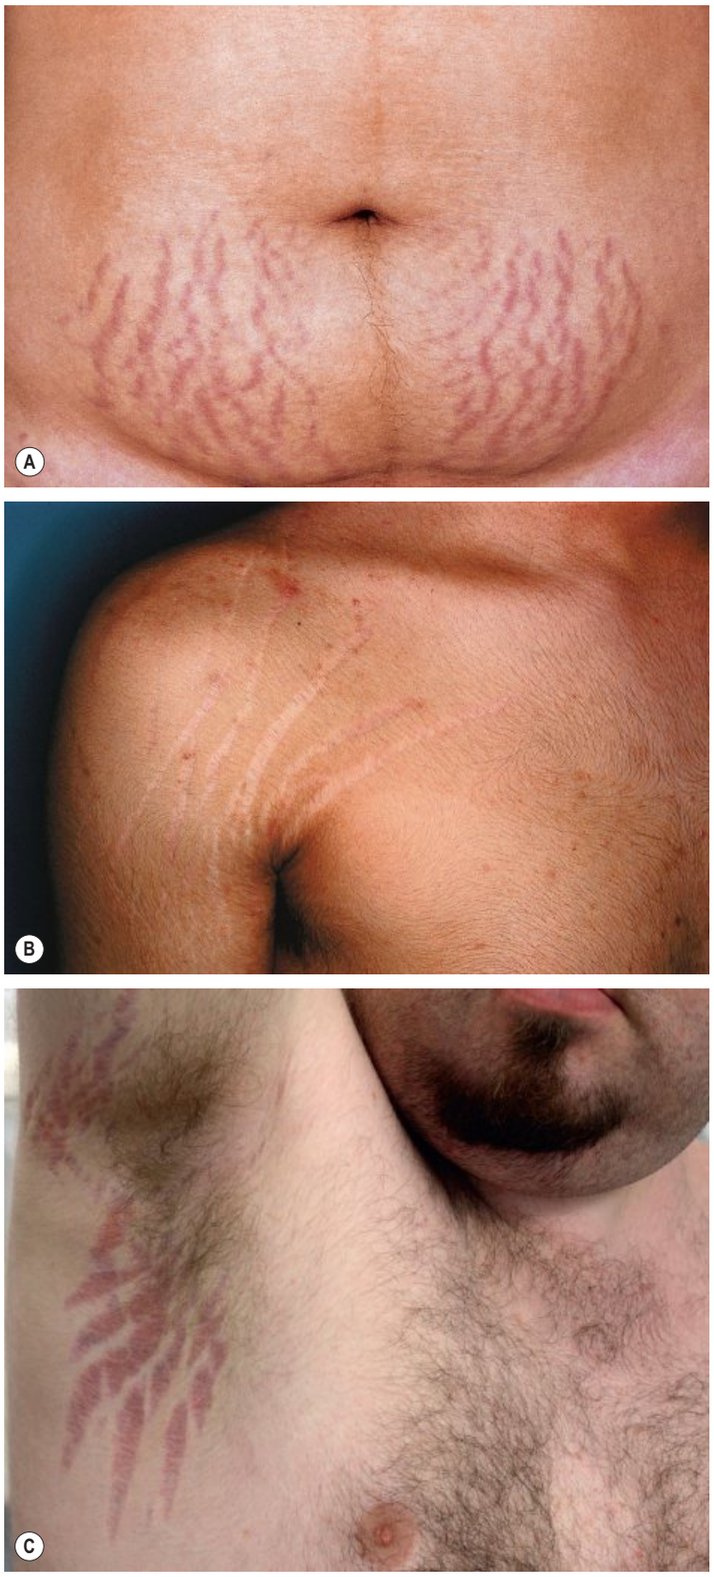

Fig. 99.5 Striae. A Linear erythematous lesions on the abdomen (striae rubrae). **B** Atrophic linear lesions of striae albae in a teenager. **C** Large axillary striae in a patient receiving chronic, high-dose systemic corticosteroids. *B, Courtesy Kalman Watsky, MD.*

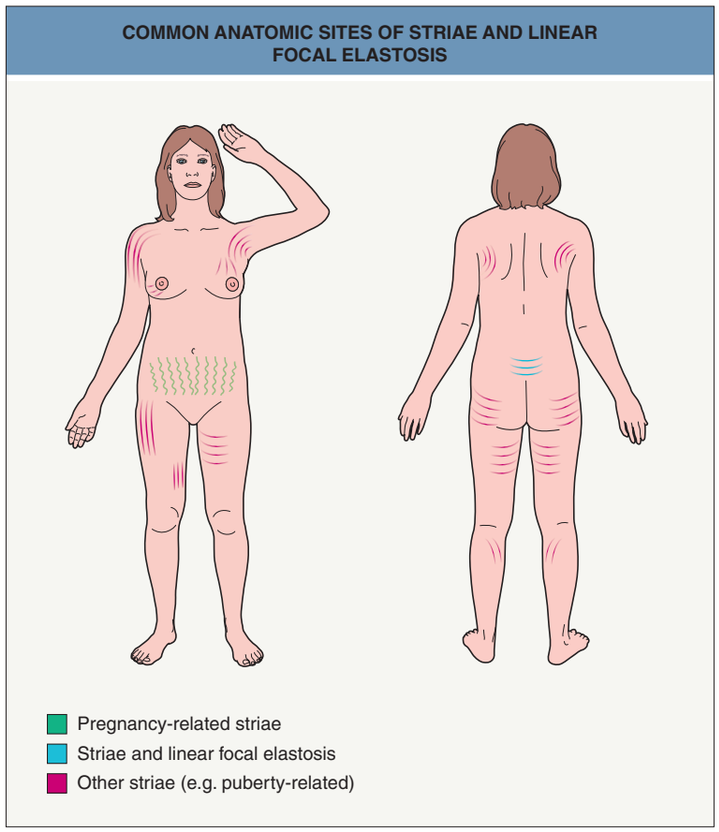

Fig. 99.6 Common anatomic sites of striae and linear focal elastosis. Striae associated with pregnancy are in green and lesions of linear focal elastosis are in blue.

Treatment

Striae distensae have no medical consequences, but they are frequently distressing to those afflicted. As striae tend to improve spontaneously over time, the value of anecdotal therapies without case controls is difficult to assess. Topical treatments that have shown some benefit in early-stage striae include tretinoin 0.1% cream[33] and a combination of 20% glycolic acid with either 0.05% tretinoin or 10% L-ascorbic acid[34]. The evidence for the effect of other topical treatments, either in prevention or treatment of striae, is inconclusive[34].

Several lasers have been used to treat striae: the 585 nm pulsed dye laser may improve the appearance of striae rubrae, but it has no effect on striae albae; secondary pigmentary alterations in darker skin are a potential complication[35]. Improvement of striae albae was noted with fractionated non-ablative lasers, presumably via neocollagenesis[36]. Use of radiofrequency and pulsed magnetic fields may also lead to improvement[37]. However, currently, there is no specific therapy that results in a complete response.

ATROPHODERMA OF PASINI AND PIERINI

Synonyms: ■ Idiopathic atrophoderma of Pasini and Pierini ■ Atrophoderma ■ Sclérodermie atrophique d'emblée ■ Morphea plana atrophica

Key features

- Depressed patches, usually on the posterior trunk and brown in color
- "Cliff-drop" or abrupt transition from normal to diseased skin
- Lesions are asymptomatic and lack induration
- Disorder lasts for many years but has a benign course

Introduction

Atrophoderma of Pasini and Pierini is a form of dermal atrophy that presents as one or more sharply demarcated depressed patches, usually on the back of adolescents or young adults. Whether atrophoderma represents an atypical, primarily atrophic form of morphea or "burnt-out" morphea or a separate distinct entity is still debated.

History

In 1923, Pasini described atrophic cutaneous lesions on the trunk of a 21-year-old woman that he referred to as progressive idiopathic atrophoderma[38]. In 1936, and over the subsequent years, Pierini and associates extensively studied and defined the condition and its possible link to morphea. This prompted Canizares et al.[39] in 1958 to rename this entity "idiopathic atrophoderma of Pasini and Pierini".

Epidemiology

This disorder is more frequently encountered in women than in men, with a ratio of 6:1 in adults[40]. It usually starts insidiously in young individuals during the second or third decade of life. However, a number of cases have been described in children younger than 13 years of age. More recently, rare congenital cases have been reported[41].

Pathogenesis

The etiology of atrophoderma of Pasini and Pierini remains as yet unknown. Some authors have suggested the possible role of *Borrelia burgdorferi* infection, as in acrodermatitis chronica atrophicans, since a positive serology can be found in up to 40%–50% of European patients[42]. However, false-positive results can occur, and results have varied widely. Given some overlap between atrophoderma and morphea, perhaps insights into the pathogenesis of the latter will provide clues to the former.

Clinical features

Lesions usually appear on the trunk, especially the back and lumbosacral region, followed in frequency by the chest, arms, and abdomen[42]. The face, hands, and feet are usually spared. The distribution is often symmetric and bilateral, but a linear pattern along the lines of Blaschko has been described (atrophoderma of Moulin; see Ch. 67).

The lesions are single or multiple and usually round or ovoid, ranging in size from a few centimeters to patches covering large areas of the trunk. They are usually asymptomatic and lack inflammation. When lesions coalesce, they can form large irregular patches. The patches usually have a brown color (Fig. 99.7), but some are blue to violet in color or occasionally hypopigmented[43]. The surface of the skin is normal in appearance, as is the consistency upon palpation. There is a lack of cutaneous induration or sclerosis.

The borders or edges of these lesions are sharply defined, and they are usually described as abrupt "cliff-drop" borders ranging from 1 to 8 mm in depth, although they can have a gradual slant and the depression may be subtle[39]. These depressed patches often give the impression of inverted plateaus, or, if multiple lesions are present, they can have the appearance of Swiss cheese. The lesions are even more apparent when present on the back, because the dermis is thicker in this area. Occasionally, dermal blood vessels are visible within the depressed patches.

The skin surrounding the patches is normal in appearance, and there is no erythema or lilac ring as in morphea. However, typical lesions of morphea, lichen sclerosus, and atrophoderma have been observed to occur simultaneously in the same patient (but in different areas), supporting the view that these conditions are related[44]. In addition, sclerodermatous changes can occasionally appear years later in the center of the depressed lesions, leading to a white, shiny induration[39]. In a series of 139 patients, 17% had a white induration in the central portions of their atrophic lesions, and, in 22%, superficial plaques of morphea coexisted in sites separate from the atrophic foci[40].

The course of this benign disease is progressive, and lesions can continue to appear for decades before reaching a standstill. Transformation to generalized morphea has not been observed.

Pathology

In general, the histologic picture is not diagnostic, so the diagnosis is primarily a clinical one. The epidermis is usually normal or slightly atrophic. Pigmentation of the basal layer may be increased. A perivascular infiltrate consisting of T cells and histiocytes may be seen. Collagen bundles in the reticular dermis show varying degrees of homogenization and clumping. Dermal thickness is reduced when compared with adjacent normal skin[45]. Dermal atrophy is difficult to evaluate on a punch biopsy, but it can be more easily demonstrated if an elliptical biopsy is taken in an area that includes the cliff-drop border and is then sectioned longitudinally to show the transition between normal and lesional skin.

Fig. 99.7 Atrophoderma of Pasini and Pierini. **A, B** Multiple light brown patches on the back; note the subtle depression of the lesions with a "cliff-drop" edge. In A, dermal blood vessels are easily seen within a few patches; the white papule is a healed biopsy site. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Catherine C. McCuaig, MD.*

In most series, no abnormality has been observed with elastic tissue stains[40,42]; however, a retrospective study described a spectrum of changes, ranging from normal to severe diminution and fragmentation of the elastic fiber network[43]. The adnexal structures are usually preserved. If sclerodermatous changes appear within pre-existing lesions, varying degrees of collagen sclerosis resembling morphea can be seen. Of note, evaluation of collagen and elastic fibers by multiphoton microscopy has suggested that the atrophic appearance of atrophoderma reflects changes in the organization of collagen and elastic fibers, not a variation in their content[46].

Direct immunofluorescence may show nonspecific IgM and C3 staining in the dermal papillary blood vessels in early lesions or at the dermal–epidermal junction[47].

Differential diagnosis

Since the original description, there has been much discussion over whether atrophoderma of Pasini and Pierini is a distinct entity or an atrophic, non-indurated, perhaps "burnt-out" variant of morphea (see Ch. 44). Active lesions of morphea present as indurated, often hyperpigmented plaques with a characteristic peripheral lilac rim.

Although atrophoderma of Pasini and Pierini lacks sclerosis[40,42,44,47], its relationship to morphea is favored by its striking clinical and

histologic similarities to the atrophy seen at sites of regressing plaques of morphea. To some, the different course and outcome of atrophoderma of Pierini and Pasini as compared with morphea justifies preservation of a distinct name.

Anetoderma, also an atrophic dermal process, is easily differentiated by palpation and histology, which consistently shows a loss of elastic fibers in the dermis (as opposed to a loss of collagen).

Treatment

The natural course of the disease is often protracted (10–20 years) but self-healing, making evaluation of therapy difficult. No treatment has been proven effective. In view of the possibility of underlying *Borrelia* infection, penicillin and doxycycline have been used to treat atrophoderma of Pasini and Pierini, but the results have been variable[42,48]. A dramatic response to oral hydroxychloroquine was reported in one patient[49], and Q-switched alexandrite laser may diminish the associated hyperpigmentation[50].

FOLLICULAR ATROPHODERMA

Follicular atrophoderma refers to dimple-like depressions at the follicular orifices. It can occur as an isolated defect of limited extent, in association with a variety of disorders in which hair follicles are plugged with keratin, or with rare genodermatoses.

In 1944, Miescher described follicular atrophoderma in an 8-year-old girl with atypical chondrodystrophy[51]. Six years later, Curth also used the term follicular atrophoderma (although there was no evidence of follicular atrophy but rather follicular agenesis) and further reported in 1978 on the genetics of follicular atrophoderma[52].

Clinical features

Distinctive follicular ice-pick depressions can be seen most commonly on the back of the hands and feet or on the cheeks. These pitted scars are often present at birth or appear during childhood. A family history may be present. Follicular atrophoderma can be associated with Bazex–Dupré–Christol and Conradi–Hünermann–Happle syndromes. When the lesions are found exclusively on the cheeks, the term "atrophoderma vermiculatum" applies. Atrophoderma vermiculatum can in turn be associated with various disorders discussed in the next section.

Atrophoderma Vermiculatum

Atrophoderma vermiculatum, a disorder limited to the face, has been described under a variety of names, including ulerythema acneiforme, acne vermoulante, atrophoderma reticulata symmetrica faciei, folliculitis ulerythema reticulata, folliculitis ulerythemosa, and honeycomb atrophy ("ulerythema" means scar plus redness and "vermiculatum" means worm-eaten).

Atrophoderma vermiculatum may: (1) occur sporadically; (2) be inherited as an autosomal dominant disorder; (3) be part of a group of related diseases that are referred to as "keratosis pilaris atrophicans" (see Table 38.2); or (4) be associated with various syndromes.

Multiple symmetric inflammatory papules on the cheeks, presumably centered around hair follicles, may precede the atrophic lesions. These papules then go on to become pitted, atrophic, depressed scars in a reticulated or honeycomb pattern (Fig. 99.8). The severity of erythema varies, as does the presence of milia and horny follicular plugs. Lesions can extend to the forehead and preauricular regions. Onset is usually in childhood or, less often, around puberty. Both sexes appear to be equally affected[53], and it usually has a slowly progressive course.

Atrophoderma vermiculatum can be associated with a group of closely related disorders referred to as keratosis pilaris atrophicans (see Table 38.2)[54]. This group also includes keratosis follicularis spinulosa decalvans and ulerythema ophryogenes. These conditions are characterized by keratotic follicular papules, variable degrees of inflammation, and secondary atrophic scarring. Ulerythema ophryogenes (or keratosis pilaris atrophicans faciei) differs from atrophoderma vermiculatum by affecting primarily the lateral portion of the eyebrows (ophryogenes) in the form of erythema, follicular papules, and alopecia. The inheritance pattern is autosomal dominant with incomplete penetrance and occasionally autosomal recessive, with progression usually ceasing after puberty. Keratosis follicularis spinulosa decalvans begins during childhood as keratotic follicular papules on the malar area and progresses to involve the eyebrows, scalp, and extremities, with associated scarring alopecia. In most patients, this disorder is inherited in an X-linked recessive fashion.

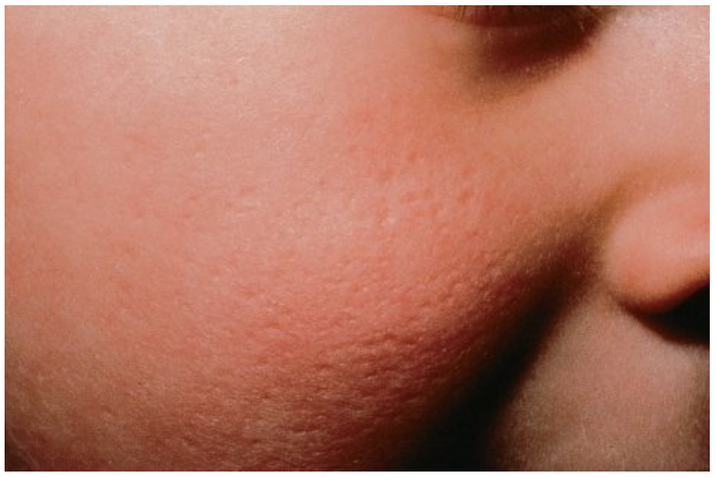

Fig. 99.8 Atrophoderma vermiculatum. Multiple small pitted scars on the cheek of a young girl. Note the honeycomb pattern on the lower inner cheek; the skin is said to appear "worm-eaten". *Courtesy Robert Hartman, MD.*

The underlying pathogenesis in atrophoderma vermiculatum as well as the other disorders in the keratosis pilaris atrophicans group appears to be abnormal follicular hyperkeratinization. The latter occurs in the upper third of the hair follicle, leading to obstruction of the growing hair shaft and production of chronic inflammation. The end result is scarring below the level of obstruction.

Histopathology is usually not very helpful and shows dilated follicles, sometimes associated with plugging, inflammation, and sclerosis of dermal collagen.

Syndromes associated with atrophoderma vermiculatum include Rombo syndrome (milia, telangiectasias, basal cell carcinomas [BCCs], hypotrichosis, acrocyanosis, and, occasionally, trichoepitheliomas) and Loeys–Dietz syndrome (see Ch. 95), in addition to the less well characterized Nicolau–Balus syndrome (syringomas and milia), Tuzun syndrome, and Braun–Falco–Marghescu syndrome (congenital poikiloderma).

The differential diagnosis of atrophoderma vermiculatum includes atrophia maculosa varioliformis cutis, keratosis pilaris rubra of the cheeks, and, in older adults, erythromelanosis faciei.

This disorder is primarily a cosmetic problem. Various topical treatments, including emollients, corticosteroids, tretinoin and keratolytics, have shown no consistent benefit. In some instances, systemic isotretinoin has been shown to stop progression and to induce remission[54]. Dermabrasion, laser therapy (e.g. CO_2, 585 nm pulsed dye), and fillers (e.g. hyaluronic acid, autologous fat) are other options for improving the appearance of the atrophic scars[55].

Bazex–Dupré–Christol Syndrome

Bazex, Dupré and Christol first described this genodermatosis in 1964, not to be confused with Bazex syndrome (acrokeratosis paraneoplastica) in which hyperkeratotic plaques of the ears, nose, cheeks, hands, feet and knees are associated with carcinomas of the upper aerodigestive tract (see Ch. 53). Bazex–Dupré–Christol syndrome is characterized by follicular atrophoderma, milia, multiple BCCs, hypotrichosis, and localized hypohidrosis (above the neck)[56]. It is inherited in an X-linked dominant fashion, and the gene has been linked to Xq24–q27[57]. Additional reported findings include facial hyperpigmentation, hair shaft anomalies, and multiple trichoepitheliomas. Systemic manifestations are absent. Recently, it was suggested that this syndrome might better be classified as an ectodermal dysplasia[58].

The follicular atrophoderma, described as multiple ice-pick marks or patulous follicles, is found most commonly on the dorsal aspect of the hands, but can also be seen on the feet, lower back, elbows, and occasionally the face; it may be present at birth or appear later during childhood. No abnormalities of the elastic fibers have been found (nor any evidence of atrophy of the epidermis, hair or dermis), making the term "follicular atrophoderma" a misnomer. The histopathology usually

shows hair follicles that are abnormally wide, plugged, and surrounded by an inflammatory cell infiltrate and clusters of basaloid cells. Sweat glands can be absent.

BCCs develop in about 40% of patients (primarily on the face) and can resemble melanocytic nevi; the age of onset varies from 9 to 50 years of age. To date, ~20 families with this syndrome have been described.

The differential diagnosis includes other genodermatoses with multiple BCCs: basal cell nevus syndrome (Gorlin syndrome), an autosomal dominant disorder most commonly due to mutations in *PTCH1* (see Ch. 108); Rombo syndrome, an autosomal dominant disorder characterized by BCCs, atrophoderma vermiculatum, milia, hypotrichosis, acrocyanosis, and, occasionally, trichoepitheliomas; and xeroderma pigmentosum (see Ch. 86).

Conradi–Hünermann–Happle Syndrome (X-Linked Dominant Chondrodysplasia Punctata, CDPX2)

Conradi–Hünermann–Happle syndrome is an X-linked dominant disorder that occurs almost exclusively in girls, since it is usually lethal in hemizygous males. This form of chondrodysplasia punctata results from mosaicism for mutations in the gene on the X chromosome that encodes the emopamil-binding protein[59,60]. The clinical manifestations include ichthyosiform streaks (composed of erythema plus feathery, adherent scale) patterned along the lines of Blaschko; they usually resolve during the first year of life and are replaced by bands of follicular atrophoderma[60]. Hyperpigmentation, cataracts, scarring alopecia, saddle-nose deformity, asymmetric limb reduction defects, and stippled calcifications of the epiphyses are additional manifestations (see Ch. 57). Within the ichthyosiform areas in newborns, keratotic follicular plugs containing dystrophic calcification is a distinctive histopathologic feature[59].

ATROPHIA MACULOSA VARIOLIFORMIS CUTIS

Atrophia maculosa varioliformis cutis was first described by Heidingsfeld in 1918[61] and is not as rare as the number of published cases would suggest. It consists of small round "varioliform" and linear facial depressions that are asymptomatic (Fig. 99.9)[62]. It occurs spontaneously on the cheeks and occasionally involves the forehead or chin. There is a gradual increase in the number of lesions, but in the absence of preceding trauma, acne, or inflammatory lesions. A familial variant has been described. Pachydermodactyly and extrahepatic biliary atresia have been associated findings, but this association is probably fortuitous. The pathogenesis is unknown.

The histologic changes include a depression of the epidermis and normal collagen fibers, but a slightly decreased number of elastic fibers. There is usually little or no inflammation. The differential diagnosis includes simple scars, which can be differentiated by history and the presence histologically of dermal fibrosis, and atrophoderma vermiculatum. The latter is harder to differentiate, but it can present with inflammatory papules that are followed by pitted scars, and atrophoderma vermiculatum usually has a honeycombed (rather than sharply linear) pattern and is usually centered on hair follicles. There is no known treatment to prevent the occurrence of these lesions.

PIEZOGENIC PEDAL PAPULES (PIEZOGENIC PAPULES)

Piezogenic pedal papules were first described by Shelley and Rawnsley in 1968[63]. This term is somewhat of a misnomer as piezogenic means "producing pressure", when in fact these lesions are produced by pressure. It is postulated that pressure induces herniation of fat through connective tissue in the dermis of the heels.

These papules are common enough in the general population to be considered normal and have also been described in association with Ehlers–Danlos syndrome, Prader–Willi syndrome, and GATA2 deficiency[64]. An infantile variant characterized by larger nodules on the medial aspect of the heel (present without weight-bearing) has been described[65] and is referred to as pedal papules of infancy and more recently, precalcaneal congenital fibrolipomatous hamartoma (Fig. 99.10). When unilateral, this entity has to be distinguished from juvenile aponeurotic fibroma which can calcify.

Skin-colored papules and nodules are seen on the sides of the heels (Fig. 99.11); they are induced by weight-bearing and disappear when the leg is

raised. The lesions are usually asymptomatic, but pain has been described during weight-bearing, and, in these cases, an orthopedic shoe or surgical excision may help. Similar lesions have been described on the wrists[66].

OTHER ATROPHIES OF THE CONNECTIVE TISSUE

Many systemic conditions (lupus erythematosus, dermatomyositis) and genodermatoses (Rothmund–Thomson syndrome, dyskeratosis congenita, Cockayne syndrome, Hallermann–Streiff syndrome) have cutaneous atrophy (epidermal, dermal, and/or subcutaneous) as an associated finding. Lichen sclerosus is discussed in Chapter 44, progeria in Chapter 63, Ehlers–Danlos syndrome and cutis laxa in Chapter 97, and acrodermatosis chronica atrophicans in Chapter 74. Cutaneous atrophy is also a well-known complication of prolonged use of either systemic or topical corticosteroids (see Ch. 125).

Unusual or Newly Described Forms of Panniculitis *1771*

INTRODUCTION

Panniculitis is a diagnostically challenging arena for both dermatologists and pathologists. Terminology is difficult, partly because various names have been applied to the same disorder (e.g. nodular vasculitis and erythema induratum), and partly because new discoveries have resulted in the introduction of new terms and the abandonment of others. From a clinical standpoint, many forms of panniculitis with diverse etiologies closely resemble one another, presenting as tender, erythematous, subcutaneous nodules. Some panniculitides can be a manifestation of different disease processes (erythema nodosum is the classic example), and, even if the type of panniculitis is correctly identified, this is only the first step in a series of investigations required to determine the underlying cause. From a pathologic standpoint, the subcutaneous fat responds to a variety of different insults in a limited number of ways, and, therefore, histopathologic differences among the various forms of panniculitis may be subtle. Management can also be difficult, since there are often at least two therapeutic desiderata:

- specific treatment of the panniculitis
- treatment of the underlying illness.

In this chapter, these issues will be addressed by introducing a schema for the classification of these disorders, recommending an approach to the histopathologic diagnosis, and providing information about the specific forms of panniculitis and their management. The categories are determined partly by clinical characteristics such as anatomic location (Fig. 100.1), partly by histopathology (Fig. 100.2), and partly by etiology. A word should be said about *septal* versus *lobular* panniculitis. These are largely artificial constructs, since there is no purely septal or purely lobular panniculitis.

Table 100.1 provides an approach to the histopathologic diagnosis of an unknown case of panniculitis. When performing a biopsy in a patient with panniculitis, it is absolutely critical that the specimen includes a generous portion of subcutaneous fat. Therefore, excisional biopsies extending through the subcutis or narrow incisional biopsies that incorporate a broad expanse of subcutaneous fat are preferable to punch biopsies.

ERYTHEMA NODOSUM

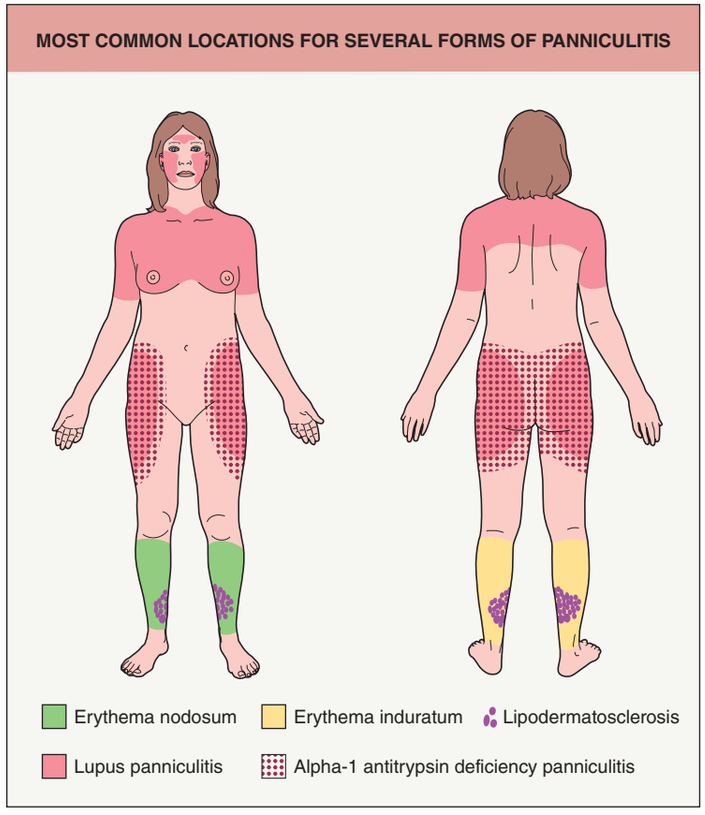
Synonyms: ■ Erythema contusiformis ■ Erythema nodosum migrans (variant form)

Key features

- Tender, erythematous, subcutaneous nodules
- Usually distributed symmetrically and favor the pretibial areas; occasionally occur elsewhere
- In later stages, lesions acquire a bruise-like appearance
- May be accompanied by fever, arthralgias, and malaise
- Associated with a wide variety of systemic disorders

Introduction

Erythema nodosum is the best known of the various forms of panniculitis, as well as the most common. It typically presents as an acute eruption of tender, erythematous, subcutaneous nodules in the pretibial areas bilaterally. It is widely regarded as a delayed hypersensitivity response to a variety of antigenic challenges[1], although the mechanisms of its development are more complex than this statement would indicate. Histopathologically, it is the prototype of a "septal"



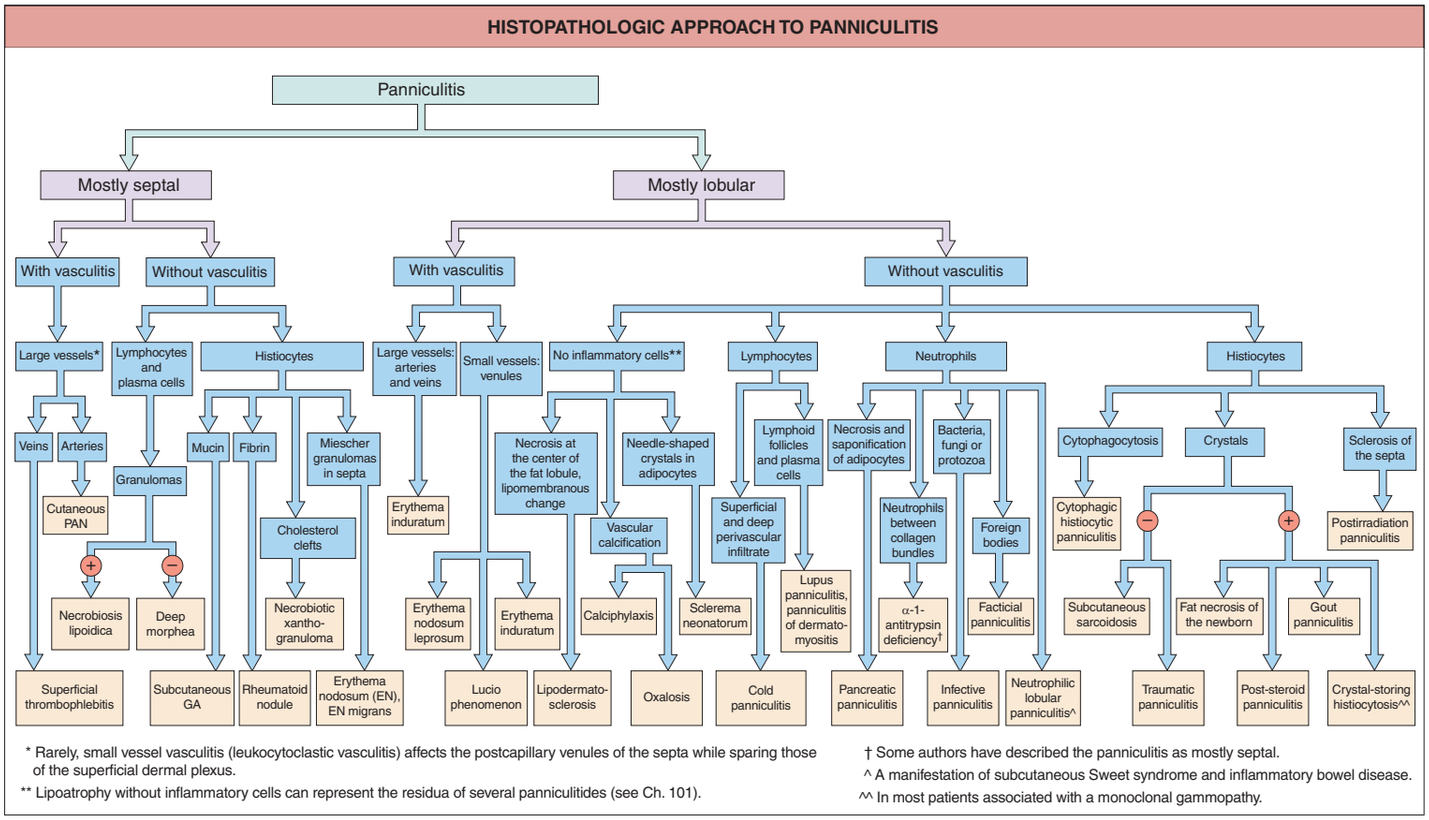


Fig. 100.1 Most common locations for several forms of panniculitis. Classification of panniculitis depends upon multiple factors, including clinical characteristics such as location and ulceration as well as histopathology and etiology.

* Rarely, small vessel vasculitis (leukocytoclastic vasculitis) affects the postcapillary venules of the septa while sparing those of the superficial dermal plexus.

** Lipoatrophy without inflammatory cells can represent the residua of several panniculitides (see Ch. 101).

† Some authors have described the panniculitis as mostly septal.

^ A manifestation of subcutaneous Sweet syndrome and inflammatory bowel disease.

^^ In most patients associated with a monoclonal gammopathy.

Fig. 100.2 Histopathologic approach to panniculitis. Drug-induced panniculitis can be primarily septal or lobular and is reviewed in Table 100.3. Leukemia cutis or lymphoma cutis may mimic panniculitis as in subcutaneous panniculitis-like T cell lymphoma, and the subcutaneous nodules observed in ANCA-associated vasculitides can contain extravascular necrotizing granulomas. GA, granuloma annulare; PAN, polyarteritis nodosa.

AN APPROACH TO THE HISTOPATHOLOGIC DIAGNOSIS OF PANNICULITIS	
Histopathologic aspects to consider	**Conclusions**
Look for the "center of gravity" of the infiltrate	Recommended originally by Pinkus, the purpose is to determine whether or not the inflammatory process is centered in the subcutis (favoring a primary panniculitis), in the dermis, or in the fascia (in which case the panniculitis may be a secondary manifestation of a deeper inflammatory process)
Determine if the panniculitis is predominantly septal, predominantly lobular, or mixed	Generally, a predominantly septal panniculitis narrows the diagnostic considerations. If the panniculitis is lobular or mixed, look for other distinguishing features (see Fig. 100.2)
Determine if there is vasculitis involving a medium-sized vessel, in the face of a lobular or mixed panniculitis	This is characteristic of **erythema induratum (nodular vasculitis)**; caveat: deeper levels are often required in order to demonstrate the involvement of vessels
Look for fat necrosis with saponification and "calcium soap" formation	This is a feature of **pancreatic panniculitis**
Look for needle-shaped clefts within lipocytes	Their presence favors a diagnosis of **sclerema neonatorum, subcutaneous fat necrosis of the newborn**, or **post-steroid panniculitis**
Determine if the panniculitis has a lymphoplasmacytic predominance	This tends to be a feature of **panniculitis due to connective tissue disease**, including lupus erythematosus; beware of lymphocytic predominance in cases of subcutaneous panniculitis-like T cell lymphoma (see Table 100.9)
Check for a "central nidus" of inflammation or evidence of a needlestick injury. Look for vacuolated spaces or foreign material	These are clues to **traumatic panniculitis including factitial panniculitis**. Polarization microscopy can be helpful
Determine if lobular panniculitis has a predominance of neutrophils	**Infection-induced panniculitis, neutrophilic panniculitis** associated with inflammatory bowel disease and rheumatoid arthritis, **subcutaneous Sweet syndrome, traumatic panniculitis, drug-induced panniculitis** (see Table 100.3), **idiopathic neutrophilic lobular panniculitis**; less so in alpha-1 antitrypsin deficiency panniculitis and pancreatic panniculitis
Look for membranocystic changes in the subcutis	This change is characteristic of (though not pathognomonic for) **lipodermatosclerosis**; it can be observed in any panniculitis with prominent degenerative changes
Determine if the panniculitis is associated with substantial cellular necrosis, vascular proliferation, hemorrhage, sweat gland necrosis, or neutrophilic aggregates	These changes are often encountered in **infection-induced panniculitis**. Tissue cultures, special stains, and PCR for organisms may be indicated
Determine if the infiltrating cells are particularly monotonous or atypical in appearance	Consider subcutaneous panniculitis-like T cell lymphoma and other lymphomas with involvement of the subcutaneous fat. Rarely, non-hematologic malignancies mimic panniculitis. Immunohistochemical stains are mandatory for a precise diagnosis
Determine if there are large cells with cytophagic activity	Cytophagic activity (hemophagocytosis) observed primarily in subcutaneous infiltrates of subcutaneous panniculitis-like T cell lymphoma and subcutaneous lesions of primary cutaneous γ/δ T cell lymphoma. This finding was previously termed "cytophagic histiocytic panniculitis"

Table 100.1 An approach to the histopathologic diagnosis of panniculitis.

panniculitis. Identification and treatment of the underlying disorder, if found, is of primary importance, but therapy directed toward the lesions themselves is also an option, especially when idiopathic.

History

At the beginning of the eighteenth century, Robert Willan gave the first clear description of erythema nodosum, and he provided its name in his famous work, *On Cutaneous Disease*[2].

Epidemiology

Erythema nodosum can occur at any age, in both sexes, and in all racial groups. It is more common among women and is more frequently observed during the second through fourth decades of life[3,4]. The relative ranking of underlying causes may vary according to geographic location; for example, in areas where *Coccidioides immitis* is endemic or regions where Behçet disease is more prevalent.

Pathogenesis

Erythema nodosum has been considered a delayed hypersensitivity response to a variety of antigenic stimuli, including bacteria, viruses, and chemical agents[1]. Llorente et al.[5] observed expression of mRNA for Th1 cytokines (interferon-γ, interleukin-2) in the skin lesions and peripheral blood of patients with erythema nodosum, and a Th1 pattern of cytokine synthesis is associated with delayed-type hypersensitivity reactions. However, a complex series of intermediate steps is involved in the development of these lesions. A variety of adhesion molecules and inflammatory mediators appear to be associated with erythema nodosum. For example, in erythema nodosum lesions, vascular cell adhesion molecule-1 (VCAM-1; CD106), platelet endothelial cell adhesion molecule-1 (PECAM-1; CD31), HLA-DR, and E-selectin are expressed on endothelial cells, while very late antigen-4 (VLA-4), L-selectin, and HLA-DR are expressed by inflammatory cells (see Ch. 102)[6].

Neutrophils are often numerous in early lesions, and it has been shown that a higher percentage of circulating neutrophils in patients with erythema nodosum leads to the production of reactive oxygen intermediates; these intermediates, in turn, may provoke inflammation and tissue damage[7]. Support for a pathogenic role for these cells and molecules is provided by studies on the effects of colchicine[8]. This inhibitor of neutrophil chemotaxis has been shown to diminish L-selectin expression on the neutrophil surface, inhibit E-selectin-mediated endothelial adhesiveness for neutrophils, and diminish stimulated expression of ICAM-1 on the endothelium[6].

Additional indirect evidence for the role of inflammatory cells and mediators includes reports of erythema nodosum following treatment with granulocyte colony-stimulating factor[9], and improvement (as well as flares) of erythema nodosum lesions with administration of tumor necrosis factor (TNF) inhibitors[10]. Erythema nodosum, especially in its chronic phase, is characterized by granuloma formation and TNF is known to play a role in granuloma formation. A link between deregulation of TNF production and granuloma formation is further supported by the strong correlation of a polymorphism in the promoter region of the gene that encodes TNF and the development of sarcoidosis-associated erythema nodosum[11].

A wide range of precipitating factors has been linked with erythema nodosum. Infectious causes are common, particularly upper respiratory infections (both streptococcal and non-streptococcal). Other commonly reported causes are listed in Tables 100.2 and 100.3[3,4,12].

Clinical Features

Erythema nodosum presents with bilateral, tender, erythematous nodules. These arise in crops and clearly the most common site is the shins (Fig. 100.3). Other locations are occasionally involved, particularly the thighs and forearms[3]. Nodules may also appear on the trunk, neck, and face[2], but this is sufficiently rare that development of lesions in these locations should prompt consideration of other diagnoses. Unlike other forms of panniculitis, ulceration is not a feature of erythema nodosum. Systemic symptoms may occur that are not necessarily related to a specific coexisting systemic disorder; these include arthritis, arthralgia, fever, and malaise[2].

Because of its close association with a variety of disorders and infections, erythema nodosum is an important skin sign of systemic disease.

CAUSES OF ERYTHEMA NODOSUM

Cause	Comments
Most common	
Idiopathic	Still the largest single category, accounting for a third to a half of cases
Streptococcal infections, especially of the upper respiratory tract	The largest single infectious cause
Other infections: Viral upper respiratory tract infections Bacterial gastroenteritis – *Yersinia* > *Salmonella, Campylobacter*	Overall, infection may account for a third or more of cases
Coccidioidomycosis	Erythema nodosum is associated with a lower incidence of disseminated disease
Drugs	See Table 100.3
Sarcoidosis*	10%–20% of cases in some series
Inflammatory bowel disease	Crohn disease has a stronger association with erythema nodosum than does ulcerative colitis
Uncommon	
Infections: *Brucella melitensis* *Chlamydophila*† *pneumoniae* *Chlamydia trachomatis* *Mycoplasma pneumoniae* *Mycobacterium tuberculosis* *Histoplasma capsulatum* Hepatitis B virus‡	
Neutrophilic dermatoses: Behçet disease Sweet syndrome	"Erythema nodosum" in Behçet disease more closely resembles erythema induratum (nodular vasculitis)
Acne fulminans, including isotretinoin-associated	
Pregnancy	
Rare	
Granulomatous mastitis	
Pernicious anemia	
Diverticulitis	
Infections: *Neisseria gonorrhoeae, N. meningitides* *Escherichia coli, Bartonella henselae, Bordetella pertussis* *Treponema pallidum* Dermatophytes (kerion), *Blastomyces dermatitidis* HIV COVID-19 Giardiasis, amoebiasis (abscesses)	*Erythema nodosum leprosum* is a different disease that is characterized by a cutaneous small vessel vasculitis
MonoMAC syndrome (*GATA2* mutations)	
Malignancy, most often acute myelogenous leukemia, Hodgkin disease	May overlap with Sweet syndrome
Lupus erythematosus	One of several forms of panniculitis reported in LE, in addition to lupus panniculitis

*Löfgren syndrome is an acute, spontaneously resolving form of sarcoidosis characterized by erythema nodosum, hilar lymphadenopathy, fever, polyarthritis and uveitis.
†Previously referred to as *Chlamydia*.
‡Erythema nodosum secondary to the hepatitis B vaccine has also been reported.

Table 100.2 Causes of erythema nodosum. LE, lupus erythematosus; TNF, tumor necrosis factor.

For example, its development may precede or accompany a flare of inflammatory bowel disease. It may also have some value as a prognostic indicator in certain disorders. For example, erythema nodosum is associated with a protective effect against disseminated disease in patients with coccidioidomycosis, and it is closely aligned with a more benign and self-limited form of sarcoidosis[1]. Nevertheless, a significant percentage of cases – more than one-third – have no known disease association, even when followed for a year or more[4]. Clinical or laboratory data that tend to predict that the development of erythema nodosum may be secondary to a systemic disease are listed in Table 100.4.

Erythema nodosum lesions usually last a few days or weeks and then slowly involute, without scar formation. Discoloration suggestive of a bruise may be seen as the erythema subsides. More chronic forms do occur, some of which show a tendency toward migration or centrifugal spread; the latter have been termed *subacute nodular migratory panniculitis* or *erythema nodosum migrans* (see below). Up to one-third of cases of erythema nodosum recur. Annual recurrences are particularly common among idiopathic cases[12].

DRUG-INDUCED PANNICULITIS	
Drug	**Histopathologic patterns**
Estrogens, oral contraceptive pills	EN-like
Antibiotics (e.g. sulfonamides, penicillins)	EN-like
Bromides, iodides	EN-like
TNF inhibitors (e.g. etanercept, infliximab, adalimumab)	EN-like, lupus-like
Immune checkpoint inhibitors (e.g. ipilimumab, nivolumab, pembrolizumab)	EN-like, granulomatous/ sarcoid-like
BRAF inhibitors (e.g. vemurafenib, dabrafenib)	EN-like, neutrophilic lobular
Tyrosine kinase inhibitors (e.g. imatinib, dasatinib, ibrutinib)	EN-like, neutrophilic lobular
Hypomethylating agents (e.g. azacitidine, decitabine, guadecitabine)	Neutrophilic lobular
Bruton's tyrosine kinase (BTK) inhibitors (e.g. ibrutinib, acalabrutinib, zanubrutinib)	Neutrophilic lobular
Gemcitabine	Lipodermatosclerosis-like

Table 100.3 Drug-induced panniculitis. Lesions can develop at multiple sites and is to be distinguished from panniculitis that can develop at sites of injection of medications, e.g. glatiramer acetate, interferon-β, phytonadione (vitamin K), interleukin-2, heparin (eosinophilic panniculitis), pentazocine, vaccines (e.g. tetanus). Additional causes of multiple lesions include G-CSF, nonsteroidal anti-inflammatory drugs (NSAIDs), abatacept, carbamezapine, and leukotriene and proton pump inhibitors. EN, erythema nodosum; TNF, tumor necrosis factor.

Pathology

Erythema nodosum is the prototypic septal panniculitis (Fig. 100.4), but this should not be taken to imply that histopathologic changes are entirely confined to subcutaneous septa[13]. Biopsy specimens of early lesions tend to show edematous septa and mild lymphocytic infiltrates. Of note, neutrophils may predominate in early lesions[6], and a variant with a predominance of eosinophils has been reported[14]. True vasculitis of the type seen in leukocytoclastic vasculitis is not observed, and erythema nodosum is not generally regarded as a vasculitic process. However, "secondary" vasculitis may be observed in lesions when they contain relatively heavy, mixed, or neutrophil-rich inflammatory infiltrates. Erythema nodosum-like lesions in Behçet disease may demonstrate leukocytoclastic or lymphocytic vasculitis involving subcutaneous venules or muscular veins; the latter changes are prone to occur in patients with more severe forms of Behçet disease[15].

In early lesions, one may also find Miescher microgranulomas, a characteristic if not pathognomonic feature of erythema nodosum. These are small collections of cells (macrophages or perhaps "histiocytoid cells" [neutrophil precursors]) that are found within septa or at a septal–lobular interface and tend to surround neutrophils or small cleft-like spaces[16]. Reported variations in the frequency of these granulomas in erythema nodosum[2,16] may result in part from differences in definition, in the acceptance of subtle changes, and in the rigor of the search. In older lesions, Miescher microgranulomas may feature epithelioid and multinucleated giant cells (Fig. 100.4, inset).

As lesions progress, the septa become widened and contain a mixed, partly granulomatous infiltrate. These cells infiltrate the periphery of fat lobules in a lace-like configuration. The extent of lobular involvement may vary, and in some cases can be prominent[6]. Nevertheless, in the case of a lobular panniculitis without the characteristic septal changes, a diagnosis of erythema nodosum should be made with caution.

FINDINGS SUGGESTIVE OF A SYSTEMIC CAUSE FOR ERYTHEMA NODOSUM
• Synovitis • Diarrhea* • Abnormal chest X-ray • Preceding upper respiratory tract infection • Elevated antistreptolysin O and/or anti-DNase B titers • Positive tuberculin skin test or interferon-gamma release assay (e.g. QuantiFERON-TB Gold In-Tube Plus, T-SPOT.TB test)
*Check for fecal blood and white blood cells; stool culture for bacteria and, if indicated, ova and parasites; fecal calprotectin.

Table 100.4 Findings suggestive of a systemic cause for erythema nodosum. Additional evaluation can include viral hepatitis panel and, in women of child-bearing age, serum β-human chorionic gonadotropin.

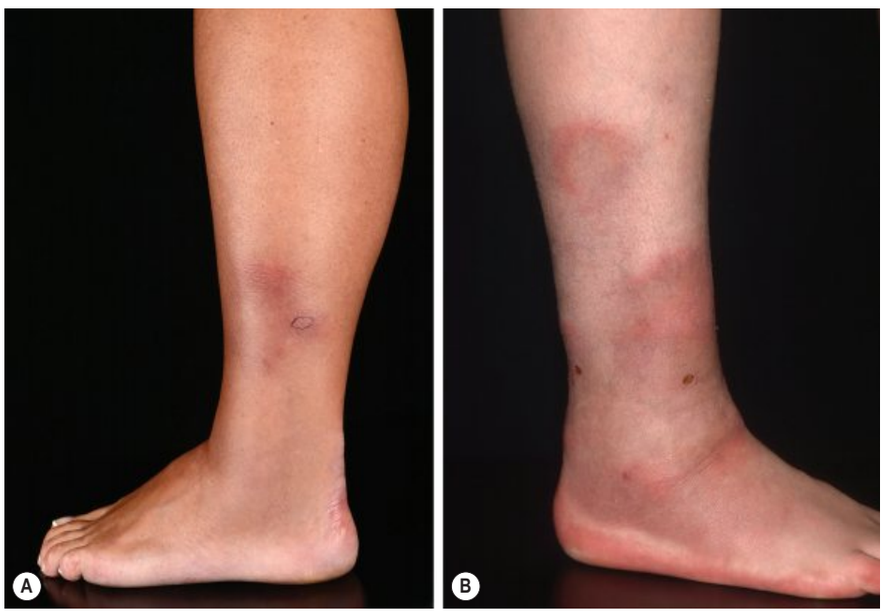

Fig. 100.3 Erythema nodosum – clinical appearance. A Cluster of dull red–brown, tender nodules on the lower leg. **B** The plaques may develop an arciform configuration and bruise-like appearance. *Courtesy Lorenzo Cerrroni, MD.*

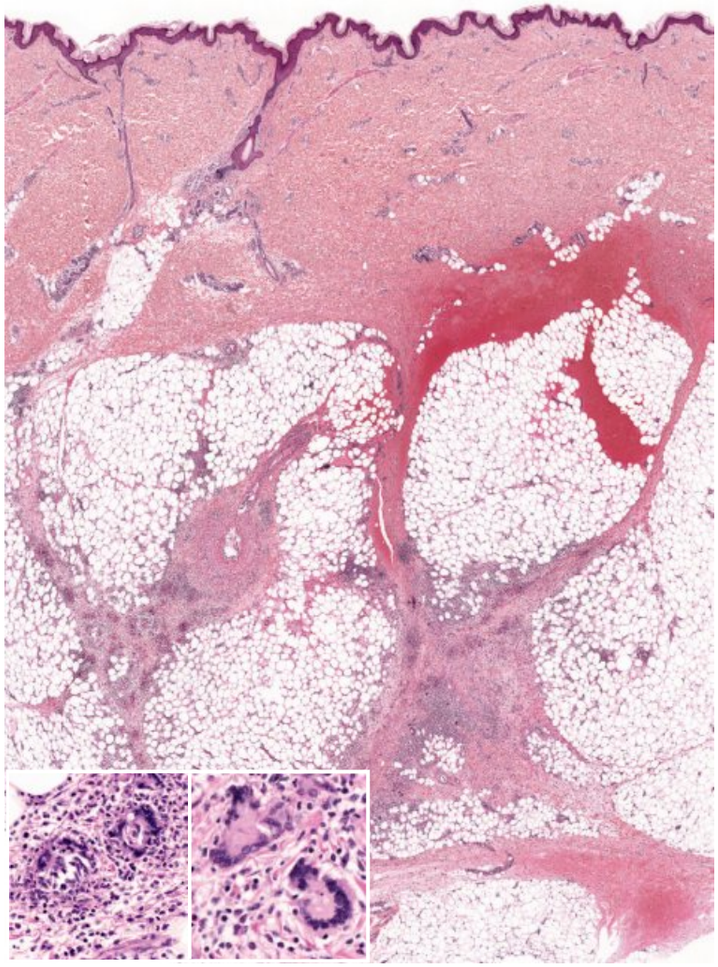

Fig. 100.4 Erythema nodosum – histopathologic features. A predominantly septal panniculitis with Miescher microgranulomas within the septa (left inset). Note the multinucleated giant cells (right inset).

Frequently, there is also a mild to moderate perivascular lymphocytic infiltrate in the overlying dermis. In later stages, the septa become fibrotic, partially replacing the fat lobules. Residual granulomas and lipophages can be observed, and a degree of vascular proliferation may be present[2]. Over the long term, a remodeling process takes place that usually results in minimal residual scarring[2].

Differential Diagnosis

The clinical scenario of an acute eruption of tender subcutaneous nodules over both shins of a young person is highly characteristic of erythema nodosum. However, when lesions are few in number, are located in sites other than the lower legs, or are of longer duration (>6 weeks), erythema nodosum can be difficult to distinguish from other forms of panniculitis. Lesions of erythema induratum (nodular vasculitis) can resemble those of erythema nodosum, but they tend to occur on the posterior aspect of the lower legs and may ulcerate. Ulceration is also a feature of pancreatic panniculitis, which occurs more frequently in other locations (although still favoring the lower legs), is more likely to be accompanied by arthritis and serositis, and is associated with elevated serum amylase and lipase levels.

Histopathologically, the picture of a predominantly septal panniculitis usually limits the differential diagnosis and tends to exclude those conditions that are chiefly lobular or mixed (see Fig. 100.2). Pancreatic panniculitis may show predominantly septal changes in its earliest stages[17], but eventually these lesions exhibit the characteristic fat necrosis, with saponification and "ghost cell" formation. Infection-induced panniculitis can sometimes mimic erythema nodosum, but there are often more extensive neutrophilic infiltrates, cellular necrosis (including sweat gland necrosis), vascular proliferation, and hemorrhage[18].

TREATMENT RECOMMENDATIONS FOR ERYTHEMA NODOSUM	
In all patients	Discontinue possible causative medications Diagnose and treat underlying cause Bed rest and leg elevation Compression
First-line	Nonsteroidal anti-inflammatory medications (3)* Salicylates Potassium iodide (2) (see Table 100.6)
Second-line†	Colchicine (3)‡ Infliximab (3)¶ Hydroxychloroquine (3)§ Adalimumab (3)§ Etanercept (3) Mycophenolate mofetil (3)
Third-line†	Systemic corticosteroids (3) Thalidomide (3)^ Cyclosporine (3) Dapsone (3)

*May trigger a flare of inflammatory bowel disease.
†Immunosuppressives to be used only if underlying infection has been excluded and/or treated.
‡Helpful for erythema nodosum associated with Behçet disease.
¶Helpful for erythema nodosum associated with inflammatory bowel disease.
§Helpful for chronic erythema nodosum.
^May transiently exacerbate erythema nodosum associated with Behçet disease.

Table 100.5 Treatment recommendations for erythema nodosum. Key to evidence-based support: (1) prospective controlled trial; (2) retrospective study or large case series; (3) small case series or individual case reports.

USE OF POTASSIUM IODIDE (KI)
Saturated solution of potassium iodide (SSKI)

• 1000 mg/ml
• Droppers are supplied with calibrations for:
  • 0.3 ml (300 mg)*
  • 0.6 ml (600 mg)
• In adults and older children, common dose = 300 mg TID po with starting dose = 150–300 mg TID
• In infants and young children, common dose = 150 mg TID po
• SSKI should be diluted in water or juice to try to minimize the bitter aftertaste
• Crystallization may occur with cold temperatures, but rewarming and shaking dissolves the crystals; discard if solution turns yellow–brown

Side effects of SSKI
• Acute – nausea, bitter eructation, excessive salivation, urticaria, angioedema, cutaneous small vessel vasculitis • Chronic – enlargement of salivary and lacrimal glands, acneiform eruption, iododerma, hypothyroidism, hyperkalemia, occasionally hyperthyroidism
*0.3 ml = 10 drops from the calibrated dropper supplied with SSKI.

Table 100.6 Use of potassium iodide (KI).

Treatment

Treatments most often recommended for uncomplicated erythema nodosum include bed rest, salicylates, and nonsteroidal anti-inflammatory drugs (NSAIDs; Table 100.5). Potassium iodide has been used with success, with adult dosages ranging from 450 to 1500 mg/day (Table 100.6)[19]. Improvement can be seen within 2 weeks. Potassium iodide may work through inhibition of cell-mediated immunity, as well as via inhibition of neutrophil chemotaxis and suppression of neutrophil-generated oxygen intermediates. In light of this treatment response, reports of erythema nodosum *triggered* by potassium iodide seem contradictory.

Treatment of erythema nodosum is influenced by underlying conditions. Thus, colchicine is useful in management of erythema nodosum that accompanies Behçet disease[6]. Various treatments for inflammatory bowel disease are also effective in managing coexistent erythema nodosum[10,20]. Both etanercept and infliximab have been reported to be effective in treating erythema nodosum[20,21], but paradoxically both have been noted to produce erythema nodosum as a cutaneous side effect[22,23]. In case reports, adalimumab has led to improvement of refractory chronic erythema nodosum[24]. Additional systemic therapies are listed in Table 100.5.

SUBACUTE NODULAR MIGRATORY PANNICULITIS

Synonyms: ■ Erythema nodosum migrans ■ Chronic erythema nodosum

Key features

- Nodules on the lower extremities that migrate or undergo centrifugal spread, with central clearing
- Often unilateral
- Most cases are idiopathic; occasionally associated with streptococcal infection or thyroid disease
- More chronic course than typical erythema nodosum

History and Clinical Features

This condition was first described by Bafverstedt in 1954 and was named *subacute nodular migratory panniculitis* by Vilanova and Piñol Aguade in 1956. Some of its clinical and microscopic characteristics are similar to chronic erythema nodosum, and it is believed by many to represent a variant of the latter[2]. However, others consider it to be a separate disorder[25]. Subacute nodular migratory panniculitis is seen predominantly in women, is often unilateral, and is characterized by nodules that migrate or expand in a centrifugal manner (with central clearing)[2] and may assume a yellowish or morpheaform appearance. Lesions tend to be less tender than those of classic erythema nodosum. There may be few, if any, associated systemic symptoms, though arthralgias have been reported and the ESR may be elevated. Most cases are idiopathic, but some are associated with streptococcal infection (as evidenced by elevated antistreptolysin O and anti-DNase B titers) or thyroid disease[25].

Pathology

Microscopically, the changes are those of a chronic septal panniculitis. However, in contrast to more classic forms of chronic erythema nodosum, subacute nodular migratory panniculitis shows greater septal thickening, more prominent granulomatous inflammation along the borders of widened subcutaneous septa, absence of phlebitis, and rare hemorrhage[25].

Treatment

Untreated, subacute nodular migratory panniculitis can last for months or years. However, treatment with potassium iodide is usually effective, resulting in clearing of lesions within several weeks.

MORPHEA/SCLERODERMA PANNICULITIS

(See also Chs. 43 & 44.)

Clinical Features

Both morphea and systemic sclerosis (scleroderma) can affect the subcutaneous fat (Table 100.7), which is the primary site of involvement in deep morphea (morphea profunda)[26]. Subcutaneous extension also occurs in variants such as disabling pansclerotic morphea of childhood, generalized morphea, and linear morphea. In addition, eosinophilic fasciitis can involve the subcutaneous fat as well as the fascia[27]. These entities may be associated with peripheral eosinophilia, polyclonal gammopathy, and serologic abnormalities[27,28]. It has been proposed that the sclerosing process in systemic sclerosis is initiated by the changes that take place in the subcutis.

Pathology

Table 100.7 outlines the microscopic changes in morphea- and systemic sclerosis-associated septal panniculitis (Fig. 100.5). Lymphocytes and plasma cells predominate[27,29,30], although macrophages and eosinophils may be present. In some cases, the number of plasma cells is striking[29]. In late stages of morphea, the subcutis is largely replaced by hyalinized connective tissue, very often accompanied by changes of lipoatrophy.

Differential Diagnosis

The combination of septal panniculitis with lymphoplasmacytic predominance and dermal and subcutaneous sclerosis is unique, and this helps to separate morphea/systemic sclerosis panniculitis from other septal forms of panniculitis. Differentiation among the several variants outlined above is more difficult, requiring clinical data for accurate classification. Sclerosis with lesser degrees of subcutaneous inflammation characterizes systemic sclerosis, while a predominance of fascial involvement with extension into the subcutis is more typical of eosinophilic fasciitis.

CLINICAL AND MICROSCOPIC FEATURES OF CONNECTIVE TISSUE PANNICULITIS

Disorder	Clinical presentation	Lesion distribution	Relation to systemic disease	Histopathology of panniculitis
Morphea and systemic sclerosis (scleroderma)	Indurated plaques	Extremities, trunk	Occurs in systemic sclerosis, but usually more pronounced in morphea	Septal, with thickening and sometimes mucin deposition; inflammation especially at dermal–subcutaneous interface; lymphocytes and plasma cells; lymphoid follicles in morphea*
Lupus panniculitis	Tender subcutaneous nodules and plaques; may have overlying lesions of discoid LE; lipoatrophy a common sequela	Face (especially cheeks), upper outer arms, shoulders, breasts, hips, buttocks, trunk	Only minority of patients have associated systemic LE	Lobular or mixed lobular/septal; mucin deposition; hyaline necrosis of lobules; lymphocytes, $CD123^+$ plasmacytoid dendritic cells and plasma cells, sometimes with prominent nuclear dust; nodular lymphocytic aggregates or lymphoid follicles
Dermatomyositis	Indurated, painful plaques and nodules; may ulcerate	Buttocks, abdomen, thighs, arms	Can arise in patients with established dermatomyositis or precede other disease manifestations	Lobular or mixed septal/lobular; fat necrosis; lipomembranous changes; sometimes calcification; lymphocytes and plasma cells; sometimes nodular lymphocytic aggregates
Annular atrophic connective tissue panniculitis of the ankles	Subcutaneous atrophy, which may be preceded by induration and tenderness	Circumferential bands around the ankles	Patients often have antinuclear antibodies and/or autoimmune disorders such as thyroiditis or rheumatoid arthritis	Lobular or mixed septal/lobular lymphohistiocytic panniculitis with areas of fat necrosis
Atrophic connective tissue panniculitis	Erythematous, indurated plaques that resolve with subcutaneous atrophy	Favors extremities; may be widespread	As above	As above

*Less often than in lupus panniculitis.

Table 100.7 Clinical and microscopic features of connective tissue panniculitis. LE, lupus erythematosus. *Based on references 27, 29, 81.*

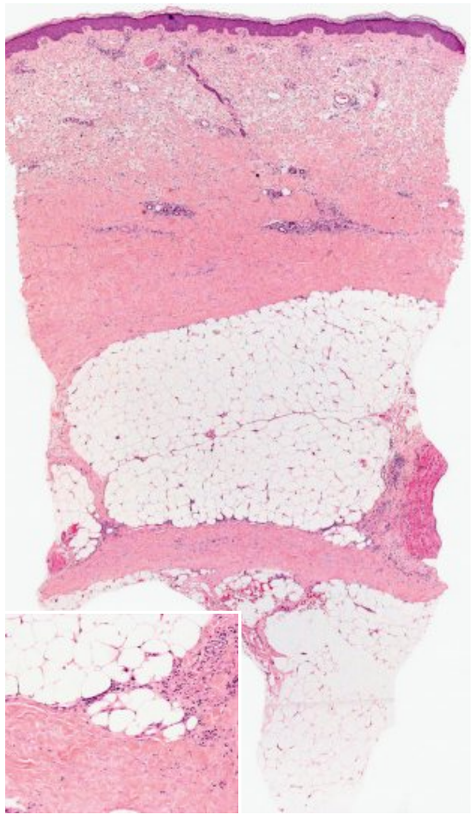

Fig. 100.5 Morphea panniculitis. Septal thickening, mucin deposition and mild lymphocytic infiltrate. Lymphoplasmacytic infiltrates concentrate at the dermal–subcutaneous interface (inset). *Courtesy Lorenzo Cerroni, MD.*

ALPHA-1 ANTITRYPSIN DEFICIENCY PANNICULITIS

Synonym: ■ Alpha-1 protease (proteinase) deficiency panniculitis

Key features

- Erythematous, painful, subcutaneous nodules or plaques that often ulcerate and drain
- Associated with alpha-1 antitrypsin deficiency; patients with the most severe disease are homozygotes for the Z allele of *SERPINA1* (PiZZ)
- A characteristic histopathologic finding is liquefactive necrosis of the dermis and subcutaneous septa, but lobular or mixed septal–lobular changes with neutrophils may occur

Introduction

Alpha-1 antitrypsin deficiency is a well-established, but uncommon, cause of panniculitis. The most severely affected individuals, with markedly decreased levels of the protease inhibitor, are most prone to the development of ulcerating neutrophilic panniculitis. Recognition of the disorder is important not only in the selection of appropriate therapy, but also in addressing other systemic manifestations of the disease and in dealing with its genetic aspects.

History

Alpha-1 antitrypsin deficiency is an inborn error of metabolism that was first delineated by Eriksson and others in the early 1960s. In 1972, Warter and colleagues identified members of a family with alpha-1 antitrypsin deficiency and "Weber–Christian syndrome". Subsequent investigations linked the clinical and microscopic findings to known effects of proteinase inhibitor deficiency.

Epidemiology

In the US, alpha-1 antitrypsin deficiency occurs most commonly in White, followed by Hispanic and Black, individuals. The incidence of panniculitis is approximately equal in men and women[31]. Age of onset ranges from infancy to the eighth decade of life[31].

Pathogenesis

Alpha-1 antitrypsin, a glycoprotein produced in the liver, is the most abundant circulating *ser*ine *p*rotease *in*hibitor (serpin). The more than 120 different alleles of the gene that encodes this protein (SERPINA1; formerly known as PI) are divided into categories based upon the electrophoretic mobility of their protein products (M = medium, S = slow, Z = very slow). The most common protease inhibitor (Pi) phenotype is MM (homozygous for M alleles), which is associated with normal serum levels of alpha-1 antitrypsin (100–200 mg/dl)[32]. Heterozygotes with one copy of the S or Z allele have mild to moderate deficiencies of the inhibitor (PiMS and PiMZ; prevalences of 1%–3% in White populations). Patients who are homozygous for the Z allele (PiZZ; prevalence of 1 : 150–1 : 5000 in White populations) or whose genotype is the rare PiZnull have severe alpha-1 antitrypsin deficiency, with serum levels in the range of 20–45 mg/dl. In these individuals, most of the aberrant alpha-1 antitrypsin protein accumulates within the endoplasmic reticulum of hepatocytes, and the small amounts that enter the circulation have decreased function and a tendency to form inactive polymers that may stimulate neutrophil chemotaxis[33]. Of note, Z-type polymers have been detected in the skin of a patient with alpha-1 antitrypsin deficiency panniculitis, further suggesting a possible proinflammatory role[34].

Alpha-1 antitrypsin acts upon a wide range of proteolytic enzymes that play a direct role in degradation of tissues, including trypsin, collagenase, and elastase[35]. It also has important effects on immune function, e.g. inhibition of membrane-bound serine proteases involved in the activation of lymphocytes and macrophages[36]. It may also inhibit complement activation, both through a direct effect on complement-related proteases[37] and by inhibiting the neutrophil proteases that activate enzymes of the complement system[38].

In addition to panniculitis, the consequences of alpha-1 antitrypsin deficiency include chronic liver disease with cirrhosis (resulting from retention of the aberrant protein within the liver), emphysema, pancreatitis, membranoproliferative glomerulonephritis, rheumatoid arthritis, c-ANCA (cytoplasmic antineutrophil cytoplasmic antibody)-positive vasculitis, other cutaneous vasculitides such as Henoch–Schönlein purpura, and angioedema (resulting from deficiency of the protease inhibitor)[38]. The initiating event in individuals who develop panniculitis is not always clear; trauma appears to play a role in some patients. Postpartum flares of the disease have been reported in genetically susceptible individuals. This is attributed to the estrogen-promoted increase in proteinase inhibitor levels during pregnancy, followed by a precipitous decline to subnormal levels postpartum.

Absence of the alpha-1 antitrypsin protease inhibitor results in activation of lymphocytes and macrophages, lack of restraint upon the complement cascade, release of chemotactic factors, accumulation of neutrophils with release of their proteolytic enzymes, and consequent attack upon fat and nearby connective tissues[33,35]. The subcutis may be particularly vulnerable to this process, since fatty acids make nearby elastin more susceptible to proteolytic degradation[38].

Clinical Features

Large, erythematous to purpuric, tender nodules or plaques appear in a variety of sites (Fig. 100.6), especially the lower trunk and proximal extremities (flanks, buttocks, and thighs)[33,35]. Ulcers develop that may be deep and necrotic, accompanied by an oily discharge[31,33,35]. A history of antecedent trauma can be elicited in approximately one-third of patients[31]. Panniculitis may be accompanied by fever, pleural effusions, and pulmonary emboli[31]. The clinical course of the panniculitis is often prolonged, and lesions are resistant to immunosuppressive therapy. Healing is accompanied by scarring and subcutaneous atrophy[31]. The most severe manifestations arise in those with profound proteinase inhibitor deficiency (PiZZ), although the panniculitis can also occur in heterozygotes.

Pathology

Descriptions of the pathology of alpha-1 antitrypsin deficiency panniculitis have varied. Early, there is a neutrophilic panniculitis, followed rapidly by necrosis and destruction of fat lobules[35]. Splaying of neutrophils

Fig. 100.6 Alpha-1 antitrypsin deficiency panniculitis – clinical appearance. Purpuric nodules on the ankle. *Courtesy Kenneth E. Greer, MD.*

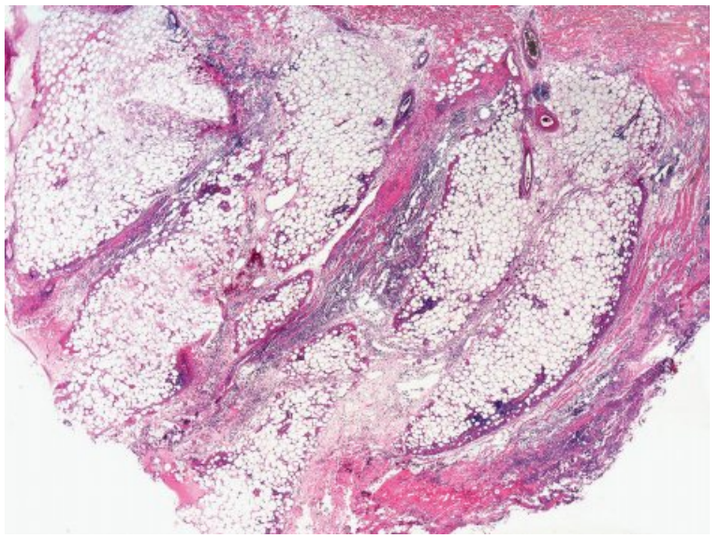

Fig. 100.7 Alpha-1 antitrypsin deficiency panniculitis – histopathologic features. Predominantly septal involvement is seen, with inflammation and collagenolysis of fibrous septa.

between collagen bundles in the reticular dermis has been described as an early clue to the diagnosis[39]. Dissolution of dermal collagen, with resultant liquefactive necrosis and separation of fat lobules from adjacent septa, is a principal change in most cases[40]. Another characteristic feature is the presence of "skip areas" of normal fat adjacent to foci of severe necrotizing panniculitis[35]. Chronic inflammation and hemorrhage may be present at the periphery of areas of involvement[35]. Most authors have not found evidence for *primary* leukocytoclastic vasculitis, although there may be evidence for lymphocytic vasculitis, *secondary* vasculitis in areas of heavy neutrophilic infiltration, or thrombosis[35]. In individuals with intermediate levels of protease inhibitor deficiency, lipophage and giant cell accumulation may be prominent[35]. Lesions heal with scarring and obliteration of fat lobules.

Views differ on whether alpha-1 antitrypsin deficiency panniculitis should be regarded as a primarily septal or lobular panniculitis. Clearly, involvement of fat lobules can be significant, and, as a result, there are authors who have labeled the process a lobular panniculitis. On the other hand, some descriptions have emphasized early septal inflammation, collagenolysis of the fibrous septa (Fig. 100.7)[40], and the prominent septal fibrosis in late-stage lesions[39].

Differential Diagnosis

Clinically, the degrees of inflammation, ulceration, and drainage associated with alpha-1 antitrypsin deficiency panniculitis may actually elicit a differential diagnosis more focused upon ulcerative skin disorders (see Fig. 105.1). Ulcers associated with alpha-1 antitrypsin deficiency generally lack the necrotic, "undermined" borders associated with pyoderma gangrenosum[35]. Tissue culture to exclude infection-induced panniculitis may be required.

Entities in the microscopic differential diagnosis include traumatic (factitial) panniculitis, infection-induced panniculitis, pancreatic panniculitis, and erythema induratum (nodular vasculitis)[35]. Each of these can be associated with infiltrates that include neutrophils and varying degrees of necrosis, yet each has other distinct findings (see below). In the appropriate clinical setting, subcutaneous Sweet syndrome, drug-induced panniculitis, and neutrophilic panniculitis in patients with rheumatoid arthritis or inflammatory bowel disease (IBD) may represent additional diagnostic considerations. Of note, the underlying IBD can be clinically silent. When no underlying disorder is detected, the term idiopathic neutrophilic lobular panniculitis may be applied.

Treatment

Treatments that are usually ineffective include corticosteroids and other immunosuppressants, cytotoxic agents, colchicine, danazol, and hydroxychloroquine[35]. Doxycycline is sometimes effective, particularly in mild cases; one suggested dosage schedule is 200 mg twice daily for 3 months[37,41]. Dapsone may also be beneficial in mild cases, by suppressing neutrophil migration and inhibiting oxidation reactions induced by myeloperoxidase. Reduction of alcohol intake has also been recommended, since ethanol (as a hepatotoxin) may precipitate alpha-1 antitrypsin-associated hepatitis[38].

The most effective therapeutic intervention is replacement of alpha-1 antitrypsin via intravenous infusions. Dosages are generally 60 mg/kg per week, administered over a period of 3 to 7 weeks[31]. Improvement is relatively rapid, in that clearing of the panniculitis can occur after three weekly doses. Recurrences are possible when alpha-1 antitrypsin levels fall below 50 mg/dl, but these typically respond to further replacement therapy. Other successful therapies include plasma exchange and liver transplantation (in appropriate clinical circumstances). There is evidence that autophagy-enhancing drugs, such as carbamazepine, may reduce systemic manifestations, including hepatic fibrosis[42]. Most recently, fazirsiran, an RNA interference therapy, has led to hepatic improvement[42a].

ERYTHEMA INDURATUM

Synonyms: ■ Nodular vasculitis ■ Erythema induratum of Bazin or Bazin disease (tuberculous etiology) ■ Erythema induratum of Whitfield (non-tuberculous etiology)

Key features

- Erythematous nodules or plaques, usually on the posterior lower legs of young to middle-aged women
- Ulceration and drainage may occur
- Microscopic features of lobular or mixed panniculitis with evidence of vasculitis involving arteries or veins
- Classically associated with tuberculosis, but similar lesions can be idiopathic or induced by other infectious agents or drugs

Introduction

Erythema induratum is a condition characterized by nodules on the lower extremities, which may ulcerate and drain. Originally regarded as a tuberculid, detection of mycobacterial DNA within cutaneous lesions in a subset of patients supports its relationship to tuberculosis, at least in a proportion of cases.

History

Erythema induratum was first described by Ernest Bazin in 1861. It was generally regarded as a tuberculid because of a strong association with tuberculosis, although Koch's postulates could not be fulfilled. In

1945, Montgomery and colleagues proposed the term *nodular vasculitis* for cases with similar clinical and pathologic features that were not of tuberculous origin. Since the early 1970s, erythema induratum and nodular vasculitis have generally been considered as synonyms referring to a clinicopathologic entity with several possible causes, one of which is tuberculosis. The detection of mycobacterial DNA in cutaneous lesions has confirmed a tuberculous origin in some patients. There are certain clinicians, however, who prefer to use the term nodular vasculitis when referring to individuals with a non-tuberculous etiology.

Epidemiology

In erythema induratum, an overwhelming female predominance is observed, but men can also develop the disease. There is no apparent racial predilection, and although there is a wide age range among affected patients, the mean is between 30 and 40 years. Erythema induratum of tuberculous etiology occurs more frequently in populations with a high prevalence of tuberculosis.

Pathogenesis

As mentioned previously, some cases have been strongly associated with *Mycobacterium tuberculosis* infection. This can be substantiated by the detection of mycobacterial DNA in skin lesions by PCR[43], with specific primers used to distinguish *M. tuberculosis* complex DNA from that of other mycobacterial pathogens[43]. Non-tuberculous cases have been related to other infectious agents (e.g. *Nocardia*[18], hepatitis C virus[44]) or to drugs (e.g. propylthiouracil[45]). There is a report of erythema induratum being induced by a tuberculin skin test.

Although it has been suggested that erythema induratum results from an immune complex-mediated vasculitis, most investigators believe that the process represents a type IV, cell-mediated response to an antigenic stimulus[46]. Biopsy specimens show a predominance of T lymphocytes, macrophages and dendritic cells, including Langerhans cells[47,48]. One study of peripheral blood mononuclear cells from a patient with erythema induratum and active tuberculosis showed a high proliferative response to purified protein derivative (PPD) and marked production of interferon-γ, suggesting a pathogenic role for these PPD-specific T cells in a delayed hypersensitivity response to mycobacterial antigens[48].

Clinical Features

Erythema induratum is characterized by tender, erythematous to violaceous nodules and plaques that most often develop on the lower legs, especially the calves[47]. Lesions have also been reported on the feet, thighs, buttocks, and arms. An annular arrangement of nodules has been described in *M. tuberculosis*-related cases[49]. Ulceration can occur (Fig. 100.8). Lesions are persistent, tend to heal with scarring, and are prone to recurrence[47,50]. In erythema induratum associated with *M. tuberculosis*, there may be clinical and radiographic evidence for active tuberculosis, positive skin tests to PPD, or a positive interferon-gamma release assay such as the QuantiFERON®-TB Gold Plus test[51]. In addition, other tuberculids, e.g. papulonecrotic, may be present. Clinical differences between tuberculous and non-tuberculous cases are minor.

Fig. 100.8 Erythema induratum – clinical appearance. Inflamed nodular lesions on the lower leg, with evidence of ulceration. *Courtesy Kenneth E. Greer, MD.*

Pathology

Erythema induratum is generally described as a lobular or mixed septal/lobular panniculitis. Inflammation is mixed, and can include neutrophils, lymphocytes, macrophages, and multinucleated giant cells (Fig. 100.9A). Vasculitis is identifiable in the vast majority of cases, and most frequently involves veins or arteries of connective tissue septa and small venules of the fat lobules[52] (Fig. 100.9B). It may be predominantly neutrophilic[47], lymphocytic[50], or granulomatous. Necrosis with a coagulative or caseous appearance may be present, sometimes with palisading granulomas[47]. Necrosis has been described in both tuberculous and non-tuberculous cases, and the incidence and degree of necrosis are greater in those cases that are positive for *M. tuberculosis* DNA by PCR methods[47]. However, this finding is absent in over half of cases.

Differential Diagnosis

Infection-induced panniculitis tends to show a more prominent neutrophilic component, granular basophilic necrosis, sweat gland necrosis and proliferation of small vessels, and organisms may be identified on

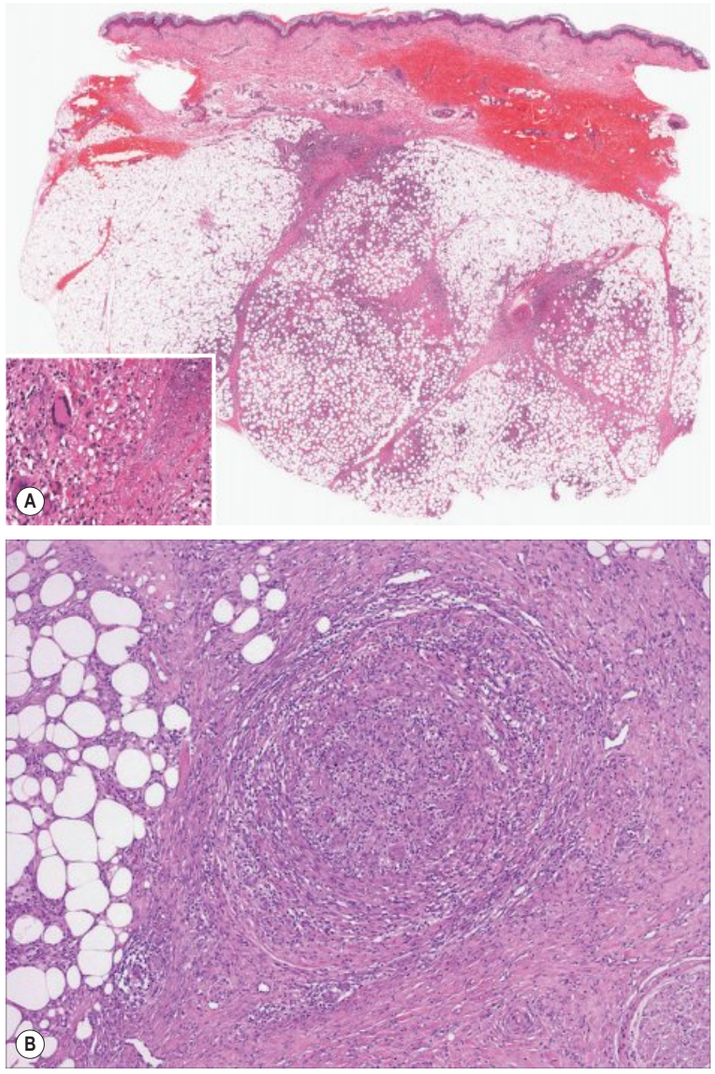

Fig. 100.9 Erythema induratum – histopathologic features. A A predominantly lobular panniculitis is seen with an infiltrate that is lymphocytic and granulomatous; note the multinucleated giant cells (inset). **B** Vasculitis involving a medium-sized vessel in the subcutis.

special staining. Lupus panniculitis tends to be less granulomatous, has a prominent lymphoplasmacellular infiltrate, may show mucin deposits, and frequently has overlying epidermal and dermal changes typical for lupus erythematosus. Both polyarteritis nodosa and thrombophlebitis tend to show inflammation limited to the immediate perivascular zone, in contrast to the extensive lobular panniculitis often encountered in erythema induratum. Histologically, perniosis can be difficult to distinguish from erythema induratum, but there is typically a history of cold exposure[47], and on microscopic examination prominent involvement of dermal vessels is often observed, with "fluffy edema" of their walls.

Treatment

Treatment should be directed at the underlying cause, if found. This includes multi-drug antituberculous therapy[49] (see Ch. 75) and discontinuing possible inciting medications. Therapeutic options for nontuberculous erythema induratum include NSAIDs, corticosteroids, tetracyclines, potassium iodide, and mycophenolate mofetil[53]. Supportive care is similar to that for erythema nodosum (see Table 100.5).

PANCREATIC PANNICULITIS

Synonyms: ■ Pancreatic fat necrosis ■ Enzymatic panniculitis

Key features

- Subcutaneous nodules, sometimes accompanied by fever, arthritis, or abdominal pain
- Associated with pancreatic disorders, including acute and chronic pancreatitis and pancreatic carcinoma
- Mixed septal/lobular panniculitis featuring "ghost cell" formation and the deposition of basophilic material due to saponification of fat by calcium salts
- Treatment primarily directed towards the underlying pancreatic disorder

Introduction

Pancreatic panniculitis is an unusual complication of pancreatic disease. In addition to the symptoms associated with fat necrosis, its chief importance is as a sign of a significant systemic disorder, particularly because the panniculitis may be recognized prior to detection of the underlying pancreatic disease. The association of pancreatitis, panniculitis, and polyarthritis is sometimes referred to as the PPP syndrome.

History

Chiari first described pancreatic panniculitis in 1883. By 1999, fewer than 100 cases had been reported[54,55]. Since then, ~100 additional patients with pancreatic panniculitis have been described, primarily as case reports.

Epidemiology

Panniculitis develops in up to 2% of patients with pancreatic disorders[56]. No geographic, racial or sex predilections have been reported.

Pathogenesis

There is considerable evidence that the enzymes lipase, amylase and trypsin are involved in producing the lesions of pancreatic panniculitis[54]. Elevated enzyme levels have been detected in the blood[55,56], urine[54], and skin lesions[57], even in the absence of detectable pancreatic disease. Lipase has the clearest relationship with the panniculitis, with a number of patients having elevated serum lipase levels but normal amylase levels[55]. Utilizing an anti-pancreatic lipase monoclonal antibody, positive intracellular adipocyte staining was observed in a biopsy of lesional skin[57].

Amylase levels, when elevated, tend to peak 2–3 days after eruption of the skin lesions and return to normal 2–3 days after regression of the lesions. Trypsin and perhaps amylase may act by promoting increased permeability of vessel walls, thereby permitting lipase to hydrolyze neutral fat to form glycerol and free fatty acids, with resulting fat necrosis and inflammation[55,56]. Venous stasis may promote this process, possibly explaining the predilection for the lower extremities. Elevated enzyme levels may not be the complete explanation for the changes of pancreatic panniculitis[58]; immunologic factors probably also play a role.

Clinical Features

Subcutaneous nodules develop in association with acute or chronic pancreatitis, pancreatic carcinoma (acinar cell > other types [e.g. neuroendocrine carcinomas]), pancreatic pseudocysts, pancreas divisum, traumatic pancreatitis, or drug-induced panniculitis (e.g. azathioprine)[55,59]. The possibility of a pancreaticoportal fistula should be considered when panniculitis develops in individuals with chronic pancreatitis, and in some of these patients, an acinar cell carcinoma can also be found. Panniculitis may precede detection of pancreatic disease by 1–7 months[56], and in the case of pancreatic carcinoma, its onset may signal the presence of metastatic disease[55,56].

In pancreatic panniculitis, subcutaneous nodules develop, frequently on the legs (Fig. 100.10) but also on the anterior trunk, arms, and scalp[55,56]. Erythematous, edematous, sometimes painful lesions arise singly or in crops. They can become fluctuant and ulcerate, discharging an oily material[55]. Panniculitis may also involve visceral fat, including the omentum and preperitoneal fat[55]. Associated findings include fever, abdominal pain, inflammatory polyarthritis, ascites, and pleural effusions[55].

The association of subcutaneous nodules, polyarthritis, and eosinophilia is known as Schmid's triad, and it is associated with a poor prognosis. Some patients have radiographic evidence of multiple lytic areas involving the cortical bone near large joints. Cutaneous lesions may involute within a period of weeks, leaving hyperpigmented scars. In acute pancreatitis, the panniculitis resolves as the acute inflammatory phase passes[55]. However, lesions may also persist and expand until the underlying pancreatic abnormality has been treated.

Fig. 100.10 Pancreatic panniculitis – clinical appearance. Multiple painful pink–violet to dark purple nodules and plaques on the shins. There is also evidence of hemorrhage. *Courtesy Sa Rang Kim, MD, and Jean L. Bolognia, MD.*

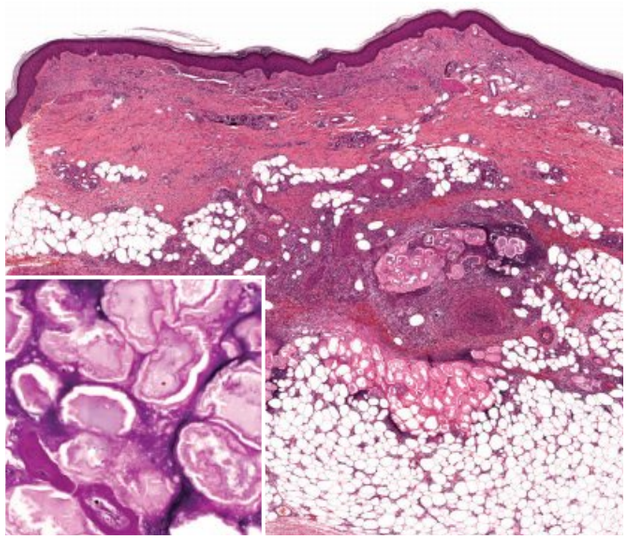

Fig. 100.11 Pancreatic panniculitis – histopathologic features. Lobular and septal panniculitis with neutrophilic inflammation, cellular necrosis, ghost cells (inset), and deposition of homogeneous basophilic material due to saponification of fat by calcium salts (seen here near ghost cells).

Pathology

Pancreatic panniculitis may begin as a septal panniculitis[17], but with progression, the lesion takes on the appearance of a lobular or mixed septal/lobular process. Even in early stages, fat necrosis with liquefaction and microcyst formation is observed[54,58]. Lipocytes lose their nuclei and develop thick, shadowy walls, forming the characteristic "ghost cells". Saponification of fat by calcium salts results in deposition of granular or homogeneous basophilic material (Fig. 100.11). Neutrophils, occasional eosinophils, macrophages, and multinucleated giant cells are sometimes present and may encroach upon the septa. Fibrosis and lipoatrophy are seen in late stages as the process resolves.

Differential Diagnosis

Clinically, the nodules of pancreatic panniculitis can resemble those of a number of other forms of panniculitis. Ulceration and discharge would argue against erythema nodosum, and an association with fever, polyarthritis, and/or abdominal pain should raise suspicion of associated pancreatic disease. Serum amylase and lipase levels, if elevated, may also be helpful. Histologic evidence of "ghost cell" formation and saponification of fat distinguishes pancreatic panniculitis from other panniculitides, with the exception of ghost cell formation in mucormycosis panniculitis. Eosinophilic "hyaline necrosis" is seen in lupus panniculitis, rather than the granular or homogeneous basophilic necrosis typical of pancreatic panniculitis.

Treatment

Although supportive measures such as compression and elevation can be helpful, effective management of pancreatic panniculitis is dependent upon treatment of the underlying pancreatic disease. In chronic pancreatitis, pancreatectomy is curative but is rarely performed because of potential complications. If a fistula or cyst is involved, minimally invasive drainage techniques are initially employed. Somatostatin analogues (e.g. octreotide) can be used to inhibit pancreatic enzyme production[55]. Resection of pancreatic cancer may be followed by regression of the panniculitis.

SCLEREMA NEONATORUM, SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN, AND POST-STEROID PANNICULITIS

Three entities – sclerema neonatorum, subcutaneous fat necrosis of the newborn, and post-steroid panniculitis – are characterized histologically by the formation of needle-shaped clefts within lipocytes. In contrast to adult fat, the subcutaneous fat of infants is thought to be prone to crystal formation because of a higher content of saturated fatty acids, including palmitic and stearic acids, and a relatively lower content of unsaturated fatty acids, such as oleic acid[60]. This increased saturated : unsaturated fatty acid ratio results in a higher melting point for stored fat and promotes crystallization under certain conditions. Microsized crystals (type A) apparently do not produce an inflammatory response; they are actually common (in a widely dispersed form) in healthy infants 6 months of age or less, but are more numerous in sclerema neonatorum. Larger, type B crystals that tend to be arranged in rosettes are capable of eliciting a granulomatous response; these larger crystals are most often seen in subcutaneous fat necrosis of the newborn and post-steroid panniculitis[60]. Crystallization and defects in fat mobilization account for the clinical findings in these disorders.

Sclerema Neonatorum

Key features

- Arises in premature infants
- Skin is diffusely cold, rigid, and board-like
- Microscopically, needle-shaped clefts are present within lipocytes and there is minimal inflammation
- Affected infants are often hypothermic and may have a variety of other medical problems; early death is common

History

Uzembenzius first recognized sclerema neonatorum in 1722, although the classic description is usually attributed to Underwood (1784). Ballantyne provided an early description of the histopathologic changes, and Knopfelmacher noted the presence of needle-shaped crystals in subcutaneous tissue in 1897.

Epidemiology

Sclerema neonatorum presents most often in premature, debilitated infants, usually during the first week of life. There is a slight male predominance, with no substantial sex differences in death rates[61].

Pathogenesis

In infants who develop sclerema, crystallization and hardening of fat occur in the setting of an increased saturated : unsaturated fatty acid ratio and a defective ability to mobilize fatty acids. Precipitating factors are listed in Table 100.8[60].

Clinical features

The clinical features are outlined in Table 100.8[60–62]. Rapid hardening of the subcutaneous tissues leads to firm, rigid skin over most of the body. Low birth weight and hypothermia as well as hemorrhagic phenomena portend a particularly poor prognosis[61].

Pathology

Table 100.8 outlines the microscopic features. Inflammation is usually sparse, and most of the needle-shaped clefts are found within lipocytes rather than within giant cells (Fig. 100.12)[60,62]. At a later stage, thickened connective tissue bands may be the only histologic finding[62].

Differential diagnosis

In contrast to sclerema neonatorum, subcutaneous fat necrosis of the newborn is a localized process with a favorable prognosis; histologically, the latter is distinguished by more prominent inflammation and localization of needle-shaped clefts within giant cells. Scleredema neonatorum is a condition seen in premature infants with congenital heart disease. In this disorder, the skin is distended and wax-like, and on biopsy the dermis appears edematous, with increased amounts of mucin[60]. Other conditions that can present with diffusely indurated skin in the neonatal period include stiff skin syndrome (usually favoring the trunk, buttocks, and thighs), restrictive dermopathy, and Hutchinson–Gilford progeria.

While subcutaneous needle-shaped clefts are generally observed in infants and children, radially arranged needle-shaped clefts

PANNICULITIDES WITH NEEDLE-SHAPED CLEFTS IN THE SUBCUTIS						
Condition	**Patient characteristics**	**Onset**	**Cutaneous findings**	**Associated systemic findings**	**Histopathology**	**Possible precipitating factors**
Sclerema neonatorum	Severely ill premature neonates	First week of life	Widespread, diffuse hardening, sparing only the genitalia, palms and soles; cool, waxy, rigid and board-like skin with purple mottled discoloration	Respiratory difficulties, congestive heart failure, intestinal obstruction, diarrhea; death, usually from septicemia, in three-quarters of patients	Needle-shaped clefts in lipocytes; septal thickening; inflammation sparse to absent (few neutrophils, eosinophils, macrophages or multinucleated giant cells may be seen)	Hypothermia, perinatal asphyxia, defective complement activity, dehydration
Subcutaneous fat necrosis of the newborn	Full-term neonates	First 2–3 weeks of life	Circumscribed, erythematous, indurated subcutaneous nodules favoring the cheeks, shoulders, back, buttocks, thighs; may become fluctuant	Hypercalcemia (onset usually within 2 months), thrombocytopenia, hypertriglyceridemia; severe hypercalcemia may be associated with fever, eosinophilia, and persistent nephrocalcinosis	Lobular panniculitis with neutrophils, lymphocytes, macrophages; needle-shaped clefts in a radial array within lipocytes and giant cells; sometimes foci of calcification, hemorrhage	Hypothermia (including exposure to cooling blankets), hypoglycemia (e.g. due to gestational diabetes), perinatal hypoxemia (e.g. due to meconium aspiration, placenta previa, umbilical cord prolapse, pre-eclampsia)
Post-steroid panniculitis	Children (ages 1–14 years)	1–40 days* after cessation of high-dose systemic corticosteroids	Firm red plaques on the cheeks, arms, trunk; small and discrete or large and confluent lesions; pruritic, tender or asymptomatic	Underlying conditions treated with systemic corticosteroids have included leukemia, cerebral edema, nephrotic syndrome, secretory diarrhea, and acute rheumatic fever as well as chronic obstructive pulmonary disease and Sjögren syndrome in adults	Lobular panniculitis with lymphocytes, macrophages, multinucleated giant cells; needle-shaped clefts in lipocytes and giant cells	Follows rapid withdrawal of systemic corticosteroids

*Usually within 10 days.

Table 100.8 Panniculitides with needle-shaped clefts in the subcutis.

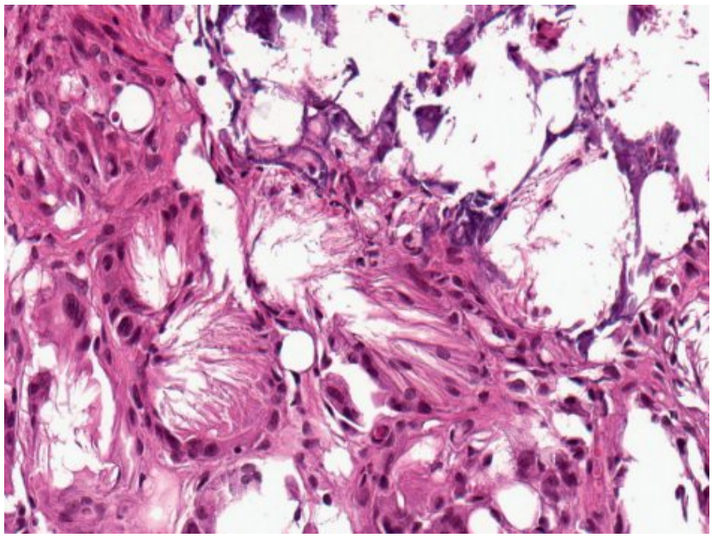

Fig. 100.12 Sclerema neonatorum. Needle-shaped clefts within lipocytes with chronic granulomatous inflammation.

(resembling those of sclerema neonatorum) were reported in an adult with gemcitabine-related thrombotic microangiopathy[63]; however, these crystals were quite small.

Treatment

Attempts to treat this disorder are disappointing[61]. Management includes treatment of sepsis, ventilatory support, correction of fluid and electrolyte imbalances, and maintenance of body temperature[60,64]. Exchange transfusions may be of value in selected instances[60,64]. Systemic corticosteroids are of questionable utility[60,61].

Subcutaneous Fat Necrosis of the Newborn

Key features

- Development of one or more mobile, firm, subcutaneous nodules or plaques during the newborn period
- Sometimes associated with hypercalcemia or thrombocytopenia
- Granulomatous lobular panniculitis with needle-shaped clefts within lipocytes and giant cells
- Prognosis is usually favorable; spontaneous resolution is common

Introduction

In contrast to sclerema neonatorum, subcutaneous fat necrosis is a localized process. Although complications can arise, particularly in relation to hypercalcemia, most cases resolve spontaneously.

History

At the beginning of the twentieth century, Fabyan described "abscesses" that spontaneously resorbed, and he provided the first microscopic description of subcutaneous fat necrosis.

Epidemiology

Subcutaneous fat necrosis of the newborn typically occurs in full-term neonates during the first 2 to 3 weeks of life[65].

Pathogenesis

It is believed that a variety of stresses imposed upon fetal fat, with its high ratio of saturated : unsaturated fatty acids, results in crystallization, adipocyte injury, and granulomatous inflammation. Hypothermia is one potential eliciting factor, as illustrated by cases of subcutaneous fat necrosis that developed following hypothermic cardiac surgery and the use of cooling blankets[66–69]. Other proposed causes are listed in Table 100.8[60,65,67]. The role of birth trauma has been questioned, since many cases have occurred in infants delivered by cesarean section[65].

Clinical features

The clinical features are outlined in Table 100.8. Smooth, circumscribed, mobile, red to violaceous, subcutaneous nodules or plaques develop, sometimes in a symmetrical fashion[60,65] (Fig. 100.13). The areas of fat necrosis can be detected by ultrasonography, CT, and MRI.

Some patients develop hypercalcemia or thrombocytopenia; the former is more common in infants with a higher birth weight and typically appears within two months of skin lesion onset[67,68]. It is believed that the hypercalcemia results from extrarenal production of 1,25-dihydroxyvitamin D_3 (calcitriol) by activated macrophages (expressing 1-α-hydroxylase) within areas of granulomatous panniculitis. This stimulates calcium absorption from the gut and mobilization from the bones[65,70]. The mechanism for thrombocytopenia may be local sequestration in the subcutis, as studies have shown normal bone marrow cellularity and resolution of the thrombocytopenia as the inflammatory process resolves[71]. Spontaneous resolution of lesions is the rule, but some patients develop residual lipoatrophy. Deaths have been reported in those with associated hypercalcemia[71].

Pathology

The microscopic changes are outlined in Table 100.8. They include a predominantly lobular panniculitis with mixed cellularity (Fig. 100.14). Needle-shaped clefts are observed within both lipocytes and giant cells (Fig. 100.14, inset). The crystals are doubly refractile and stain with oil red O[60]. Occasionally, however, needle-shaped clefts are not evident in otherwise typical cases. Eosinophilic granules are sometimes found within multinucleated giant cells; their origin is not entirely certain, but they may be derived from degranulating eosinophils[72].

Differential diagnosis

The extensive cutaneous involvement in sclerema neonatorum is usually distinguishable from the localized, self-limited process of subcutaneous fat necrosis; histologically, inflammation in sclerema is minimal. Post-steroid panniculitis is microscopically indistinguishable from subcutaneous fat necrosis, but it arises in a different clinical setting (see below).

Treatment

Since many lesions resolve spontaneously, the emphasis is on supportive care. Systemic corticosteroids may be indicated to control the inflammation in severe cases[60]. Serial monitoring of calcium levels (for at least 2 months after skin lesion resolution) is recommended[68]. Hypercalcemia is managed by hydration, dietary restriction of both calcium and vitamin D, calcium-wasting diuretics (e.g. furosemide), calcitonin, and bisphosphonates (e.g. etidronate, pamidronate)[65,67,73]. Corticosteroids may be helpful in managing hypercalcemia, by interfering with the metabolism of vitamin D to calcitriol and by inhibiting calcitriol production by macrophages[67].

Fig. 100.13 Subcutaneous fat necrosis of the newborn – clinical appearance. Red–violet indurated plaques, primarily on the back and shoulders. *Courtesy Lorenzo Cerroni, MD.*

Post-Steroid Panniculitis

Key features

- A rare complication of rapid withdrawal of systemic corticosteroids
- Subcutaneous nodules develop on the cheeks, arms, and trunk
- Lesions resolve spontaneously, or when corticosteroids are readministered
- Microscopically, granulomatous lobular panniculitis with needle-shaped clefts within both lipocytes and giant cells

History

In 1956, Smith and Good reported 11 children with acute rheumatic fever who were treated with large doses of corticosteroids that were rapidly tapered. Five children developed pruritic, erythema nodosum-like lesions.

Epidemiology

Post-steroid panniculitis is typically a disorder of children. It occurs in an older age group than either sclerema neonatorum or subcutaneous fat necrosis of the newborn, with reported ages ranging from 20 months to 14 years[74]. Occasionally, the disorder occurs in adults[75].

Pathogenesis

Post-steroid panniculitis occurs after rapid withdrawal of systemic corticosteroids that have been administered either orally or intravenously. For patients who had received prednisone, cumulative dosages ranged from 2000 to 6000 mg[74]. The precise mechanism by which the panniculitis arises is not known.

Clinical features

Patients who have developed this form of panniculitis received corticosteroid therapy for a variety of conditions[74,76], including those listed

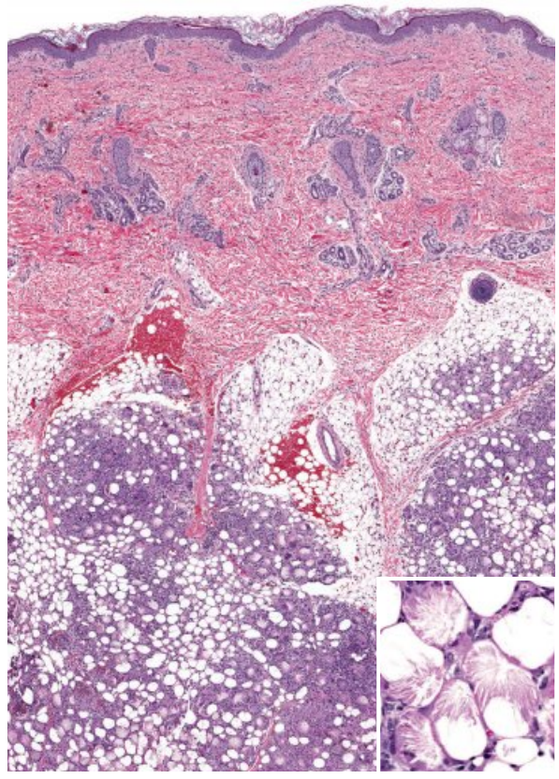

Fig. 100.14 Subcutaneous fat necrosis of the newborn – histopathologic features. A predominantly lobular panniculitis is seen. Needle-shaped clefts in a radial configuration are present within giant cells (inset). Similar findings are seen in post-steroid panniculitis.

in Table 100.8. Lesions appear 1 to 40 days after rapid corticosteroid withdrawal and disappear spontaneously over a period of months to a year[76].

Pathology

Microscopic changes are outlined in Table 100.8[76]. Needle-shaped clefts, some with a "starburst" pattern, can be identified within lipocytes or giant cells.

Differential diagnosis

A less nodular presentation involving the cheeks can mimic non-panniculitic disorders such as erythema infectiosum, atopic dermatitis, lupus erythematosus, or facial cellulitis. The microscopic changes in these conditions would be quite different from those of post-steroid panniculitis. Cold panniculitis has clinical and microscopic similarities, but the history of cold exposure and the lack of needle-shaped clefts histologically permit distinction. The microscopic changes of post-steroid panniculitis are virtually identical to those of subcutaneous fat necrosis of the newborn, although calcification and hemorrhage are more commonly observed in the latter condition. Clinical history allows distinction.

Treatment

Since spontaneous resolution is the rule, treatment is usually unnecessary. Readministration of corticosteroids followed by a more gradual taper may be helpful[76].

LUPUS ERYTHEMATOSUS PANNICULITIS (LUPUS PANNICULITIS)

Synonyms: ■ Lupus profundus ■ Subcutaneous lupus erythematosus

Key features

- Tender subcutaneous nodules and plaques arising on the face, proximal extremities, hips, and trunk
- Associated with discoid lupus erythematosus in at least one-third of patients; less often associated with systemic lupus erythematosus (10%–15% of patients)
- Often precedes onset of other manifestations of lupus erythematosus
- Characteristic microscopic changes include lobular panniculitis with hyaline necrosis and a predominantly lymphoplasmacytic infiltrate; nodular aggregates of lymphocytes are common
- Overlying epidermal or dermal changes of lupus erythematosus are frequently present

History

Kaposi first described the clinical characteristics of lupus panniculitis in 1869. In 1940, it was recognized as a manifestation of lupus erythematosus (LE) by Irgang. Lupus panniculitis was firmly established as a specific subtype of LE in 1956 by Arnold.

Epidemiology

Lupus panniculitis constitutes a small subset of all cases of cutaneous LE, representing 2%–3% of this group[77]. It usually occurs in adults, with a median age of onset of 30–40 years[78]. Children can also develop lupus panniculitis, and an association with neonatal lupus has been described. There is a predominance among women, with a female : male ratio ranging from 2 : 1 to 4 : 1[28,78]. Sometimes there is a family history of either LE or another autoimmune connective tissue disease[77].

Pathogenesis

The autoimmune basis of lupus panniculitis is thought to be similar to that of other types of LE (see Ch. 41). The cells comprising the infiltrates of lupus panniculitis are T lymphocytes and macrophages[79]. Lupus panniculitis, often with a childhood onset and widespread distribution, has been described in patients with partial C4 deficiency[80]. This complement deficiency causes defective opsonization of immune complexes, which may play a role in the pathogenesis of the disease[80]. Immunohistochemical analysis has shown an interferon-driven Th1-biased immune response in active lesions of lupus panniculitis; this may result in recruitment of cytotoxic CXCR3-positive lymphocytes[81].

Clinical Features

Lupus panniculitis is characterized by tender subcutaneous nodules and plaques that may arise in crops (see Table 100.7). A history of trauma can sometimes be elicited. Lesions tend to develop on the face, upper arms, hips, and trunk (Fig. 100.15). Linear scalp lesions are more common among, but not restricted to, East Asian populations. The lack of involvement of the distal extremities is noteworthy[78]. Changes in the overlying skin range from a light pink color to those of discoid LE, i.e. scaling, follicular plugging, dyspigmentation, telangiectasias, atrophy, and scarring. At times, findings of discoid LE are too subtle to be recognized clinically but can be seen on microscopic examination of biopsy specimens. The overlying skin may also be "tethered" to the subcutaneous nodule or plaque, creating a surface depression, and ulceration occasionally occurs. Lupus panniculitis has a chronic, relapsing clinical course. It usually eventuates in subcutaneous atrophy, which can be disfiguring (see Chs. 41 & 101).

Lupus panniculitis often occurs prior to other manifestations of LE and in the absence of other autoimmune connective tissue diseases[78]. For example, lesions of discoid LE have developed up to 10 years after the appearance of the panniculitis. However, manifestations of systemic LE or discoid LE can also occur long before or simultaneously with the panniculitis[28]. There is a closer relationship of lupus panniculitis to other forms of chronic cutaneous LE (e.g. discoid LE) than to systemic LE. Coexistent discoid lesions are observed in at least one-third of patients, whereas only 10%–15% meet the diagnostic criteria for systemic LE[78,82]. Most individuals in the latter group have relatively mild systemic manifestations, usually arthralgias or Raynaud phenomenon[77]. It is common for patients to have low-titer antinuclear antibodies; they can also have other circulating autoantibodies (e.g. anti-dsDNA, anti-RNP), leukopenia, hypocomplementemia, and an elevated ESR[77].

Pathology

Lupus panniculitis is a predominantly lobular process with a variable degree of inflammation (Fig. 100.16A). Nodular aggregates of lymphocytes, usually B cells, are often present (Fig. 100.16B), as are variably

Fig. 100.15 Lupus panniculitis – clinical appearance. Red–brown plaques on the upper outer arm. Note the significant subcutaneous atrophy and overlying lesions of discoid lupus erythematosus. *Courtesy Kenneth E. Greer, MD.*

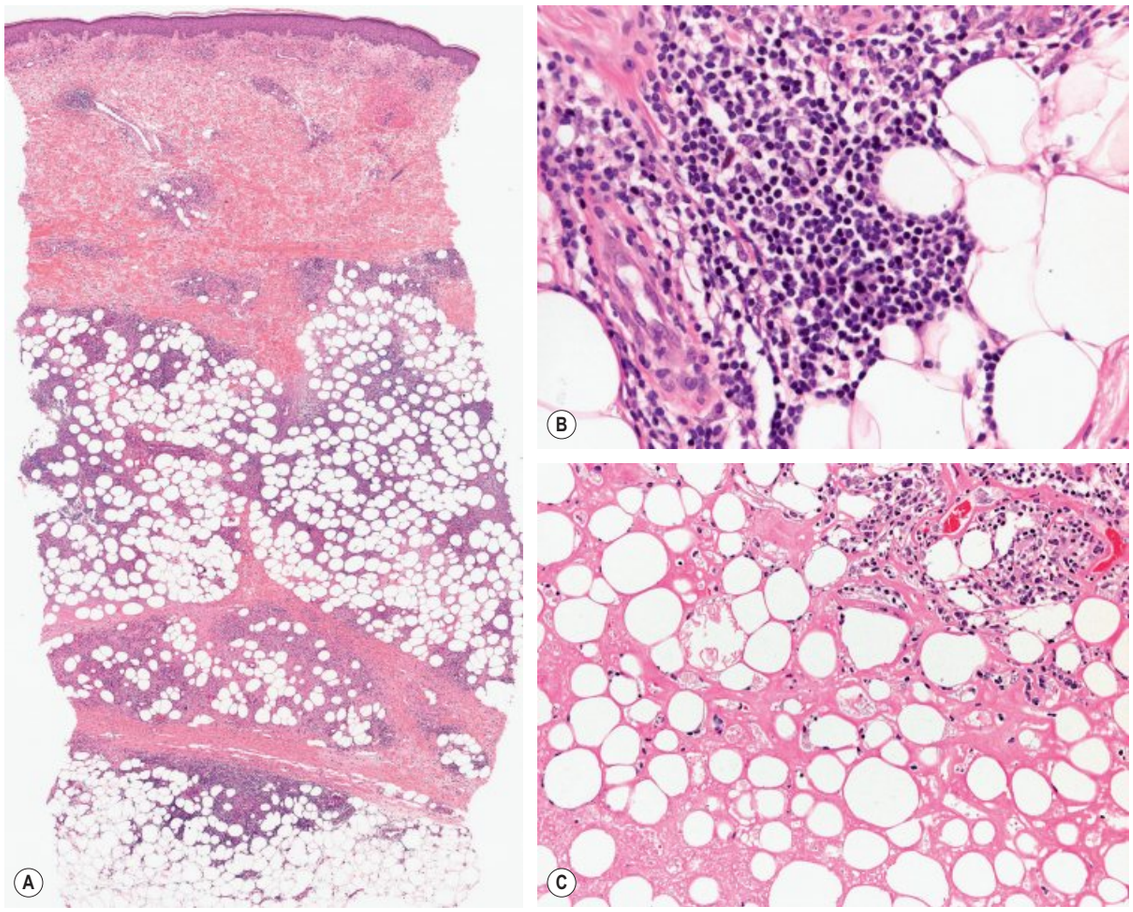

Fig. 100.16 Lupus panniculitis – histopathologic features. **A, B** A primarily lobular panniculitis with nodular aggregates of lymphocytes. **C** Hyaline necrosis of fat lobules is also a characteristic feature. A focus of lipomembranous changes, a nonspecific finding observed in the late stages of several types of panniculitis, is present. *Courtesy Lorenzo Cerroni, MD.*

large clusters of CD123$^+$ plasmacytoid dendritic cells. The characteristic microscopic changes, e.g. hyaline necrosis of the fat lobules (Fig. 100.16C), are outlined in Table 100.7. Granulomas can occur and tend to encroach upon the septa, but they are usually not prominent. Other features include lymphocytic vasculitis and mucin or calcium deposition.

The subcutaneous findings alone are considered sufficiently characteristic to permit a diagnosis of lupus panniculitis. However, overlying epidermal or dermal changes of discoid LE occur in one-half to two-thirds of cases and are also helpful diagnostically[79,82,83]. With direct immunofluorescence, a positive lupus band can be identified in the overlying skin in a high percentage of cases, even in those where the histopathologic changes are nonspecific[83].

Differential Diagnosis

Clinically, lesions of lupus panniculitis can resemble other forms of panniculitis. The rarity of involvement of the distal lower extremities helps to distinguish it from conditions such as erythema nodosum and erythema induratum. It should also be remembered that other forms of subcutaneous inflammation may occur in patients with LE, including erythema nodosum, thrombophlebitis, pancreatic panniculitis, and juxta-articular, rheumatoid nodule-like lesions.

Microscopically, lupus panniculitis can resemble the panniculitis associated with morphea and dermatomyositis (see Table 100.7), traumatic panniculitis (which often has evidence of foreign material), and, in its later stages, localized lipoatrophy due to other etiologies[77]. The most important entity in the differential diagnosis is subcutaneous panniculitis-like T cell lymphoma, as there can be considerable histopathologic overlap between the two disorders. The distinguishing features are outlined in Table 100.9. It should be noted, however, that changes such as vacuolar alteration of the basilar layer and dermal mucin deposition have been reported in panniculitis-like T cell lymphoma[84]. In some cases, overlapping histopathological features of lupus panniculitis and subcutaneous panniculitis-like T cell lymphoma have been reported[85], and these cases probably represent examples of "atypical" lupus panniculitis.

Treatment

Antimalarials are frequently used to treat lupus panniculitis, and they produce improvement in most patients[76]. Addition of a second antimalarial may prove useful in patients who do not respond to a single agent. In view of the chronic, relapsing nature of the disease, treatment may be required for several years[77].

Systemic corticosteroids, when used, are often restricted to initial phases of the disease[77]. Other systemic therapies include dapsone, immunosuppressive agents (e.g. mycophenolate mofetil), thalidomide, IVIg, and rituxumab[78,80,86]. Overlying discoid lesions, if present, can be treated with potent topical or intralesional corticosteroids.

PANNICULITIS OF DERMATOMYOSITIS

Key features

- An uncommon manifestation of dermatomyositis
- More frequently, incidental microscopic changes of panniculitis (in the absence of clinical lesions) are observed
- Can precede or follow other manifestations of dermatomyositis
- Microscopically, it is a lobular or mixed panniculitis with lymphoplasmacytic predominance
- Usually responds to therapy

Introduction

Panniculitis is an uncommon but established clinical manifestation of dermatomyositis. However, there is some evidence that microscopic involvement of subcutaneous fat without overt clinical features of panniculitis is more frequently observed.

LUPUS PANNICULITIS VS SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA (SPTCL) – DISTINGUISHING FEATURES	
Lupus panniculitis	**SPTCL**
Clinical features	
• Subcutaneous nodules, indurated plaques; sometimes large painful ulcers; lipoatrophy	• Multiple plaques and nodules; usually do not ulcerate
• Proximal extremities, hips, trunk; face and scalp in Asian populations	• Favors the extremities, but can be generalized
• Precedes, accompanies, or follows the development of other manifestations of LE	• Fever, weight loss, and/or hemophagocytic syndrome in a small subset of patients
• Treatment: corticosteroids (intralesional, ultrapotent topical), antimalarials, cyclosporine, dapsone	• Treatment: systemic corticosteroids; cyclosporine; chemotherapy and HSCT reserved for advanced disease
Microscopic and laboratory features	
• Epidermal and dermal changes of LE in half of cases • Lobular lymphocytic panniculitis • Nuclear dust can be observed in later stages	• Epidermal changes occur rarely; changes confined to the subcutis • Lobular lymphocytic involvement • Nuclear dust can be observed in later stages
• Cytologic atypia or adipocyte rimming by lymphocytes: uncommon • Lymphoid follicles: 20%–50% of cases • Clusters of B cells: present	• Cytologic atypia and adipocyte rimming by lymphocytes: seen more frequently • Lymphoid follicles: generally absent • Clusters of B cells: absent
• Staining for MxA: more extensive • Clusters of $CD123^+$ plasmacytoid dendritic cells	• Staining for MxA: less extensive • Clusters of plasmacytoid dendritic cells not observed
• Infiltrate: plasma cells commonly seen, sometimes eosinophils • Fat necrosis: hyaline or lipomembranous • TCR gene rearrangements: polyclonal	• Infiltrate: plasma cells usually absent, granulomas may be seen • Fat necrosis: fibrinoid/coagulative • TCR gene rearrangements: monoclonal

Table 100.9 Lupus panniculitis versus subcutaneous panniculitis-like T cell lymphoma (SPTCL) – distinguishing features. HSCT, hematopoietic stem cell transplant; LE, lupus erythematosus; MxA, human myxovirus resistance protein 1; TCR, T cell receptor.

Clinical Features

The characteristic lesions are persistent, indurated, painful plaques and nodules that may ulcerate and lead to lipoatrophy (see Table 100.7)[87]. They can arise in the setting of established dermatomyositis[87] or represent the initial manifestation of the disease[88]. In affected individuals, the other clinical and laboratory features as well as the incidence of malignancy appear to be similar to those of dermatomyositis patients without panniculitis[87]. Partial or generalized lipoatrophy without preceding clinical lesions of panniculitis (occasionally accompanied by increased abdominal fat) occurs in up to one-quarter of patients with juvenile dermatomyositis, and it is often associated with metabolic abnormalities such as hypertriglyceridemia and insulin resistance (see Ch. 101).

Pathology

The microscopic features are outlined in Table 100.7. Lymphocytic vasculitis has been described, and fat necrosis has been noted in several reports[87]. Membranocystic changes have been observed in some cases (see section on lipodermatosclerosis), and lesions with these changes may be particularly resistant to therapy[87]. Calcification is variable and is an expected finding in cases of dermatomyositis associated with calcinosis of deep soft tissues and skeletal muscle[27,87]. Vacuolar alteration of the basal layer of the overlying epidermis has been described[87], and the dermis may be edematous or mucinous with perivascular lymphocytic inflammation[89]. Direct immunofluorescence is reported to be negative for deposits along the dermal–epidermal junction[87], although immunoreactants have been detected in vessel walls[89].

Differential Diagnosis

Lupus panniculitis is more likely to show hyaline necrosis and lymphoid nodules, but clinical and laboratory findings may be needed to make a distinction. Overlying poikilodermatous changes can occur in both diseases, but lupus is more likely to show appendageal involvement and is associated with positive basement membrane zone fluorescence.

Treatment

Good responses to therapy have generally been reported[89], and treatments include prednisone, methotrexate, azathioprine, JAK inhibitors, cyclosporine, and IVIg[87,89]. Panniculitis lesions have shown variable responses to hydroxychloroquine. Residual facial lipoatrophy has been successfully treated with hyaluronic acid and poly-L-lactic acid dermal fillers.

TRAUMATIC PANNICULITIS

Key features

- Inflammation in the subcutis resulting from external injury
- The injurious event may be accidental, purposeful, or iatrogenic, and it may be a manifestation of an underlying psychiatric disturbance
- A variety of histopathologic changes are observed, depending upon the inciting agent
- Identification of foreign material is of greatest help in diagnosis

Introduction

Extrinsic injury of varying types can produce panniculitis. There are four broad categories: cold panniculitis (Haxthausen disease), sclerosing lipogranuloma, panniculitis due to other injectable substances or therapies (e.g. megavoltage radiation), and panniculitis due to blunt trauma.

History

Lemez described cold panniculitis in 1928, when he noted that newborns and infants up to 6 months of age were particularly susceptible to cold injury, as demonstrated by the production of a subcutaneous nodule following application of an ice cube. In 1941, Haxthausen described a condition occurring in small children a few days after exposure to cold, consisting of firm infiltrated nodules of the cheeks and chin. A similar type of cold injury due to popsicles was reported by Epstein and Oren in 1970.

Injection of foreign lipid material into the skin for cosmetic or other purposes has been performed for centuries. In 1950, Smetana and Bernhard reported 14 cases of what they termed *sclerosing lipogranuloma* of the male genitalia. They believed it was an endogenous process, but subsequent studies demonstrated the presence of mineral oil in similar cases.

Epidemiology

Infants and small children are most at risk for cold panniculitis. A form of the disease also occurs on the thighs of young women who are equestrians[90]. Sclerosing lipogranuloma of the male genitalia is seen mostly in young adults[91]. A sclerosing, pseudosclerodermatous panniculitis has been reported following megavoltage radiation for metastatic carcinoma[92] and as a radiation recall reaction after cyclophosphamide therapy[93].

Pathogenesis

Cold injury to fat favors small children, due in part to the previously discussed characteristics of their fat[94]. Cold injury is also related to

fluctuations in blood flow that occur with declining temperatures (the "hunting phenomenon"), ice crystal formation, and the changes that occur with thawing[94]. Injections of oils (and associated impurities) are known for producing subcutaneous inflammation. Substances include mineral oil (paraffin) as well as camphor, cottonseed, and sesame oils. Even medical grade silicone may contain impurities, and since encapsulation of this material is desirable when used for cosmetic purposes, fibrosis-inducing substances such as olive oil or castor oil are often added. Injected substances responsible for factitial panniculitis have included milk, feces, and a host of other substances.

Panniculitis has also been produced at the sites of injection by numerous therapeutic agents, such as pentazocine, phytonadione (vitamin K)[95], glatiramer acetate, interferon-β, interleukin-2[96], heparin, and vaccines (e.g. tetanus), as well as substances that have been used for tissue augmentation such as bovine collagen[97] or poly-L-lactic acid. More recently, panniculitis due to "mesotherapy" (injection of substances such as phosphatidylcholine and deoxycholate to treat localized fat accumulations; see Ch. 156)[98] and electroacupuncture[99] have been described. In addition to the foreign body response elicited by many of these agents, other immune mechanisms may also be involved. With blunt trauma, granulomas contain material that may be derived from the breakdown of erythrocyte membranes[100].

Clinical Features

In cold panniculitis (including popsicle panniculitis), erythematous, firm nodules develop, particularly on the cheeks and chin[94]. In equestrian cold panniculitis, erythematous to violaceous, tender plaques appear on the thighs following exposure to cold while wearing tight-fitting clothing (Fig. 100.17)[90]. While equestrian cold panniculitis is a commonly used term in the literature, it has been suggested that equestrian perniosis would be a more apt term given that the inflammatory infiltrate is primarily in the dermis.

In lipogranuloma, nodules are sometimes migratory and can be accompanied by varying degrees of swelling, erythema, abscess formation, lymphangitis, and fibrosis. The term *sclerosing lipogranuloma* often refers to lesions arising on the male genitalia due to self-injection of oily materials (see Ch. 94). There has also been a report of a sclerosing lipogranuloma that apparently resulted from topical application of vitamin E cream[101]. In several Japanese patients, Y-shaped induration of the scrotum (in which exogenous lipids could not be detected) was described as eosinophilic sclerosing lipogranuloma[102]. Patients with sclerosing lipogranuloma frequently deny self-injection, making diagnosis difficult. Another variant of lipogranuloma is the *grease gun granuloma*, which results from accidental firing of the grease gun used by mechanics. This results in formation of a verrucous nodule, often on the dorsum of the hand[103].

Fig. 100.17 Cold panniculitis. Violaceous nodules and plaques, some with central crusting, on the thigh of a young woman. Collarettes of scale developed as the lesions healed. While equestrian cold panniculitis is a commonly used term in the literature, it has been suggested that equestrian perniosis would be a more apt term given that the inflammatory infiltrate is primarily in the dermis. *Courtesy Kendra Lesiak, MD.*

Inflamed nodules with varying degrees of pain and fibrosis have been observed in other forms of panniculitis due to injection, with the distribution of lesions sometimes providing a clue to their cause. A dramatic example of this is *Texier disease*, a panniculitis due to phytonadione (vitamin K) injections. In this disorder, sclerotic lesions with lilac-colored borders form on the buttocks and thighs, in a configuration resembling a "cowboy gunbelt and holster"[95]. Lesions due to blunt trauma often have an ecchymotic character and involve locations such as the shin, arm, or hand[100]. Hypertrichosis may also be present, possibly the consequence of local hyperemia or angiogenesis.

Pathology

Table 100.10 outlines the microscopic changes in various forms of traumatic panniculitis[91,93,103–106]. In addition, sclerosing lipogranuloma is discussed in Chapter 94.

Differential Diagnosis

In cold panniculitis, the absence of needle-shaped clefts in lipocytes and location of the most intense inflammation near the dermal–subcutaneous interface help to distinguish this condition from subcutaneous fat necrosis of the newborn. In sclerosing lipogranuloma and related lipogranulomas, distinctive large vacuoles are found in the dermis and subcutis (Fig. 100.18). Mineral oil in non-processed tissue can be identified by infrared spectroscopy[103] or mass spectrometry[107].

Panniculitis due to injectable substances can be diagnosed when foreign material (often identified by polarization microscopy) is present. Cosmetic fillers have distinctive histologic features (see Fig. 94.11), and silicone can be distinguished from other cosmetic fillers by cutaneous ultrasonography[108]. Cases with acute inflammation and necrosis may resemble infection-induced panniculitis, and, in fact, infection may accompany injection panniculitis; special stains and cultures for organisms (including atypical mycobacteria) are useful in this regard. Sclerosing traumatic panniculitis (e.g. due to phytonadione or pentazocine injections) may resemble morphea clinically, but would not present as a septal panniculitis histologically[95].

Treatment

Treatment of these disorders should focus on removal of the inciting stimulus and eradication of any associated infection. Intralesional or systemic corticosteroids can be helpful in controlling the inflammation, and they have been used in the management of sclerosing lipogranuloma and granulomatous panniculitis due to other injected substances[97]. Surgical excision may also be an option for sclerosing lipogranuloma.

LIPODERMATOSCLEROSIS

Synonyms: ■ Sclerosing panniculitis ■ Hypodermitis sclerodermiformis ■ Chronic panniculitis with lipomembranous changes

Key features

- Favors the medial aspect of the lower extremities above the malleolus
- Acute phase with erythema, warmth, and tenderness, which may be misdiagnosed as infectious cellulitis
- Chronic phase with induration and red–brown to violet–brown discoloration
- Usually develops in the setting of chronic venous insufficiency
- Both septal and lobular panniculitis; lipomembranous changes are common, particularly in chronic lesions

Introduction

Erythema, induration, and pigmentary changes have long been known to be associated with venous insufficiency. Because of the variety of clinical appearances and histopathologic findings that can occur at different stages of the disease, a number of diagnostic terms have been

MICROSCOPIC FEATURES OF TRAUMATIC PANNICULITIS		
Condition	**Microscopic features**	**Special considerations**
Cold panniculitis	Septal/lobular inflammation, especially at the dermal–subcutaneous border and periadnexally; lymphocytes, neutrophils, foamy macrophages, poorly developed granulomas; mucin, adipocyte necrosis, microcysts	Needle-shaped clefts are not observed
Lipogranuloma	*Sclerosing lipogranuloma* – granulomatous lobular panniculitis with marked fibrosis and numerous round or oval vacuoles of various sizes in the dermis and subcutis, producing a "Swiss cheese" appearance (Fig. 100.18); nodular aggregates of lymphocytes, plasma cells, eosinophils, macrophages or giant cells often present *Grease gun granuloma* – also pseudoepitheliomatous hyperplasia	Exogenous oils within the vacuoles can be identified in frozen sections stained with oil red O, silver bromide and osmium tetroxide; infrared spectroscopy; mass spectrometry
Injection-induced panniculitis	Central nidus of subcutaneous inflammation; sometimes fibrosis* or polarizing foreign material	*Povidone panniculitis* – gray–blue material within macrophages on routine staining that also stains with Congo red and chlorazol-fast pink *Cancer vaccines*, *heparin* – eosinophils may be numerous
Panniculitis due to aluminum in vaccines	Nonspecific lobular panniculitis with fibrosis; formation of numerous lymphoid follicles; may resemble lupus panniculitis, pseudolymphoma (see Table 121.1)	Macrophages display grayish to violaceous, granular cytoplasm due to lysosomes that contain aluminum salts; can be identified using X-ray microanalysis or possibly aluminum staining
Panniculitis due to injectable aesthetic microimplants	Diffuse granulomatous infiltrate that may involve the dermis and subcutis; focal areas of collagen degeneration	Different "fillers" can have specific histopathologic features (see Fig. 94.11 & Table 94.5)
Blunt trauma	Organizing hematoma, focal granuloma	Deposits of glycosaminoglycans (mucopolysaccharides) and iron can be seen
Postirradiation or radiation recall panniculitis	Deep fibrosis, mixed inflammation	Inflammation includes lymphocytes, plasma cells, macrophages, eosinophils

*Especially with phytonadione (vitamin K) and pentazocine injections; lipid-containing vacuoles, fat necrosis, foam cells, thrombosis and endarteritis are also observed in the latter.

Table 100.10 Microscopic features of traumatic panniculitis.

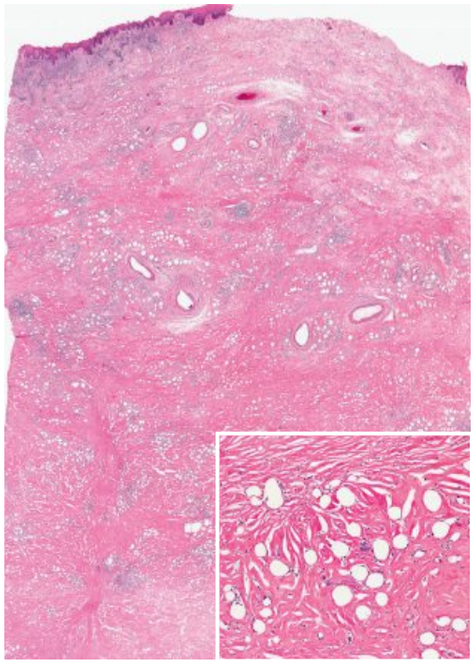

Fig. 100.18 Mineral oil granuloma (paraffinoma). There is sclerosis throughout the dermis and subcutis as well as numerous vacuolated spaces (inset). Scattered histiocytes and lymphocytes are also seen. *Courtesy Lorenzo Cerroni, MD.*

employed to explain the changes. Recently, the various manifestations of this panniculitis have been consolidated under the heading of *lipodermatosclerosis* or *sclerosing panniculitis*.

History

In 1955, Huriez drew attention to a related indurated lesion, which he termed *hypodermitis sclerodermiformis*.

Epidemiology

Most patients are women over the age of 40 years, but appearance after the age of 75 years has also been reported[109,110].

Pathogenesis

There is considerable evidence for venous insufficiency in patients with lipodermatosclerosis[111], and fibrinolytic abnormalities are also present in these individuals. Venous hypertension leads to a compromised ability to reduce foot vein pressure during exercise. This results in increased capillary permeability, which causes leakage of fibrinogen, its polymerization to form fibrin cuffs around vessels, impedance of oxygen exchange, and tissue anoxia (see Ch. 105)[110]. Pericapillary fibrin deposits can be seen in uninvolved, clinically normal extremities of patients with healed venous ulcers of the opposite extremity, suggesting that this abnormality precedes the clinical changes of lipodermatosclerosis[112].

There may also be an abnormal regulation of angiogenesis within lesions of lipodermatosclerosis. In particular, increased expression of vascular endothelial growth factor receptor 1 (VEGFR-1), which can act as a negative regulator of VEGF-mediated angiogenesis, has been observed, along with increased expression of angiopoietin-2 (Ang-2)[113]. Additional factors contributing to the pathogenesis of lipodermatosclerosis may include protein C and S deficiencies[114], local stimulation of collagen synthesis[110], including an increased number of cells expressing procollagen type 1 mRNA[115], and obesity.

Clinical Features

The acute phase of lipodermatosclerosis presents with pain, warmth, erythema, and some induration (Fig. 100.19), most often initially on the medial lower leg above the malleolus. Other dependent sites such as the lower aspect of the abdominal pannus can also develop lipodermatosclerosis. At this point, the changes are relatively diffuse[110]. In the chronic phase, there is marked sclerosis of the dermis and subcutis, resulting in induration that is more sharply demarcated from adjacent normal skin. Brown discoloration due to hemosiderin deposition may also be present[109]. These features give the affected leg the appearance of an inverted wine bottle[116].

Pathology

Early lesions show mid-lobular ischemic necrosis, a lymphocytic infiltrate in the septa that rims the fat lobules, variable degrees of capillary congestion and thrombosis, and hemorrhage with

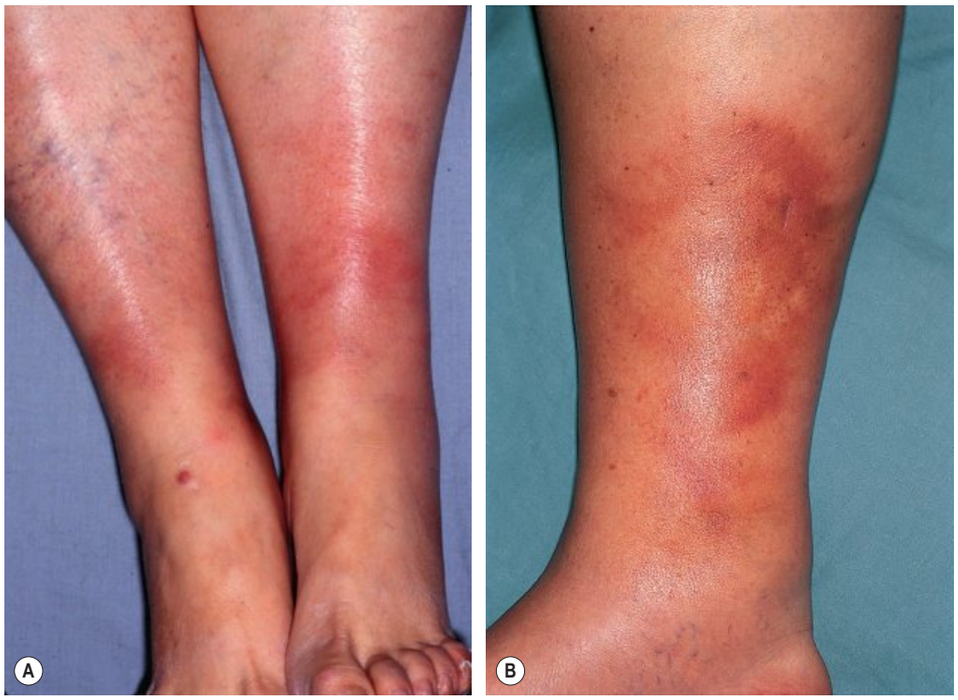

Fig. 100.19 Lipodermatosclerosis – clinical appearance. A Acute phase with tender erythematous plaques on both lower extremities. **B** Chronic phase with sclerotic red–brown plaque on the lower medial leg. *B, Courtesy Kenneth E. Greer, MD.*

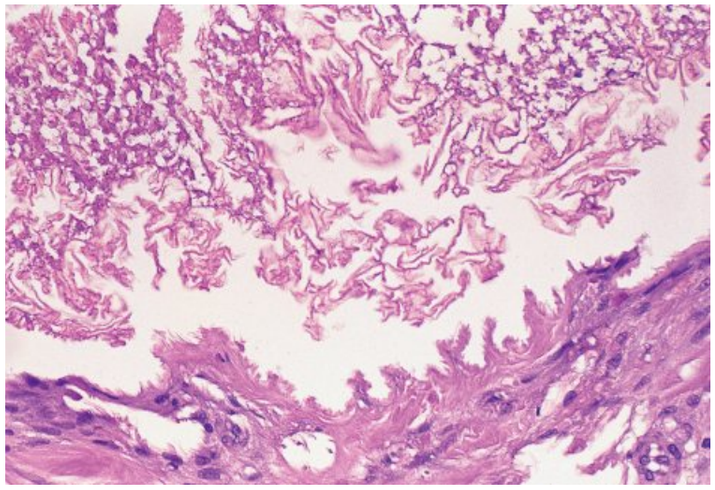

Fig. 100.20 Lipodermatosclerosis – histopathologic features. Lipomembranous change, consisting of cystic formation with elaborate papillary configurations.

hemosiderin deposition. With progression, septal thickening, hyaline sclerosis involving lipocytes, lipophage formation, and mixed inflammatory cell infiltrates appear[109]. Advanced lesions show marked septal sclerosis and membranocystic change in the face of a marked reduction in inflammation.

Membranocystic change is a key feature in lipodermatosclerosis[117]. This consists of thickened, undulating membranes that form cysts and papillary configurations (Fig. 100.20). The membranes are believed to result from degenerated cell membranes of lipocytes and/or macrophages. The material comprising the membranes is ceroid, an oxidation product of unsaturated fatty acids[118].

Short, frayed elastic fibers can be present within the subcutaneous septa, and these may be calcified, features that resemble pseudoxanthoma elasticum[119]. Myospherulosis, a foreign-body type of granulomatous reaction to lipid-containing material and blood, has been described in lesions of lipodermatosclerosis[120]. By phosphotungstic acid–hematoxylin stain or by immunofluorescent methods, pericapillary fibrin can also be demonstrated in lesions of lipodermatosclerosis[117]. Dermal changes include fibrosis, tortuous thick-walled veins, and superficial and deep perivascular inflammation[109]. Biopsy should be avoided if the diagnosis is obvious, since poor wound healing and ulceration frequently result. When necessary, a thin elliptical excision should be obtained from the margin of a lesion.

Differential Diagnosis

Difficulties in clinical diagnosis arise most often in early lesions, when the process is more diffuse and erythematous. At this stage, consideration is often given to infectious cellulitis, erythema nodosum, or erythema induratum[109,110,116]. Persistence of a lesion, association with stasis changes, and lack of response to antimicrobials suggest the correct diagnosis, perhaps aided by studies of venous function[111].

As induration develops and progresses, differentiation from morphea and scleromyxedema may be necessary. In morphea, subcutaneous involvement is predominantly septal, and lipophagic and lipodystrophic changes are not as prominent as they are in lipodermatosclerosis[109]. Membranocystic changes, when present, can be of great diagnostic help; however, these findings can occur in a variety of other conditions, including lupus and dermatomyositis panniculitis, liposarcoma, erythema nodosum, and diabetic dermopathy[118].

Treatment

Leg elevation and consistent compression therapy are the mainstays of treatment for lipodermatosclerosis[110]. Traditional anti-inflammatory therapies are usually ineffective in this condition[109], although intralesional corticosteroids (e.g. triamcinolone 5–10 mg/cc) may be of benefit when used in conjunction with compression therapy. Good results were reported with the anabolic steroid stanozolol[110] especially in the earlier phases of the disease, but this medication is no longer commercially available. As a result, danazol has been used (successfully) as a substitute[121]. Anabolic steroids enhance fibrinolysis, and they can reduce pain, extent of involvement, and induration of the skin. However, side effects of sodium retention, lipid profile abnormalities, hepatotoxicity, and virilization in women do limit their use. Oxandrolone, an anabolic steroid with less hepatotoxicity and fewer androgenic effects, represents another therapeutic option[113]. Other reported treatments include ultrasound, pentoxifylline, fasciotomy, and phlebectomy[110,122].

INFECTION-INDUCED PANNICULITIS

Synonym: ■ Infective panniculitis

Key features

- A wide variety of infectious agents has been reported to produce panniculitis
- Some degree of immunosuppression is common, but not invariable
- Histopathologic findings vary, but often include mixed septal/lobular panniculitis, neutrophilic infiltration, hemorrhage, and necrosis
- Special staining and culture of drainage and tissue can provide a definitive diagnosis

Introduction

Panniculitis can result from a distant focus of infection (a classic example being erythema nodosum) or panniculitis can be *directly* induced by an infectious agent. The latter can produce a variety of clinical and microscopic appearances, although there are some features that infection-induced lesions have in common, regardless of the etiologic agent.

History

While multiple reports of panniculitis directly caused by infectious agents have been published, most early studies of deep skin infections did not focus upon the changes in the subcutaneous fat. In 1989, Patterson et al.[18] studied 15 cases of infection-induced panniculitis, with an emphasis upon the histopathologic features in the subcutis. Since that time, additional reports of panniculitis due to infection have continued to appear.

Epidemiology

There appears to be no age, sex, or racial predilection among cases of infection-induced panniculitis. Many of these patients are immunosuppressed[18] or have predisposing medical conditions such as diabetes mellitus.

Pathogenesis

In this group of disorders, infectious agents are considered to be directly responsible for the panniculitis. Examples of reported microorganisms to date are listed in Table 100.11[18,123–126].

Involvement of the subcutis can result from direct inoculation or septicemia. Other potential modes of spread include transfascial from an enteric source, in the case of abdominal panniculitis or via "persorption", a proposed mechanism by which *Candida* migrates across intact endothelium from the gut to a subcutaneous site[124]. Immunosuppression is common, but not invariable, among individuals with infection-induced panniculitis.

Clinical Features

Patients develop local swelling and erythema. There may be one or more fluctuant nodules that ulcerate and drain. Lesions on the legs and feet are common, but other sites of involvement include the gluteal region, abdomen, axillae, arm, or hand. In addition to sepsis, underlying conditions include diabetes mellitus, leukemias or solid tumors, autoimmune connective tissue disease, AIDS, and organ transplantation.

Pathology

Individual cases can mimic other primary forms of panniculitis. Common changes (regardless of the infectious agent) include a mixed septal/lobular panniculitis, neutrophilic infiltration, vascular proliferation, hemorrhage, and necrosis that involves lipocytes, inflammatory cells, and eccrine sweat coils[18] (Fig. 100.21). In Q fever due to *Coxiella burnetii*, there may be a "doughnut-like" granulomatous lobular panniculitis, in which fibrin and inflammatory cells form a ring around a central clear space; similar changes have been found in the liver and bone marrow of patients with Q fever[123]. In lobular panniculitis due to *Stenotrophomonas maltophilia* (previously *Pseudomonas maltophilia*), phagocytosis of bacteria leads to foamy histiocytes whose cytoplasm is filled with bluish, granular material.

INFECTION-INDUCED PANNICULITIS – REPORTED CAUSATIVE AGENTS
Bacteria
Staphylococcus aureus Group A *Streptococcus* *Pseudomonas aeruginosa* *Stenotrophomonas maltophilia* *Brucella melitensis* *Nocardia asteroides* *Tropheryma whipplei* (causative agent of Whipple disease)
Mycobacteria
M. tuberculosis *M. marinum, M. avium-intracellulare, M. chelonae, M. fortuitum, M. ulcerans*
Coxiella
C. burnetii
Borrelia
B. burgdorferi
Fungi
Blastomyces dermatitidis, Histoplasma capsulatum *Microsporum* spp. (including *M. canis*) *Candida* spp. (including *C. albicans*) *Cryptococcus neoformans* *Aspergillus* spp. (including *A. flavus*), *Mucor* or related zygomycetes, *Fusarium* spp., *Aureobasidium pullulans*
Helminths & protozoa
Nematodes (*Gnathostoma* spp.) Trematodes (*Fasciola hepatica*, *Schistosoma* spp.)

Table 100.11 Infection-induced panniculitis – reported causative agents.

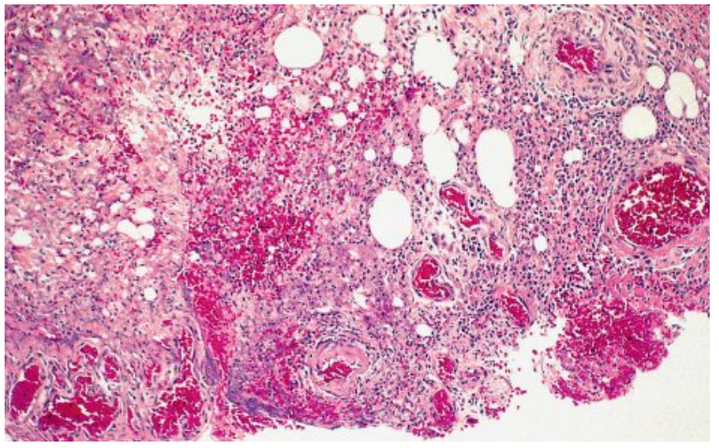

Fig. 100.21 Infection-induced panniculitis. Bacterial panniculitis, showing heavy neutrophilic infiltration, basophilic necrosis, vascular proliferation, and hemorrhage.

Differential Diagnosis

Fluctuant, ulcerating nodules also occur in pancreatic panniculitis, traumatic panniculitis, and alpha-1 antitrypsin deficiency panniculitis. Clinical and laboratory data can usually permit distinction. As noted previously, traumatic panniculitis may be accompanied by infection. Examples of infection-induced panniculitis with predominantly septal involvement or vasculitis could be confused with acute erythema nodosum or erythema induratum, respectively. Panniculitis due to mucormycosis may feature "ghost cells" and granular calcium deposits and thus resemble pancreatic panniculitis; it can also mimic gouty panniculitis due to the presence of intracellular crystalline deposits[126]. Special stains for organisms and cultures of drainage and tissue are keys to the diagnosis. In one study, special stains were positive for organisms in 14 of 15 cases[18].

Fig. 100.22 Cytophagic histiocytic panniculitis – clinical appearance. Subcutaneous nodules with purpura. *Courtesy Kenneth E. Greer, MD.*

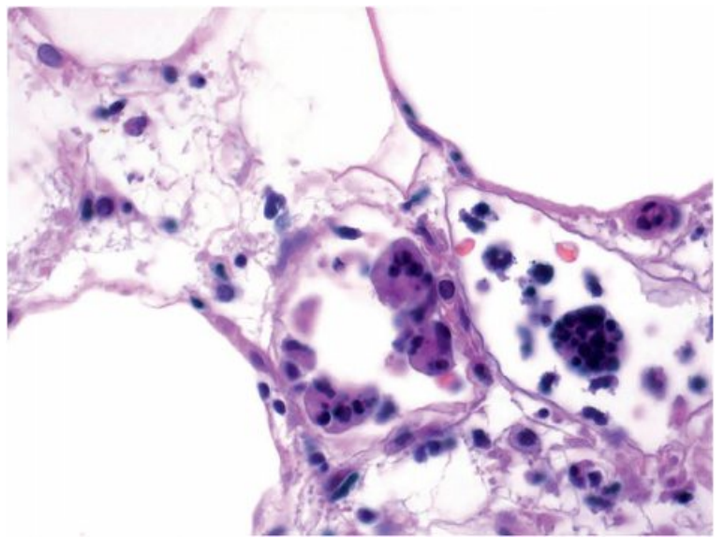

Fig. 100.23 Cytophagic histiocytic panniculitis – histopathologic features. Macrophages engaged in cytophagic activity. Some of them have the appearance of "bean bag" cells.

Treatment

Treatment consists of appropriate antimicrobial therapy. Surgery may be indicated for isolated lesions caused by grain-forming fungi or bacteria, such as mycetoma or botryomycosis. A more radical surgical approach has been used successfully in treating abdominal panniculitis due to enteric bacteria.

CYTOPHAGIC HISTIOCYTIC PANNICULITIS

The term "cytophagic histiocytic panniculitis" (CHP) has been used to describe subcutaneous nodules or plaques that on histologic examination show infiltrates of macrophages containing erythrocytes, lymphocytes, and/or karyorrhectic debris, i.e. exhibiting hemophagocytosis (Figs. 100.22 & 100.23)[127]. These macrophages with cytophagic activity have been referred to as "bean bag" cells. With the advent of immunophenotyping and genetic techniques, it has become apparent that the vast majority of patients have lymphoma, with atypical lymphoid cells also present within the panniculus[128]. In general, the lymphomas represent subcutaneous involvement of primary cutaneous γ/δ T cell lymphoma or EBV-associated extranodal NK/T cell lymphoma, nasal type (see Ch. 120)[129]. Occasionally, patients have subcutaneous panniculitis-like T cell lymphoma, and, rarely, no lymphoma[130]. Individuals in the latter group may still have a fatal course due to a hemophagocytic syndrome that involves the liver, spleen, and bone marrow (leading to pancytopenia). Mutations in a number of genes can predispose individuals to the development of hemophagocytic syndrome, including that which encodes perforin (see Table 91.1). Of note, a child with microscopic findings of CHP but no evidence of lymphoma was found to have a heterozygous nonsense mutation in the gene that encodes perforin[131].

MALIGNANT SUBCUTANEOUS INFILTRATES

Malignant infiltrates may involve the subcutis, mimicking the clinical and microscopic appearance of panniculitis. The best known of these is subcutaneous panniculitis-like T cell lymphoma (see Ch. 120). While cytophagia can be seen in the latter disorder, it is particularly characteristic of subcutaneous involvement of primary cutaneous γ/δ T cell lymphoma and EBV-associated extranodal NK/T cell lymphoma, nasal type (see above). Other lymphomas (e.g. B cell), leukemias, and metastatic solid tumors may infiltrate the subcutis. Obviously, clinical information is crucial in such cases.

Histopathologic clues include the recognition of significant pleomorphism or monotony among infiltrating cells in the subcutis, infiltration between collagen bundles of the dermis or around adnexal structures, and supporting immunohistochemical studies. Of note, the diagnosis of subcutaneous panniculitis-like T cell lymphoma can sometimes be elusive as the initial impression may be lupus panniculitis (see Table 100.9) or even a nonspecific panniculitis with lipomembranous changes[132].

UNUSUAL OR NEWLY DESCRIBED FORMS OF PANNICULITIS

Table 100.12 lists several more recently described or unusual forms of panniculitis. In addition, there is an ever-expanding list of drugs that can induce panniculitis, especially with the introduction of immuno- and targeted therapies (see Table 100.3). When a patient presents with panniculitis that is not readily classifiable, it may be worthwhile to consider these alternative diagnoses. Several of them probably do not actually represent distinct entities but rather overarching terms that include established forms of panniculitis. For example, plasma cell panniculitis could include not only morphea and postirradiation pseudosclerodermatous panniculitis but also other autoimmune connective tissue diseases or infectious diseases. The fasciitis–panniculitis syndrome is a term that has appeared from time to time, primarily in the non-dermatology literature. While sometimes discussed as if it were a single entity, fasciitis–panniculitis syndrome has been used to include eosinophilic fasciitis, morphea profunda, lupus panniculitis, lipodermatosclerosis, and a variety of other conditions. Sweet syndrome and Lyme disease are established entities that can occasionally have panniculitis as a significant finding. Two other more recently described conditions, atypical lymphocytic lobular panniculitis and panniculitic bacterid, may require further study and experience before being widely accepted as distinct entities. No doubt this list will change as disease mechanisms are better understood and disorders are reclassified or absorbed into other classification schemes.

Additional figures and table on Classification of the panniculitides, available in our eBook (see inside front cover for access code).

UNUSUAL OR RECENTLY DESCRIBED FORMS OF PANNICULITIS			
Type of panniculitis	**Clinical features**	**Microscopic findings**	**Comments**

Crystal deposition panniculitis	Red nodules, sometimes with necrosis; may have drainage; legs and elsewhere	Necrotizing and/or granulomatous panniculitis; calcium oxalate crystals in subcutaneous vessels; subcutaneous deposits of sodium urate crystals
		Crystals of Igs in the cytoplasm of histiocytes
			• Metabolic
			  • Oxalosis: primary (inherited) or secondary (chronic renal failure)
			  • Urate deposition: may be an isolated cutaneous finding in gout
			• Paraneoplastic
			  • Crystal-storing histiocytosis: associated with hematologic malignancies

Idiopathic palmoplantar hidradenitis (see Ch. 39)	Sudden onset of painful erythematous nodules; soles > palms Self-limited	Neutrophilic eccrine hidradenitis	More common in children Precipitated by trauma (mechanical, thermal) Mimicked by erythema nodosum, pseudomonas hot-foot syndrome, cold panniculitis
Sweet panniculitis (subcutaneous Sweet syndrome)*	Erythematous nodules that may be painful; extremities; associated with leukemias (e.g. AML, hairy cell leukemia), treatment of acute promyelocytic leukemia with all-*trans*-retinoic acid, and, rarely, solid tumors	Predominantly neutrophilic lobular panniculitis, without vasculitis; immature myeloid forms have been described	Must exclude other neutrophil-rich forms of panniculitis, such as infection-induced, traumatic, alpha-1 antitrypsin deficiency and pancreatic panniculitides
Panniculitic bacterid	Sudden onset of tender subcutaneous nodules; lower extremities; polyclonal hypergammaglobulinemia, cold agglutinins, cryofibrinogens	Lobular panniculitis, predominantly neutrophils with microabscesses; angiopathy; extravascular granulomas	Triggered by non-tuberculous infections; underlying disorders include atopy, antiphospholipid antibody syndrome
Plasma cell panniculitis	Hyperpigmentation and induration; trunk and extremities	Sclerosis of subcutaneous septa; plasma cells prominent component of infiltrate	Not a single entity; manifestation of morphea profunda, other autoimmune connective tissue disorders, and postirradiation pseudosclerodermatous panniculitis
Panniculitis of Lyme disease	Tender nodules or diffuse fasciitis; fever, chills, photophobia, polyarthritis	Acute septal panniculitis; may contain eosinophils, plasma cells; lymphocytic vasculopathy	Detection of *Borrelia* spp. in tissues; positive serologies confirm the diagnosis
Fasciitis–panniculitis syndrome	Subcutaneous induration, sometimes with regional pain	Chronic inflammation, accompanied by replacement of fat lobules by fibrous tissue; thickening of fascia	Term used primarily in the rheumatologic literature; encompasses several autoimmune connective tissue diseases; also described as a paraneoplastic syndrome with hematologic, pancreatic, and gastrointestinal malignancies
Atypical lymphocytic lobular panniculitis	Recurrent, infiltrative plaques; lower extremities, abdomen	Interstitial subcutaneous infiltrate with well-differentiated lymphocytes; no significant fat necrosis	Molecular studies show clonal or oligoclonal profile; no progression to lymphoma; considered T cell dyscrasia
Infantile-onset panniculitis with uveitis and systemic granulomatosis	High fever, anemia, hepatosplenomegaly, uveitis, arthritis	Histiocytic lobular panniculitis, with lymphocytes and neutrophils initially; granulomas in later stage	Resemblance to Blau syndrome, but lacks *NOD2/CARD15* mutations; may respond to TNF inhibitors
*Neutrophilic panniculitis also may precede the lipodystrophy of proteasome-associated autoinflammatory syndrome/CANDLE (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) syndrome (see Table 45.7).			

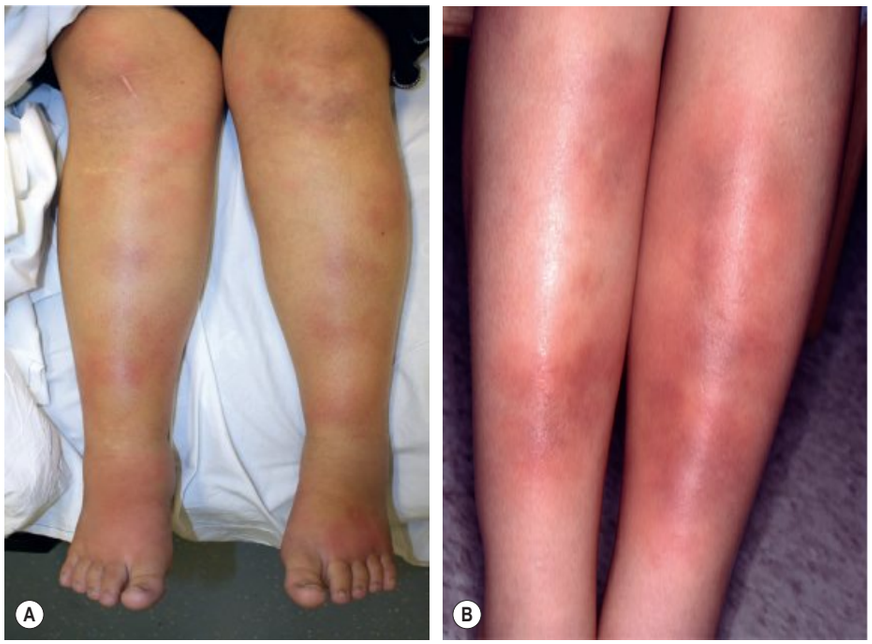

Table 100.12 Unusual or recently described forms of panniculitis. AML, acute myelogenous leukemia; TNF, tumor necrosis factor.

CLASSIFICATION OF THE PANNICULITIDES
Predominantly septal panniculitis
• Erythema nodosum   • Erythema nodosum migrans (subacute nodular migratory panniculitis) • Panniculitis of morphea/systemic sclerosis • Alpha-1 antitrypsin deficiency panniculitis*
Lobular and mixed septal–lobular panniculitis

• With vasculitis involving septal veins or arteries, lobular venules or small veins
  • Erythema induratum (nodular vasculitis)
• With necrosis as an early finding
  • Pancreatic panniculitis
• With needle-shaped clefts within lipocytes
  • Sclerema neonatorum
  • Subcutaneous fat necrosis of the newborn
  • Post-steroid panniculitis
• Associated with autoimmune connective tissue disease
  • Lupus erythematosus panniculitis (lupus profundus)
  • Panniculitis of dermatomyositis
• Lipodystrophic panniculitis (see Ch. 101)
  • Lipoatrophy
  • Lipohypertrophy
• Traumatic panniculitis, including factitial panniculitis
  • Cold panniculitis (popsicle panniculitis, Haxthausen disease)
  • Sclerosing lipogranuloma (including grease gun granuloma)
  • Panniculitis due to other injectable substances
  • Panniculitis due to blunt trauma
• Lipodermatosclerosis
• Infection-induced panniculitis
• Malignancy-related panniculitis-like infiltrates
  • Subcutaneous panniculitis-like T cell lymphoma (see Ch. 120)
  • Other lymphomas with involvement of subcutaneous tissues

*Descriptions vary; some authors regard this as a lobular or mixed septal–lobular panniculitis.

eTable 100.1 Classification of the panniculitides. The categories for classification of panniculitis are determined partly by clinical characteristics such as location and associated diseases and partly by histopathology. This classification scheme does not include Weber–Christian disease as cases initially assigned this designation have subsequently been reclassified as other forms of panniculitis, including alpha-1 antitrypsin deficiency, lipodermatosclerosis, lupus panniculitis, and traumatic panniculitis.

101 Lipodystrophies

Suat Hoon Tan, Hong Liang Tey and Joel Hua Liang Lim

Subtypes: ■ Lipodystrophy: lipoatrophy, lipohypertrophy

Key features

- Lipodystrophies are inherited or acquired disorders characterized by a paucity or complete absence of fat that may be generalized, partial, or localized; lipohypertrophy may accompany the lipoatrophy
- Though the terms lipodystrophy and lipoatrophy are often used interchangeably, lipoatrophy should be used specifically for selective loss of fat, with lipodystrophy implying a redistribution of fat, in part due to a hypertrophic compensation of the non-atrophic fat
- Lipodystrophy syndromes represent a heterogeneous group of disorders that are characterized by lipoatrophy ± fat accumulation in characteristic body distribution patterns
- Fat is a metabolically active organ, thus fat loss can be associated with metabolic derangements, which parallel the extent and duration of lipoatrophy
- Lipodystrophy is often accompanied by the metabolic syndrome, which includes insulin resistance, diabetes mellitus, hyperinsulinemia, dyslipidemia, cardiovascular disease, and hepatic steatosis
- In addition to the metabolic syndrome, systemic manifestations of generalized and partial lipodystrophy syndromes include hormonal abnormalities, organ dysfunction, anabolic features, glomerulonephritis, and autoimmune disorders
- A distinct syndrome of peripheral lipoatrophy, central obesity, breast hypertrophy, dorsocervical fat pad enlargement, hyperlipidemia and insulin resistance occurs in patients with HIV infection undergoing treatment with antiretroviral therapy (ART)
- Isolated or localized lipoatrophy can occur at the site of medication injection, trauma or pressure, in association with autoimmune connective tissue disease, or following certain panniculitic inflammatory or neoplastic processes
- Microscopically, there may be a complete absence of subcutaneous fat or a decrease in adipocyte size and number. An inflammatory panniculitis may be seen in early disease

INTRODUCTION

Lipodystrophy describes a heterogeneous group of diseases characterized by a selective fat loss in a characteristic body distribution pattern, often accompanied by secondary fat accumulation. Adipose tissue has crucial metabolic and endocrine functions, in addition to its role in mechanical protection. The loss of subcutaneous fat and a compensatory accumulation of visceral fat is closely associated with insulin resistance, diabetes mellitus, dyslipidemia, hypertension, and coronary artery disease. These metabolic abnormalities and their sequelae constitute the metabolic syndrome and underscore the important functions of fat, in its role as a diverse and crucial body organ.

More than a century after the first description of lipodystrophy[1] and then delineation of generalized lipodystrophy into congenital and acquired forms[2], the genetic bases of several of the inherited lipodystrophies have now been elucidated. Mutations have been found in genes ranging from those encoding proteins essential for adipocyte differentiation to those encoding nuclear lamins (see below).

Clinically, lipodystrophy can be broadly classified into inherited or acquired forms and then further subclassified based on the extent of fat loss, in conjunction with genetic mutations, age of onset, and systemic manifestations (Fig. 101.1 & Table 101.1). Based upon the distribution pattern, lipodystrophy may be subdivided into three major groups: (1) generalized; (2) partial (extensive, but not generalized); and (3) localized (involving an isolated area).

Localized lipodystrophy, which may be due to injections of medications or vaccines, pressure, previous surgery, trauma or panniculitis, is the most commonly encountered form. It typically presents as lipoatrophy but occasionally lipohypertrophy develops, e.g. at sites of insulin injection (see Table 21.22). Less often, lipodystrophy associated with antiretroviral therapy (ART) for human immunodeficiency virus (HIV) infection[3] and with administration of immune checkpoint inhibitors are seen. Dermatologists may also play a key role in diagnosing acquired generalized lipodystrophy and its preceding panniculitis. Finally, there are several rare genetic syndromes that will be discussed (see Table 101.1).

PATHOGENESIS

Adipose tissue functions as an endocrine organ via its secretion of hormones and adipocytokines, such as leptin, TNF, interleukin (IL)-6, and adiponectin. Altered expression and activity of these factors play a role in the development of insulin resistance and other metabolic sequelae seen in lipodystrophic syndromes, which are similar to those observed in the metabolic syndrome and obese individuals[4,5].

There appears to be a final common pathway of defective adipocyte triglyceride storage in conditions characterized by fat loss as well as fat excess. This defect can result from impaired triglyceride synthesis due to an enzyme deficiency (e.g. 1-acylglycerol-3-phosphate *O*-acyltransferase 2), defective adipocyte development caused by mutations in genes critical to adipocyte differentiation (e.g. *BSCL2/seipin, PPARG, LMNA*), adipocyte apoptosis, or autoimmune- or drug-mediated adipocyte destruction. These various processes impair normal adipocyte differentiation, development, lifespan, and/or function[6].

The destruction or impaired differentiation of adipocytes leads to a cascade of hormonal and metabolic consequences. Adiponectin, the protein product of *ADIPOQ*, is expressed in and secreted exclusively by differentiated adipocytes. It plays a positive role in regulating insulin sensitivity and glucose and lipid homeostasis. Plasma adiponectin levels are inversely correlated with fasting insulin levels and insulin resistance[7]. Serum adiponectin and leptin levels are reduced both in murine models of lipoatrophy with insulin resistance and in humans with congenital and acquired lipodystrophies,[8] including HIV/ART-related lipodystrophy[9,10]. Leptin replacement has been shown to reverse insulin resistance in mouse models with a deficiency of mRNAs that encode leptin.[11] This replacement also results in significant and sustained improvements in hyperglycemia, dyslipidemia, and hepatic steatosis in patients with different forms of lipodystrophy[12,13].

Congenital Generalized Lipodystrophy (Berardinelli–Seip Congenital Lipodystrophy, Berardinelli–Seip Syndrome)

Congenital generalized lipodystrophy (CGL) is an autosomal recessive disorder with four known genetic subtypes. The two major forms, types 1 and 2, are due to mutations in *AGPAT2*, which encodes 1-acylglycerol-3-phosphate *O*-acyltransferase 2, and *BSCL2/seipin*, respectively (see Table 101.1). It has been postulated that these genetic mutations cause lipodystrophy primarily by affecting adipocyte differentiation or lipid droplet formation in adipose tissue. In type 1, aberrant AGPAT2

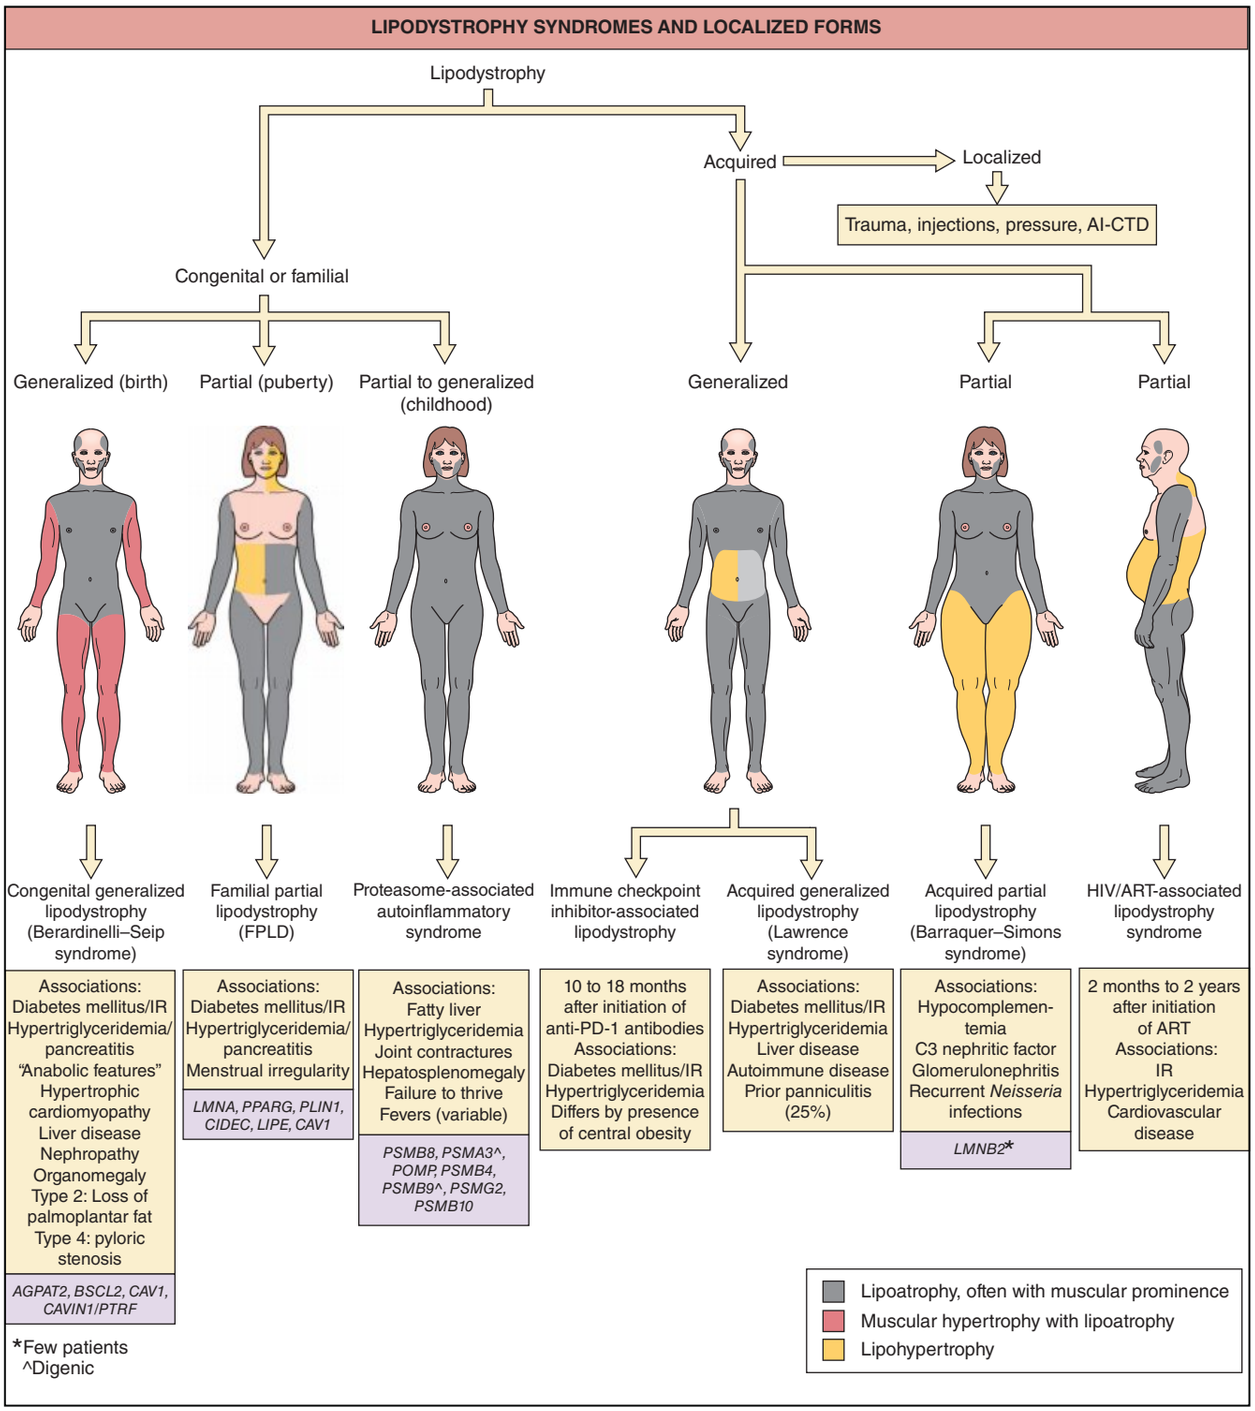

Fig. 101.1 Lipodystrophy syndromes and localized forms. Schematic representation of the predominant sites of lipoatrophy and lipohypertrophy. Additional syndromes, including familial partial lipodystrophy with mandibuloacral dysplasia, are outlined in Table 101.1. Tables 63.9 and 63.10 review progeroid syndromes in which lipoatrophy can be seen. AI-CTD, autoimmune connective tissue disease; ART, antiretroviral therapy; IR, insulin resistance; PD, programmed cell death. *AGPAT2*, encodes 1-acylglycerol-3-phosphate *O*-acyltransferase 2 (triglyceride and phospholipid synthesis); *BSCL2*, encodes seipin (lipid droplet formation); *CAV1*, encodes caveolin 1 (binds fatty acids and translocates them to lipid droplets); *CAVIN1/PTRF*, encodes caveolae associated protein 1 (biogenesis of caveolae and expression of caveolins 1 and 3); *CIDEC*, encodes cell death-inducing DNA fragmentation factor-like effector C (adipocyte apoptosis); *LIPE*, encodes lipase E, hormone sensitive type (hydrolysis of triglycerides to free fatty acids); *LMNA*, encodes lamins A/C (structural integrity of the nuclear lamina); *LMNB2*, encodes lamin B2 (structural integrity of the nuclear lamina); *PLIN1*, encodes perilipin 1 (formation, maturation, and function of lipid droplets within adipocytes); *POMP*, encodes proteasome maturation protein; *PPARG*, encodes peroxisome proliferator-activated receptor-gamma (essential role in lipogenesis); *PSMA3*, encodes proteasome subunit alpha 3; *PSMB4, -B8, -B9, -B10*, encode proteasome subunit beta 4, 8, 9, 10; *PSMG2*, encodes proteasome subunit gamma 2.

enzyme activity causes a marked reduction in triglyceride and phospholipid synthesis, resulting in abnormal adipocyte function[14]. In type 2, *BSCL2* mutations affect the endoplasmic reticulum membrane protein seipin which is critical for lipid droplet morphology.

In types 3 and 4 CGL, genetic mutations alter the function of caveolae, which are invaginations of the plasma membrane involved in signal transduction and endocytosis, including internalization of the insulin receptor. Patients with type 3 CGL have mutations in *CAV1* which encodes caveolin 1[15]; caveolins are essential components of caveolae and caveolin 1 binds fatty acids and translocates them to lipid droplets. Type 4 CGL is due to mutations in *CAVIN1/PTRF*, whose protein product is involved in the biogenesis of caveolae and the expression of caveolins 1 and 3[16].

Differences in the molecular basis of CGL may account for the phenotypic heterogeneity[17]. *AGPAT2* has been found to be highly expressed in human omental adipose tissue, which may explain the preferential loss

LIPODYSTROPHY SYNDROMES							
Syndrome	**Age of onset**	**Sex**	**Genetics**	**Distribution of fat changes**	**Metabolic derangements**	**Systemic associations**	**Additional cutaneous and systemic features**
Inherited							
Congenital generalized lipodystrophy (CGL; Berardinelli–Seip syndrome)	Birth	F = M	AR Type 1: *AGPAT2* Type 2: *BSCL2/seipin* Type 3: *CAV1* Type 4: *CAVIN1/PTRF*	Fat: face, trunk, extremities, viscera Types 1, 3, 4: loss of metabolically active adipose tissue in the skin and viscera, but preservation of mechanical adipose tissue (palmoplantar, retro-orbital) Type 2: both metabolically active and mechanical adipose tissue are lost Types 1, 2: lack of bone marrow fat Types 3, 4: preserved bone marrow fat	+++: IR, DM, ↑ TG; anabolic features; ↑ metabolic rate	Type 3: associated with vitamin D resistance	Hypertrophic cardiomyopathy, liver failure/cirrhosis, acute pancreatitis, organomegaly,osteosclerosis, proteinuric nephropathy (see Table 101.3) More severe disease in type 2, with higher incidence of intellectual disability and cardiomyopathy Type 4: prominent skin veins, cardiac conduction defects, pyloric and esophageal stenosis, muscle weakness
Familial partial lipodystrophy (FPLD; previously referred to as Köbberling–Dunnigan syndrome)	Puberty	F > M	AD FPLD1 (Köbberling type): not known FPLD2 (Dunnigan type): *LMNA* [lamin A/C] FPLD3: *PPARG* FPLD4: *PLIN1* FPLD7: *CAVI* AR* FPLD5: *CIDEC* FPLD6: *LIPE*	FPLD1: ↓ fat on extremities ± ↑ fat on face/neck, trunk FPLD2: ↓ fat on extremities ± trunk, ↑ fat on face/neck (double chin), muscular hypertrophy FPLD3: ↓ fat on extremities/buttocks (less severe than FPLD2); trunk/viscera spared FPLD4: ↓ fat on lower extremities with small adipocytes and increased fibrosis of adipose tissues FPLD5: ↓ fat on lower extremities/buttocks; small, multilocular lipid droplets histologically FPLD6: ↓ fat on lower extremities, ↑ fat of abdomen and axillae	IR, DM, ↑ TG, ↓ HDL (more severe in FPLD3 than FPLD2)	None preceding	Chylomicronemia syndrome with acute pancreatitis, eruptive xanthomas Clinical findings and metabolic complications more severe in women
Familial partial lipodystrophy with mandibuloacral dysplasia (MAD)	Childhood or puberty	M > F	AR Type A: *LMNA* Type B: *ZMPSTE24*	fat on extremities Type B – may have generalized lipodystrophy	IR, DM, ↑ TG, ↓ HDL in some patients	None preceding	Premature aging, hypoplasia of mandible, clavicles and terminal digits, short stature, scleroderma-like skin lesions with mottled skin pigmentation
Proteasome-associated autoinflammatory disorders (PRAAS; PRAAS1 has also been referred to as CANDLE syndrome and Nakajo–Nishimura syndrome)	Childhood	M = F	AR PRAAS1: *PSMB8, PSMA3* (digenic) PRAAS2: *POMP* PRAAS3: *PSMB4*, *PSMB9* (digenic) PRAAS4: *PSMG2* PRAAS5: *PSMB10*	Common features: ↓ facial fat, partial lipoatrophy involving upper half of body Occasionally, generalized lipoatrophy	↑ TG, ↓ HDL cholesterol	None preceding	Panniculitis, pernio-like lesions, eyelid edema and erythema Hepatosplenomegaly, basal ganglia calcifications (for additional features see text)

Table 101.1 Lipodystrophy syndromes.

Table 101.1 Lipodystrophy syndromes. Facial lipoatrophy can be seen in patients with POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes) syndrome and generalized lipoatrophy in children who have undergone an allogeneic hematopoietic stem cell transplant. AR, autosomal recessive; AD, autosomal dominant; *AGPAT2*, 1-acylglycerol-3-phosphate O-acyltransferase 2; *BSCL2*, Berardinelli–Seip congenital lipodystrophy 2 (Seipin) gene; CANDLE, chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature; *CAV1*, caveolin 1 gene; *CAVIN1*, caveolae associated protein 1; *CIDEC*, cell death-inducing DFFA-like effector C; CVID, combined variable immunodeficiency; DM, diabetes mellitus; HDL, high-density lipoproteins; HIV, human immunodeficiency virus; LDL, low-density lipoproteins; IR, insulin resistance; *LIPE*, lipase, hormone-sensitive; PI, protease inhibitor; *PLIN*, perilipin 1; *PPARG*, peroxisome proliferator-activated receptor-γ; PTRF, polymerase I and transcript release factor; POMP, proteasome maturation protein; *PSMA*, proteasome subunit alpha; *PSMB*, proteasome subunit beta; *PSMG*, proteasome subunit gamma; SLE, systemic lupus erythematosus; TG, triglycerides; *ZMPSTE24*, gene that encodes a zinc metalloproteinase.

of metabolically active intra-abdominal adipose tissue but preservation of mechanical palmoplantar adipose tissue in patients with type 1 CGL. *BSCL2* has been found to also be highly expressed in the brain[18], which may account for the higher prevalence of intellectual disability in type 2 patients.

Familial Partial Lipodystrophy

Familial partial lipodystrophy (FPLD) is a heterogeneous group of autosomal dominantly, and rarely autosomal recessively, inherited disorders (see Table 101.1). The most prevalent subtype is FPLD2, which is due to mutations in *LMNA*[19]. *LMNA* encodes lamins A/C, with lamins belonging to the intermediate filament family of structural proteins that compose the nuclear lamina. *LMNA* mutations lead to a disruption in nuclear function, resulting in apoptosis and premature cell death of adipocytes, and they lead to alterations in the extracellular matrix of adipose tissue. There is also aberrant TGF-β signaling and this is associated with abnormal responses to metabolic requirements. Decreased plasma leptin and increased fasting plasma insulin and C-peptide levels are additional findings[20], as is premature senescence of vascular cells; the latter contributes to the observed cardiovascular complications[21]. Of note, *LMNA* mutations are responsible for a group of disorders known as laminopathies that includes premature aging syndromes (e.g. progeria), muscular dystrophies, cardiomyopathies, and one form of Charcot–Marie–Tooth neuropathy (see Tables 63.9 & 63.10). The clinical phenotype/syndrome is determined by the site and type of *LMNA* mutation(s)[22].

While the genetic basis of FPLD1 is unknown, FPLD3 results from heterozygous missense mutations of the gene that encodes peroxisome proliferator-activated receptor-γ (PPAR-γ)[23]. PPAR-γ plays an essential role in adipogenesis (see Fig. 101.14), but the entire pathogenesis remains unclear. Although this subtype has a milder phenotype than FPLD2, with a later age of onset and involvement confined to the distal

extremities, metabolic abnormalities are more severe, suggesting that *PPARG* mutations may have additional effects on metabolism.

In patients with FPLD4, heterozygous loss-of-function mutations have been described in the gene that encodes perilipin-1 (*PLIN1*)[24,25]. Perilipin is responsible for the formation, maturation, and function of lipid droplets within adipocytes. Lipoatrophy of the lower extremities is accompanied by marked hypertriglyceridemia and severe insulin resistance with type 2 diabetes.

To date, FPLD5 and FPLD6 are based on a single patient and three sets of siblings, respectively, and because of homozygous mutations (missense, nonsense) or deletions (FPLD5, FPLD6) and consanguinity (FPLD6), an autosomal recessive pattern is favored. The associated genes encode a member of the cell death-inducing DNA fragmentation factor-like effector family (*CIDEC*) that is thought to play a role in adipocyte apoptosis[26] and lipase E, hormone sensitive type (*LIPE*). While homozygous mutations in *CAV1* lead to congenital generalized lipodystrophy (see above), patients with FPLD7 are heterozygotic for *CAV1* mutations.

Partial lipodystrophy may also be seen in association with mandibuloacral dysplasia (MAD), an autosomal recessive syndrome associated with mutations in *LMNA* (type A), or with mutations in *ZMPSTE24*, which encodes a zinc metalloproteinase involved in post-translational proteolytic processing of prelamin A (type B)[27]. The latter has been associated with severe mandibuloacral dysplasia, premature aging, and generalized lipodystrophy.

Mesangiocapillary glomerulonephritis type 2 (MCGN II) has been reported in a case of partial lipodystrophy due to a mutation in *LMNA*, suggesting that partial lipodystrophy of both the sporadic and familial subtypes may predispose to this condition and the observed renal abnormalities and hypocomplementemia may be secondary to other factors associated with lipodystrophy[28].

Acquired Generalized Lipodystrophy (Lawrence Syndrome)

There is no known genetic defect. A third of patients have an antecedent autoimmune disease or viral or bacterial infection, but a causal relationship with the latter has not been established. The preceding panniculitis observed in 25% of patients (see Table 101.1)[29] and the frequent association of autoimmune disease imply immunologically mediated lipolysis. Autoantibodies against the adipocyte membrane have been reported in one patient with this condition[30], and anti-perilipin 1 antibodies in a second.[31] This autoimmune diathesis could also explain the high incidence of type 1 diabetes mellitus and reports of co-existing common variable immunodeficiency (CVID)[32].

Acquired Partial Lipodystrophy Syndrome (Barraquer–Simons Syndrome)

Acquired partial lipodystrophy syndrome occurs sporadically or may be autosomal dominant, with mutations in *LMNB2* detected in some patients[33]. Subcutaneous fat is often lost acutely after a viral illness. The exact pathogenesis is not known, but it may be related to adipsin, a protein produced by adipocytes which is identical to factor D (a component of the alternative complement pathway; see Ch. 60), as well as C3 nephritic factor (C3NeF), an IgG autoantibody against an alternative pathway enzyme. There is dysregulated activation of the alternative pathway, associated with C3NeF binding to the rate-limiting C3 convertase enzyme (C3bBb). This results in unopposed activation of the alternative complement pathway, excessive consumption of C3, and complement-dependent lysis of adipocytes.

Regional differences in factor D expression parallel the regional distribution of adipocyte loss in partial lipodystrophy, which may explain the cephalocaudal distribution of fat. Renal cells also express complement components, and a similar mechanism of complement-mediated injury may be responsible for the MCGN II seen in these patients[28].

Localized Lipoatrophy

The pathogenesis of localized lipoatrophy is heterogeneous. Circumscribed areas of lipoatrophy may follow inflammation from pyogenic abscesses, lobular panniculitides due to autoimmune connective tissue diseases (e.g. lupus erythematosus, dermatomyositis), or subcutaneous panniculitis-like T cell lymphoma.

Iatrogenic causes include traumatic and inflammatory responses to injected medications (Table 101.2). Anti-sense oligonucleotides (AONs), which modulate protein expression via hybridization with cellular RNA, represent the most recent addition to this list. One example of AONs is the experimental drug drisapersen[34].

In the case of insulin lipoatrophy, it may be induced by impurities and is significantly associated with the presence of anti-insulin antibodies[35]; mononuclear infiltrates near insulin injections suggest a localized immune response. Because repeated use of the same injection site increases the risk of lipoatrophy, the latter can be largely prevented by regular rotation of injection sites. Of note, lipoatrophy is fairly rare with the use of human insulin and insulin pump therapy. Lipoatrophy may also occur at injection sites of growth hormone and glatiramer acetate due to a direct lipolytic effect and panniculitis, respectively.

Lipoatrophia semicircularis may represent repetitive trauma or pressure-induced changes (Fig. 101.2), due to constant or intermittent pressure from leaning against the edges of furniture, basins and counters, or from tight-fitting clothing and elastic undergarments. Both resolution of the lesions when trauma is avoided and the occurrence of similar lesions in multiple employees in the same workplace provide support for microtrauma as the etiology[36]. Local hyperproduction of

INJECTED MEDICATIONS THAT CAN CAUSE LOCALIZED LIPOATROPHY
Most common
• Insulin*
• Non-human ≫ human, insulin analogues
• Rarely, can occur at distant sites
• Corticosteroids
Less common
• Antibiotics
• Benzathine penicillin†
• Amikacin
• Immunomodulatory drugs
• Glatiramer acetate (multiple sclerosis)
• Methotrexate†
• Vaccines
• Diphtheria–pertussis–tetanus vaccine
• Quadrivalent human papillomavirus vaccine
• Growth hormone
• Heparin
• Iron dextran
• Anti-sense oligonucleotides
• Anti-programmed cell death protein 1 (PD-1) antibodies
• Exogenous material
*Lipohypertrophy can also occur.
†Including semicircular lipoatrophy.

Table 101.2 Injected medications that can cause localized lipoatrophy. Lipoatrophy can also be seen at sites of acupuncture.

Fig. 101.3 Localized lipoatrophy of the upper lateral calf due to pressure. A fairly common finding in women who cross their legs while seated. *Courtesy Jean L. Bolognia, MD.*

Fig. 101.4 Congenital generalized lipodystrophy syndrome (Berardinelli–Seip syndrome). A Lipoatrophy of the trunk leading to muscle definition. **B** Extensive acanthosis nigricans. *Courtesy Edward Cowen, MD.*

TNF by macrophages has been implicated[37]. Localized lipoatrophy of the upper and lateral calf due to pressure is commonly observed in women who cross their legs when seated (Fig. 101.3).

Up to 60% of *involutional lipoatrophy* (see below) may be associated with prior local injections, suggesting a trauma-related phenomenon[38]. Although lipophagocytizing macrophages seen by electron microscopy suggest an initial stimulation by injectable material, an active foreign body reaction is typically absent.

Lipodystrophia centrifugalis abdominalis infantilis is usually idiopathic, but has been reported to be associated with mechanical trauma or focal infection. Predominance of this condition in East Asia is notable and reports in twins and siblings point to the possibility of an HLA predisposition. In one patient with lipodystrophia centrifugalis abdominalis infantilis, positive immunohistochemical staining for Fas, Bcl-2 and p53, as well as terminal transferase-mediated dUTP nick end-labeling (TUNEL) in degenerating fatty tissue, suggested apoptosis as a possible factor[39].

CLINICAL FEATURES

Congenital Generalized Lipodystrophy (CGL)

CGL is rare, with an estimated prevalence of <1 case in 10 million[40]. As an autosomal recessive disorder, there is often consanguinity. All subtypes are characterized by generalized loss or absence of metabolically active subcutaneous fat from birth, resulting in a cadaveric facies and distinctive muscular-appearing body habitus (Fig. 101.4A). Anabolic features are evident in early childhood (Table 101.3). There is also a deficiency of bone marrow fat (types 1, 2) and visceral fat (types 1, 3, 4). Type 2 CGL also lacks mechanical fat, in addition to metabolically active fat.

The inability to store sufficient fat in the adipocytes results in the metabolic syndrome (see Table 53.5), which becomes more profound during puberty[40]. Diabetes mellitus is evident by adolescence, but hyperinsulinemia can be detected as early as infancy. Clitoromegaly is seen in women and may be associated with polycystic ovarian syndrome and infertility. Hepatosplenomegaly is typical and may be associated with umbilical herniation. Cutaneous findings (see Table 101.3) include acanthosis nigricans, which is noted by adolescence and may be extensive (Fig. 101.4B). Serious medical complications and metabolic derangements include cirrhosis from fatty liver, premature atherosclerosis, sequelae of diabetes, pancreatitis from hypertriglyceridemia, osteosclerosis[41], and a high mortality rate from hypertrophic cardiomyopathy[40]. Type 2 appears to be a more severe disorder that is associated with intellectual disability, hypertrophic cardiomyopathy, and a higher incidence of premature death while type 4 patients have arrhythmias from myocardial fibrofatty infiltration, esophageal dysmotility, and pyloric stenosis[16]. In one series of CGL, there was an ~35-year reduction in lifespan, with liver disease and infection as the most common causes of death[42].

Familial Partial Lipodystrophy

Familial partial lipodystrophy (FPLD) was first described by Dunnigan and Köbberling[42], who outlined the clinical characteristics of large Scottish and German pedigrees with familial syndromes of partial lipodystrophy. FPLD is classified based upon genetic mutations and clinical phenotype (see Table 101.1). This group of disorders differs from other forms of inherited lipodystrophy by a later onset (after puberty) and fat loss predominantly affecting the extremities, with sparing of the face[40]. FPLD is a rare disorder, with a prevalence of <1 in 15 million[40].

In FPLD2, a normal childhood is followed by a progressive, symmetric loss of subcutaneous fat; the latter uniformly involves the extremities and variably extends to the trunk (anterior > posterior). Compensatory accumulation of excess fat occurs and results in a fat head and neck, with a round face, as well as increased supraclavicular fat (see Fig. 101.1). Acromegalic facies with submental fullness ("double chin") is characteristic. As a result of the loss of fat in the limbs, there is an accentuation of subcutaneous veins and muscular prominence (Fig. 101.5). Although FPLD3 has milder clinical features and an onset after the second decade of life, the metabolic disturbances may be more severe[40].

Metabolic disturbances in FPLD are similar to those in the generalized lipodystrophy syndromes. Glucose intolerance, ranging from mild to severe, develops during young adulthood. Acute pancreatitis and hepatic steatosis and cirrhosis may occur, with complications from diabetes mellitus, atherosclerotic cardiovascular disease, or hypertrophic cardiomyopathy leading to premature death[40]. When compared to men, affected women have been reported to have more severe triglyceride elevations (chylomicronemia syndrome)[43]. Dermatologic manifestations include tuberous xanthomas, acanthosis nigricans and hirsutism, while gynecologic findings include menstrual irregularities, polycystic ovaries, and fat hypertrophy within the labia majora.

Familial partial lipodystrophy with mandibuloacral dysplasia is a rare variant of partial lipodystrophy characterized by mandibular and clavicular hypoplasia, short stature, a high-pitched voice, and ectodermal abnormalities of the skin, teeth, nails, and hair[27,40]. There are multiple craniofacial defects, including dental overcrowding and bird-like facies. Skeletal abnormalities include osteolysis of the clavicles, acro-osteolysis, delayed closure of cranial sutures, and joint contractures. Mottled hyperpigmentation, alopecia, atrophy of extremity skin, and nail dysplasia are the characteristic cutaneous findings. Less common clinical features include sensorineural hearing loss, delayed puberty, a high-arched palate, and cutaneous calcinosis. Features of the metabolic syndrome may be present (see Table 53.5).

FEATURES OF CONGENITAL GENERALIZED LIPODYSTROPHY
Lipodystrophic features
• Lack of fat in the buccal region, resulting in a cadaveric facies • MRI studies show near total absence of subcutaneous fat and other metabolically active adipose tissues • Preservation of fat deposits in "mechanical" sites (types 1, 3, 4): orbit, palms, soles, tongue, breasts, vulva, and in periarticular and epidural regions • Muscular body habitus due to the extreme paucity of subcutaneous fat
Anabolic features
• Muscular hypertrophy with prominent superficial veins • Acromegalic facial and acral features • Voracious appetite • Increased basal metabolic rate • Heat intolerance • Accelerated growth with a normal to slightly increased adult height • Advanced bone and dental age • Osteosclerotic and lytic skeletal changes • Masculine features in females (clitoromegaly rare) • Enlarged genitalia (usually limited to infancy and childhood)
Metabolic disturbances
• Insulin resistance and severe fasting or postprandial hyperinsulinemia from early infancy • Insulin levels may decrease after several years, due to exhaustion of pancreatic β cells • Very insulin-resistant diabetes mellitus: noted at puberty with growth cessation • Impaired glucose tolerance is noted around age 8–10 years • Hypertriglyceridemia and sequelae (chylomicronemia, pancreatitis) • Hyperlipidemia accelerates at puberty (with growth cessation) • Low HDL-cholesterol levels (accurate assessment may be hindered by the increased TGs) • Low plasma leptin levels, corresponding to decreased body fat • Osteosclerosis (increased density)
Dermatologic manifestations
• Acanthosis nigricans, often early onset and widespread • Hypertrichosis, including increased (often curly) scalp hair at birth • Hyperhidrosis • Coarse skin on the upper body • Hyperkeratotic epidermal papillomatosis (may represent an exaggerated form of acanthosis nigricans) • Xanthomas
Gynecologic disturbances
• Oligomenorrhea • Polycystic ovaries • Infertility (females)
Organomegaly and organ dysfunction
• Hypertrophic cardiomyopathy (often fatal) • Fatty liver, hepatomegaly, cirrhosis, liver failure • Organomegaly: tonsils and adenoids, lymph nodes, spleen, kidneys, adrenals, pancreas, ovaries • Central nervous system abnormalities: hypothalamic–pituitary dysfunction, ventricular dilation, below average intelligence, ± mild mental retardation • Proteinuric nephropathy

Table 101.3 Features of congenital generalized lipodystrophy.[2,33] HDL, high-density lipoprotein; MRI, magnetic resonance imaging; TG, triglyceride.

Proteasome-Associated Autoinflammatory Syndromes

To date, five types of proteasome-associated autoinflammatory syndrome (PRAAS) have been identified and are due to mutations in seven genes that encode proteasome-associated proteins (see Table 45.7). PRAAS1 has also been referred to as CANDLE (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) syndrome[44] and Nakajo–Nishimura syndrome[45]. In addition to recurrent fevers, annular violaceous plaques, eyelid erythema, and pernio-like lesions that begin during infancy or early childhood[46], patients can develop panniculitis-induced lipodystrophy. Partial (e.g. PRAAS1) or generalized (e.g. PRAAS4) lipoatrophy has been described. In biopsy specimens of nodules, a dense dermal infiltrate of atypical myeloid cells that resembles leukemia cutis or "histiocytoid" Sweet syndrome is seen, along with mature neutrophils. Treatment options include JAK inhibitors, corticosteroids, and methotrexate.

Fig. 101.5 Lipoatrophy of the lower extremities, leading to muscular prominence. *Courtesy William D. James, MD.*

Recurrent lipoatrophic panniculitis of children

In this syndrome, painful subcutaneous nodules are accompanied by fever, malaise, abdominal pain, and arthralgias[47]. Localized lipoatrophy then develops at the sites of nodules. Histopathologically, there is a lobular panniculitis with a mixed infiltrate composed of neutrophils, lymphocytes, macrophages, and mononuclear myeloid cells. Methotrexate and/or corticosteroids led to clinical improvement. The authors proposed that this constellation may represent an autoinflammatory disease. Of note, whole genome sequencing did not detect a form of PRAAS (see previous section)[47].

Acquired Generalized Lipodystrophy (Lawrence Syndrome)

To date, ~80 cases of acquired generalized lipodystrophy (AGL) have been reported in the English literature. New diagnostic criteria for AGL have been proposed, as well as a sub-classification into three subtypes (Table 101.4).

In approximately one-third to one-half of patients, there is a preceding systemic illness, in particular, a viral or bacterial infection or an autoimmune disorder (e.g. a connective tissue disease, thyroiditis)[40]. The rare patients who also have CVID can have recurrent infections (see Ch. 60). Drug-induced lipodystrophy, e.g. due to immune checkpoint inhibitors, needs to be excluded (see below).

Clinical features of AGL are similar to those of the congenital variant, but are of later onset and milder. The lipoatrophy typically does not become apparent until childhood or adolescence and rarely develops during adulthood. This disorder is three times as common in women. Large areas of the face, trunk, and extremities have fat loss (Fig. 101.6), and the palms and soles may even be involved. Loss of acral subcutaneous fat as well as perinephric and intra-abdominal fat can be documented by MRI scans. However, bone marrow fat is preserved, and this feature can be helpful in differentiating AGL from CGL types 1 and 2.

Tender subcutaneous nodules of panniculitis may precede the lipoatrophy in the type 1 variant and there may be an overlap in the

panniculitic and autoimmune subtypes. Progression can occur rapidly or over an extended period. When the lipodystrophy becomes generalized, metabolic abnormalities begin to manifest. Although the latter are less severe in AGL than in CGL, the period between the appearance of lipoatrophy and development of frank diabetes (~4 years) is shorter in AGL[40]. The extent of fat loss mirrors the severity of insulin resistance and hypertriglyceridemia.

Compared to the autoimmune and idiopathic types of AGL, the panniculitic variant may have less severe fat loss and a lower prevalence of diabetes and hypertriglyceridemia (see Table 101.4)[30]. In addition, the associated anabolic features are variable and less prominent and its severity is less striking when the condition starts in later childhood or adulthood.

In AGL, hepatic steatosis is commonly present in affected children, leading to a higher incidence of hepatomegaly, cirrhosis, and liver-related mortality than in CGL. Gynecologic abnormalities include true or pseudo-clitoromegaly (the latter due to fat loss), polycystic ovarian syndrome, and menstrual irregularities. Premature coronary artery disease and carotid or peripheral arterial disease may occasionally be seen. Renal and central nervous system abnormalities are usually absent.

ACQUIRED GENERALIZED LIPODYSTROPHY: PROPOSED DIAGNOSTIC CRITERIA AND SUBTYPES
Essential criterion
Selective loss of fat involving large regions of the body beginning during childhood or adolescence
Supportive criteria

• Clinical
  • Loss of subcutaneous fat from the palms and soles
  • Acanthosis nigricans
  • Hepatosplenomegaly
  • Panniculitis prior to onset (by clinical history and/or histologic confirmation; see below)
  • Associated autoimmune diseases (see below)
• Laboratory
  • Diabetes mellitus or impaired glucose tolerance
  • Severe hyperinsulinemia (fasting and/or postprandial)
  • Increased serum triglyceride and/or decreased HDL-cholesterol levels
  • Reduced serum leptin and/or adiponectin levels
  • Anthropometric or MRI evidence of large regions of fat loss
  • MRI evidence of preserved bone marrow fat

Subtypes

• Panniculitic variant (type 1)
  • Panniculitis precedes the onset of lipoatrophy, which may be noted in the center of expanding annular lesions or at distant sites
  • Mean age of onset is 7 years; slight female predominance (~1.5-fold)
  • Associated symptoms include low-grade fever, malaise, arthralgias, and abdominal pain
  • May be associated with autoimmune diseases (see below)
  • Relatively mild metabolic derangements and leptin abnormalities
  • Histopathologic evaluation reveals a mostly lobular lymphohistiocytic subcutaneous infiltrate ± granulomatous foci
• Autoimmune variant (type 2)
  • Concurrent or prior autoimmune disease without preceding panniculitis; associated with juvenile dermatomyositis, Sjögren syndrome, juvenile idiopathic arthritis, vitiligo, chronic urticaria/angioedema, and autoimmune thyroiditis, hepatitis or hemolytic anemia
  • Mean age of onset is 15 years; female predominance (~3-fold)
  • Hepatomegaly is invariably present; hypertriglyceridemia and diabetes mellitus occur in most patients
  • Laboratory abnormalities may be observed without clinical evidence of autoimmune disease, including antinuclear, anti-smooth muscle, antiglomerular basement membrane, anti-salivary duct, antimitochondrial, and anti-adrenal/ovary/placenta/testis antibodies
• Idiopathic (type 3)
  • No evidence of panniculitis or autoimmune disease
  • Mean age of onset is 20 years (range, <2–60 years); female predominance (~3-fold)

Table 101.4 Acquired generalized lipodystrophy: proposed diagnostic criteria and subtypes. *Adapted from reference 29.*

Dermatologic features of AGL, in addition to panniculitis and lipoatrophic areas, include acanthosis nigricans, localized or generalized hyperpigmentation, eruptive xanthomas, telangiectasias, mild palmar/plantar keratoderma, and hair abnormalities, including mild hirsutism, curly hair, and occasional alopecia. The acanthosis nigricans begins in childhood and involves the neck, axillae, groin, umbilicus, and nipples. Associated autoimmune diseases include juvenile dermatomyositis, Sjögren syndrome, and vitiligo. In addition, patients may have chronic urticaria and angioedema (see Table 101.4).

Acquired Partial Lipodystrophy (Barraquer–Simons Syndrome)

Acquired partial lipodystrophy, also known as progressive lipodystrophy or cephalothoracic lipodystrophy, is the second most common type of non-localized lipodystrophy, after HIV/ART-related lipodystrophy. It has been reported worldwide, with more than 250 patients described in the literature[40,48].

Three phenotypic subtypes have been noted: (1) fat loss in the upper half of the body; (2) fat loss in the upper half of the body, with hypertrophy of adipose tissue in the lower half; and (3) hemi-lipodystrophy, where one half of the face or body is affected.

Lipodystrophy begins during childhood or pre-puberty (median age at diagnosis is 8–10 years) and sometimes follows a viral illness. It is characterized by an insidious onset, with symmetric and progressive loss of subcutaneous fat in a cephalocaudal direction (Fig. 101.7). Extension of the lipoatrophy usually takes place over a 1- to 2-year period, but can occur over many years. Physical findings may be apparent by adolescence, although the onset may be delayed until 40 years of age. Women are affected three times more often than men.

The face is usually affected first, with sunken eyes due to loss of retro-orbital and periorbital fat. This is accentuated by concurrent loss of buccal and temporal fat, resulting in a progeria-like or cadaveric appearance (Fig. 101.8). The hips and legs tend to be spared, and often demonstrate fat hypertrophy, especially in women. Growth delay or stunted growth is not characteristic of this disorder.

MCGN II with nephritic syndrome, seen in approximately one-fifth of patients, may occur many years, usually about eight, after the onset of lipodystrophy. Almost all patients with acquired partial lipodystrophy have low levels of C3 in addition to circulating C3 nephritic factor (C3NeF), composed of polyclonal IgG[28]. This leads to unopposed activation of the alternative complement pathway (see above) and C3NeF-induced lysis of adipocytes. The low C3 level also predisposes

these patients to recurrent *Neisseria meningitidis* infections and repeat vaccinations may be required.

Other autoimmune associations include systemic lupus erythematosus, juvenile dermatomyositis, systemic sclerosis, Sjögren syndrome, pernicious anemia, hypothyroidism, celiac disease, dermatitis herpetiformis, temporal arteritis, and small vessel vasculitis.

Metabolic syndrome is less common in APL than in other lipodystrophies, but acanthosis nigricans, menstrual abnormalities, hirsutism, insulin resistance, type 2 diabetes mellitus, and hyperlipidemia may be seen.

Localized Lipoatrophy

Localized lipoatrophy presents as one or multiple depressed areas, usually on the proximal extremities, ranging from under a few centimeters to greater than 20 cm in diameter. *Drug-induced lipoatrophy* is most commonly due to injections of corticosteroids and non-human insulin (see Table 101.2); it may be accompanied by local lipohypertrophy. Of note, multifocal lipoatrophy due to intravenous corticosteroid use has been described and insulin injection-related lipoatrophy can appear at distant sites.

Fig. 101.9 Localized lipoatrophy secondary to lupus panniculitis. **A** An area of depression on the cheek due to burnt-out lupus panniculitis; note the dyspigmentation and scarring from an overlapping lesion of discoid lupus erythematosus. **B** Circular depressions on the upper arm, a common location for lupus panniculitis. *A, Courtesy National Skin Centre, Singapore.*

Involutional lipoatrophy is an idiopathic lipoatrophy characterized clinically by non-inflammatory focal loss of fat. Based on reported cases, there is a strong female predominance. Focal oval areas of lipoatrophy, 2 to 8 cm in diameter, occur predominantly on the buttocks and proximal extremities, especially the upper arm, corresponding to locations frequently used as injection sites. Although it is estimated that up to 60% of cases of involutional lipoatrophy may be associated with prior local injections (see above), this type of lipoatrophy may occur without prior injections.

Atrophic connective tissue panniculitis is rare, and it often occurs on the upper or lower extremities. In "pure" cases of this condition, there is no prior clinical inflammation although there is evidence histologically of lymphocytic panniculitis. In other patients, the lipoatrophy may be the direct result of clinical panniculitis. The latter is common on the head and neck or proximal extremities if associated with lupus panniculitis (also referred to as lupus profundus; Fig. 101.9). Other associated autoimmune diseases include dermatomyositis, thyroiditis, juvenile idiopathic arthritis, vitiligo, and insulin-dependent diabetes mellitus.

Lipoatrophia semicircularis (semicircular lipoatrophy) has been reported primarily in women in their 20s to 30s and rarely in children. It presents as symmetric, asymptomatic, 4–8 cm curvilinear horizontal depressions on the anterolateral thighs (see Fig. 101.2). Infrequent presentations include two or three parallel depressions, a unilateral distribution, or symptoms of cramps, pain after sports, heavy legs, or a burning sensation. The lesions usually appear over a few weeks and spontaneously resolve between 9 months to 4 years. The lipoatrophy may recur. MRI can assist in differentiating this from an inflammatory panniculitis.

Annular lipoatrophy presents with a deep, persistent, pseudosclerotic band approximately 9–11 cm in length that encircles the arm or ankle[49]. More extensive lesions have been reported that were 14–16 cm in length. It may be preceded by tenderness and swelling of the limb, or be associated with discomfort and arthritis. This entity may represent a variant or end-stage presentation of atrophic connective tissue disease panniculitis. Thus, there may be patients with associated autoimmune diatheses.

Fig. 101.10 Lipodystrophia centrifugalis abdominalis infantilis (centrifugal lipodystrophy). A 5-year-old Malay boy with a two-year history of progressive lipoatrophy involving the groin bilaterally and the lower abdomen. The veins in the involved area are readily visible. *Courtesy National Skin Centre, Singapore.*

Lipodystrophia centrifugalis abdominalis infantilis (centrifugal lipodystrophy) has largely been reported from East Asia, with most patients of Japanese, Korean, or Chinese origin[50]. Onset is usually before 3 years of age, with >90% of patients presenting by age 5 years. In Koreans, there is a four-fold female predominance[51]. Although lipodystrophia centrifugalis abdominalis infantilis affects primarily Asian children, it may occasionally occur in Caucasians and in adults.

Clinically, a well-demarcated area of lipoatrophy with a periphery of erythema and scale is seen on the abdomen or elsewhere on the trunk, often with associated regional lymphadenopathy. The lipoatrophy begins on the lower abdomen or in the groin region (and may include the genitalia) in about 80% of patients, and in the axillary region in about 20% of patients; it spreads onto the abdomen or chest, respectively, in a centrifugal fashion (Fig. 101.10). The underlying blood vessels become visible and ulceration may occur within the depressed areas. Contrary to its original name, this condition can affect non-abdominal sites such as the face, neck, and lumbosacral region (Fig. 101.11A), and it is not limited to infants. The lesions may progress slowly over several years, then often cease enlarging by 13 years of age[49]. Although there is no specific therapy, >60% of patients spontaneously improve (Fig. 101.11B).

Progressive hemifacial atrophy (Parry–Romberg syndrome) is considered to be a form of severe linear morphea (see Ch. 44). In addition to lipoatrophy, there may be atrophy of the underlying muscle and bone as well as the potential for ophthalmologic, dental, and neurologic involvement. An association with *Borrelia burgdorferi* infection has been reported in Europe.

Non-progressive late-onset linear hemifacial lipoatrophy occurs on the malar cheek, primarily in elderly individuals.

Inflammatory reactions due to material injected for cosmetic purposes or from self-inflicted injections of foreign material can lead to lipoatrophy which may be associated with scarring and dyschromia.

Lipohypertrophy

Lipohypertrophy remains a frequent complication of insulin therapy, irrespective of the insulin source and mode of administration[52]. As with insulin lipoatrophy, anti-insulin antibodies are associated with lipohypertrophy in children and adolescents with type 1 diabetes. The clinical consequence is that injection of insulin into a site of lipohypertrophy, while painless, may lead to erratic absorption of the insulin with poor glycemic control and rebound phenomenon[52]. Of note, insulin-induced nodular amyloidosis may have a clinical appearance similar to lipohypertrophy.

Injection of pegvisomant, a growth hormone receptor antagonist used to treat acromegaly, is another cause of lipohypertrophy (Table 101.5).

Fig. 101.11 Lipodystrophia centrifugalis infantilis (centrifugal lipodystrophy) of the face. A A 2-year-old girl with a serpentine violaceous band involving the cheek in association with lipoatrophy. **B** The same child two years later, with spontaneous resolution. The most common location for lipodystrophia centrifugalis infantilis is the abdomen (see Fig. 101.10). *Courtesy National Skin Centre, Singapore.*

CAUSES OF LIPOHYPERTROPHY
• **Insulin therapy –** risk factors include duration of therapy, frequent injections, failure to rotate sites of injections, and poor injection technique
• **Pegvisomant (growth hormone receptor antagonist) injections***
• **Growth hormone injections**
• **Excess corticosteroids** – includes Cushing disease (excessive ACTH production by the pituitary gland) and Cushing syndrome (iatrogenic, adrenal tumors, nodular adrenal hyperplasia, ectopic ACTH production)
• **HIV/ART-associated** – risk factors include extended exposure to nucleoside reverse transcriptase inhibitors, exposure to protease inhibitors, age ≥40 years, longer duration of therapy, higher body mass index before onset of therapy, and presence of metabolic derangements (elevated serum triglyceride and insulin levels; depressed serum testosterone levels)
• **Lipodystrophy syndromes** – familial partial lipodystrophy (neck and face), acquired partial lipodystrophy (hips and lower extremities)
*Used to treat acromegaly.

Table 101.5 Causes of lipohypertrophy.

PATHOLOGY

Generally speaking, the histologic picture of the various lipodystrophy syndromes (see Table 101.1) is non-inflammatory. In *generalized lipodystrophy*, there is complete or near-complete loss of subcutaneous fat, with the dermis and fascia in direct apposition. Less often,

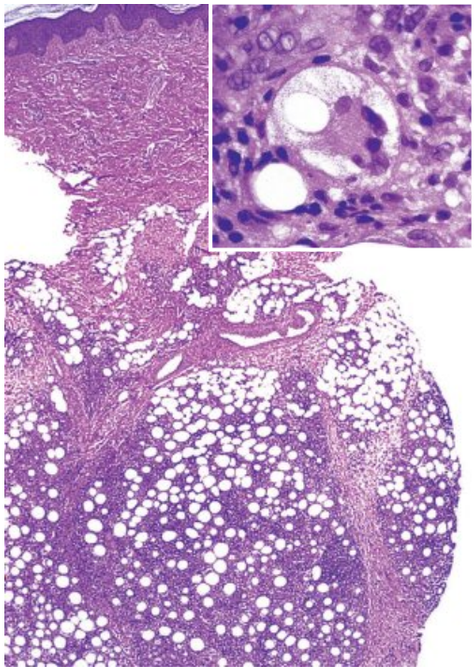

Fig. 101.12 Histopathologic features of the preceding panniculitis in type 1 acquired generalized lipodystrophy. Lobular panniculitis with infiltrate of lymphocytes, histiocytes, multinucleated giant cells, and lipophages. There is also cytoplasmic vacuolization of the fat cells (inset). See Table 101.4 for three types. *Courtesy Jacqueline Junkins-Hopkins, MD.*

biopsy specimens appear to have no overt abnormalities, except for an increased amount of collagen, which has replaced the subcutaneous fat. In contrast, biopsies of *acquired generalized lipodystrophy*, in particular type 1, may show a lobular panniculitis (Fig. 101.12; see Table 101.4).

In *acquired generalized lipodystrophy* and areas of lipoatrophy in some forms of *partial lipodystrophy*, two histologic patterns have been recognized: (1) non-inflammatory with involutional changes of the fat; and (2) inflammatory in the form of a lobular panniculitis with lymphocytes, lipophages, and plasma cells[53]. Whether these two patterns are stage-related remains to be clarified, as even in patients without panniculitis clinically, biopsies of early lesions may show inflammation, but it is usually mild.

Involutional changes of the subcutaneous fat are characterized by small fat lobules with a reduction in the size and number of adipocytes (Fig. 101.13). *Involutional lipoatrophy* can be further divided into two histologic subtypes[38]. In the first type, the lobules may be composed of faintly acidophilic, small fat cells that retract from one another as well as the surrounding connective tissue, leading to an appearance similar to embryonic fat; the lobules often have an eosinophilic appearance. These histologic findings are more prominent at the periphery of the clinically depressed area, with tiny acidophilic fat cells present more centrally. Inflammation is absent to sparsely mononuclear. The second type, with indistinguishable clinical features, shows small atrophic adipocytes with a normal fat cell membrane surrounded by prominent vasculature. At scanning magnification, the lobules are collapsed (with an orientation parallel to the skin surface) and surrounded by numerous capillaries. Acid mucopolysaccharide deposition within the fat lobules and fibrosis of the septae may be seen, as well as occasionally lipomembranous changes.

Although birefringent, non-crystalline material may occasionally be observed, foreign body giant cells and lipophages are typically absent in both subtypes of involutional lipoatrophy. $CD68^+$ macrophages can be demonstrated with immunohistochemical staining. Ultrastructural studies have shown that these are lysosomally active macrophages adjacent to lipocytes and likely containing degenerated lipid remnants[38]. In *localized lipodystrophy*, a loss of fatty tissue is seen, along with a variable degree of fibrosis. There is usually no inflammatory infiltrate, although panniculitis has been reported in a few cases. Deposits of immunoreactants can be seen within blood vessel walls or the basement membrane, particularly in the inflammatory type.

Histologically, well-developed areas of *lipodystrophia centrifugalis abdominalis infantilis* show a diminution of subcutaneous fat with scant or absent inflammation. The erythematous rim tends to correspond to a moderate or marked lymphohistiocytic infiltrate in the subcutaneous fat; a deep dermal and peri-eccrine lymphocytic infiltrate

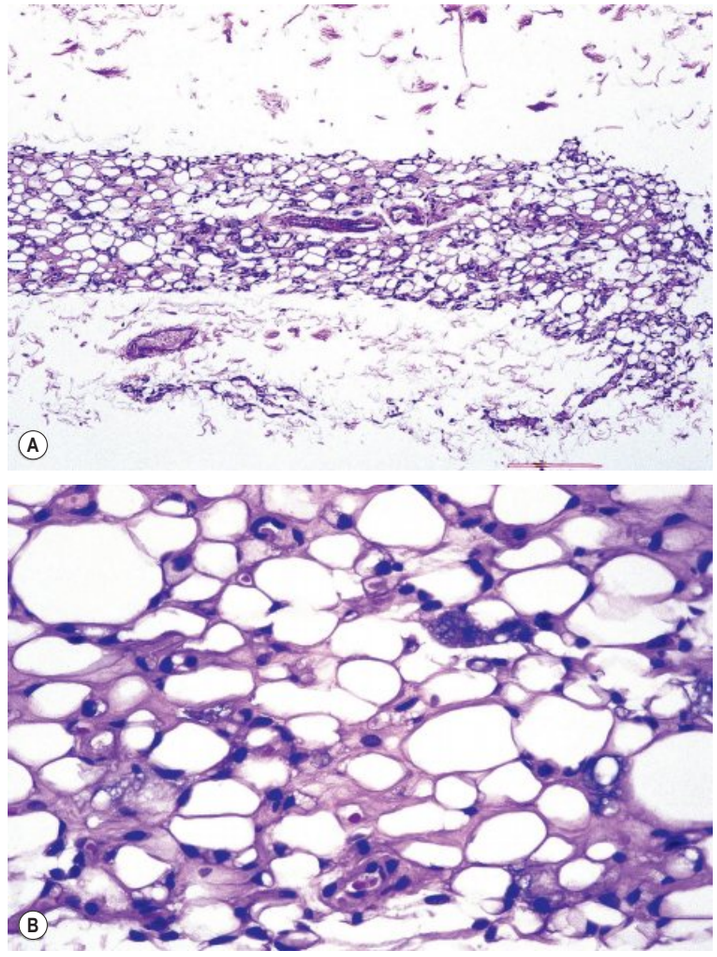

Fig. 101.13 Histopathologic features of involutional lipoatrophy secondary to corticosteroid injection. A There is marked diminution and collapse of the fat lobules, without inflammation. **B** Higher power demonstrates decreased size of fat cells with eosinophilic thickened cell walls with a hyalinized and mucinous stroma. *Courtesy Jacqueline Junkins-Hopkins, MD.*

is an uncommon finding. There may be fibrosis and thickening of the septae within the subcutis. The few adipocytes that are present may have myxoid changes.

Other localized variants such as *lipoatrophia semicircularis* (semicircular lipoatrophy) and *drug-induced lipoatrophy* usually show a loss of fatty tissue and replacement by collagen, with no features of panniculitis. There are often scattered lipophages. However, at sites of glatiramer acetate injections, panniculitis that resembles lupus profundus histologically can be seen. Lastly, HIV/ART-associated lipodystrophy resembles the non-inflammatory pattern of lipodystrophy.

DIFFERENTIAL DIAGNOSIS

There are a variety of other complex syndromes that present with lipoatrophy along with a number of other physical and systemic features (see below). A detailed discussion of these syndromes is beyond the scope of this chapter.

The excessive fat accumulation seen in patients with FPLD2 and HIV/ART-associated lipodystrophy could be confused with Cushing syndrome and obesity. Acromegaly can have overlapping features with generalized lipodystrophy.

In an infant with generalized lipodystrophy, the following conditions should also be considered:

- *Leprechaunism* (Donohue syndrome) is included in some lipodystrophy classifications, as the patients present with generalized lipodystrophy, severe insulin resistance, acanthosis nigricans, and hirsutism. In contrast to CGL, these patients have a distinct elfin facies, severe intrauterine growth retardation, prominent nipples, cutis laxa, mutations in the insulin receptor gene, and death during infancy.

- *SHORT syndrome* (*s*hort stature, *h*yperextensible joints or *h*ernia, *o*cular depression, *R*ieger anomaly [iridocorneal mesodermal dysgenesis], and *t*eething delay) is also included in some lipodystrophy classifications, as there is congenital lipoatrophy of the face and upper body. This condition is distinguished by the above-outlined abnormalities, intrauterine growth retardation, delayed bone age, mutations in *PIK3R1*, and a dysmorphic facies, which includes a triangular shape, micrognathia, deep-set eyes, and anteverted ears. Metabolic abnormalities are rare to absent.
- *Progeria-type syndromes* are characterized by limb lipoatrophy, cardiovascular disease and diabetes, but they are accompanied by muscle wasting, sclerodermatous changes, cataracts, and other signs of premature aging. Some of the progeric syndromes have *LMNA* mutations similar to those associated with FPLD, and may be considered as part of a broader group of disorders termed laminopathies (see Table 63.10).
- In *Cockayne syndrome*, lipoatrophic changes are accompanied by growth delay, retinal abnormalities, photosensitivity, and defects in DNA repair (see Chs. 63 & 87).
- *AREDYLD syndrome*: congenital generalized lipoatrophic diabetes is associated with an acrorenal field defect and ectodermal dysplasia.

In the case of partial lipodystrophy, there was a report of diffuse, symmetrical lipoatrophy of the lower extremities following extensive inflammation due to lobular panniculitis[54]. Neither underlying autoimmune diseases nor exogenous causes were identified.

Localized lipodystrophies should be differentiated from initial phases of progressive lipodystrophy, morphea, lupus panniculitis, and atrophoderma of Pasini and Pierini. Although there is overlap amongst the various types of localized lipodystrophy, the distribution and morphology combined with a history of injections, the presence clinically or histologically of panniculitis, and associated autoimmune disorders may aid in the diagnosis.

Poland syndrome is a rare congenital disorder consisting of unilateral partial or total absence of a breast and/or pectoralis major muscle plus ipsilateral symbrachydactyly, which may simulate lipoatrophy. Lipohypoplasia, as is seen in disorders such as Proteus syndrome, can also mimic lipoatrophy.

Lastly, whole-body MRI has been shown to assist in differentiating the various subtypes of lipodystrophies, based upon the amount and extent of residual adipose tissue and the absence or preservation of marrow fat[55]. This information, in combination with the clinical phenotype and especially genetic testing, improves diagnostic accuracy and prognostication.

TREATMENT

Therapeutic interventions for lipodystrophy syndromes focus on three aspects: (1) cosmetic concerns; (2) metabolic derangements; and (3) systemic associations[56]. For volume loss due to lipoatrophy, soft tissue fillers and autologous fat transplantation can be helpful, albeit temporarily[57,58]. Solid synthetic volumetric midfacial implants, constructed using computer-aided design and manufacturing technology, may offer a more durable correction of the defects[59]. A conservative approach can be undertaken when spontaneous improvement may occur as in pressure-induced or traumatic lipoatrophy. For lipohypertrophy, liposuction and lipectomy represent moderately effective treatments[60]. Switching to purified human insulin may improve lipoatrophy at sites of insulin injections, but it may require 1 to 3 years[52].

The treatment of metabolic abnormalities requires input from dieticians and endocrinologists[56]. Several medications are used to address insulin resistance and glucose control including thiazolidinediones, metformin, sulfonylureas, dipeptidyl peptidase 4 inhibitors ("gliptins"), glucagon-like peptide 1 agonists, sodium-glucose cotransporter-2 inhibitors (gliflozins), and insulin[56]. Treatment of hypertriglyceridemia includes diet, fibrates, omega-3 fatty acids, niacin, and statins[56,61]. For refractory metabolic disease, bariatric surgery can be considered[62].

Of note, recombinant methionyl human leptin (metreleptin) is FDA-approved for the treatment of congenital or acquired *generalized* lipodystrophy. Metreleptin binds to hypothalamic leptin receptors, leading to decreased appetite and increased insulin sensitivity. Marked improvements in glycemic control, hyperlipidemia, hepatic steatosis, and diabetic complications such as proteinuria have been reported[63]. Metreleptin is generally well tolerated, with sustained effects as long as neutralizing anti-metreleptin antibodies do not develop. There is also a black box warning regarding risk of lymphoma. It has also been shown to be an effective steroid-sparing therapy for the acquired generalized lipodystrophy that can follow allogeneic hematopoietic stem cell transplantation[64].

In acquired partial lipodystrophy, longitudinal evaluation will allow identification of associated autoimmune connective tissue diseases (e.g. lupus, dermatomyositis), thyroid disease, or renal disease that requires treatment. Such treatment may halt the progression of the lipodystrophy. If proteinuria, a low serum C3, and C3 nephritic factor (C3NeF) are detected, a renal biopsy to exclude MCGN II may be required. Encouraging results following the use of IVIg have been reported, presumably due to the IVIg containing neutralizing antibodies against C3NeF[65]. When no secondary cause is found, treatment is limited.

Additional potential therapies include volanesorsen, an antisense oligonucleotide that binds to apoC-III mRNA and is EMA-approved for familial chylomicronemia syndrome but not FDA-approved because of the risk of thrombocytopenia. Both evinacumab, a human angiopoietin-like 3 (ANGPTL3) blocking antibody that is currently FDA-approved for homozygous familial hypercholesterolemia, and gemcabene calcium, a dialkyl ether dicarboxylic acid which has orphan drug designation for the same indication, have also shown efficacy in patients with severe hypertriglyceridemia[56]. Setmelanotide, a melanocortin-4 receptor agonist, is FDA-approved for obesity due to deficiencies of proopiomelanocortin (POMC), proprotein convertase subtilisin/kexin type 1 (PCSK1), or leptin receptor (LEPR) and may reduce triglyceride levels.

ACQUIRED LIPODYSTROPHY DUE TO OTHER CAUSES

Medications

HIV/ART-associated lipodystrophy

Worldwide, HIV/ART-associated lipodystrophy is still the most common form of non-localized lipodystrophy. Fortunately, its incidence has fallen significantly with the advent of new ARTs and increased awareness of its association with protease inhibitors (PI) and nucleoside analogue reverse transcriptase inhibitors (NRTIs) such as stavudine and didanosine. There are several proposed mechanisms to explain this particular type of lipodystrophy (Fig. 101.14; Table 101.6) and they include:

- impaired pre-adipocyte differentiation and increased adipocyte apoptosis[66,67]
- impaired insulin-stimulated lipogenesis and increased lipolysis[66], leading to decreased adipocyte size
- mitochondrial toxicity[68].

HIV/ART-associated lipodystrophy reflects an interplay of several factors including the type of ART administered, direct effects of HIV proteins, and other host factors such as age and severity of HIV infection. The key contributor is extended use of higher-risk ARTs, in particular the older-generation NRTIs (e.g. stavudine, didanosine), early PIs (e.g. indinavir, full-dose ritonavir), and raltegravir (an integrase strand transfer inhibitor [INSTI])[69]. Host risk factors include an age >40 years and more severe HIV infection (e.g. $CD4^+$ count <200/mcl, higher nadir viral load) at the onset of therapy[70,71]. Baseline subcutaneous body fat composition prior to ART also plays a role, with a higher risk of lipoatrophy in individuals with lower body fat and a higher risk of lipohypertrophy in those with higher body fat[70,71].

The clinical findings in HIV/ART-associated lipodystrophy include: (1) irreversible lipoatrophy of peripheral sites, primarily the face, extremities, heel pads, and buttocks (Fig. 101.15 & 101.16); (2) central lipohypertrophy or adipose tissue accumulation, especially dorsocervical, supraclavicular and mammary, as well as intra-abdominal and visceral (e.g. liver); and (3) development of metabolic abnormalities. In cross-sectional studies utilizing DEXA scans and computed tomography, a 15%–65% prevalence of central lipohypertrophy was noted within 1 to 2 years of initiation of ART[70]. Patient self-report, in concert with physician examination, represent the earliest and best indicators of body contour changes. The latter are a major cause of both social stigmatization and reduced drug adherence.

Distinct clinical syndromes of fat redistribution can result, depending upon the particular drug or combination of drugs. In patients who developed lipohypertrophy, INSTIs were associated with increased weight

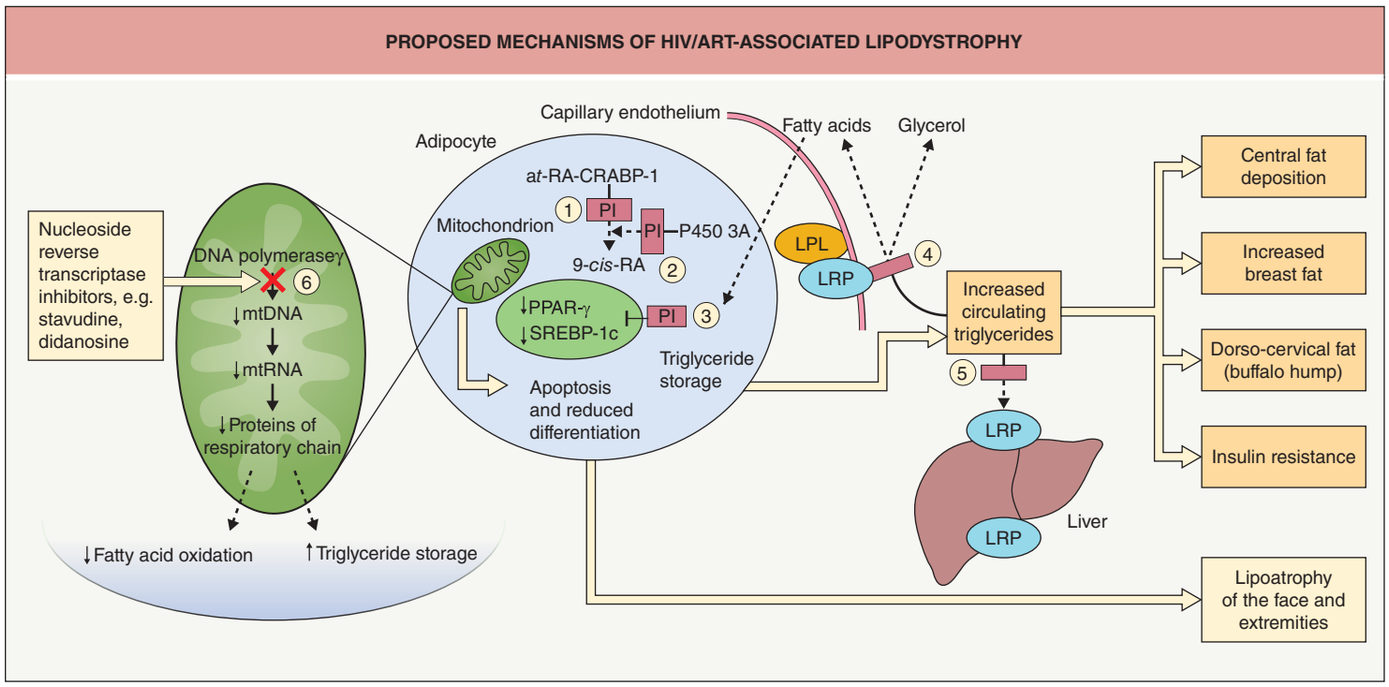

Fig. 101.14 Proposed mechanisms of HIV/ART-associated lipodystrophy. The combination of decreased PPAR-γ expression and decreased fatty acid oxidation capacity resulting from drug exposure could explain how these drugs cause adipocyte toxicity and lipoatrophy. See Table 101.6 for additional details. The numbers represent sites of drug effects. ART, antiretroviral therapy; *at*-RA, all-*trans*-retinoic acid; CRABP-1, cytoplasmic retinoic acid binding protein type 1; LPL, lipoprotein lipase; LRP, low-density lipoprotein receptor-related protein; mtRNA, mitochondrial RNA; mtDNA, mitochondrial DNA; PIs, protease inhibitors; PPAR-γ, peroxisome proliferator-activated receptor-γ; RXR, retinoid X receptor; SREBP-1c, sterol regulatory element-binding protein-1c. *Adapted from Carr A. HIV protease inhibitor-related lipodystrophy syndrome. Clin Infect Dis 2000;30:S135–42.*

MECHANISMS OF ANTIRETROVIRAL THERAPY (ART)-ASSOCIATED LIPOATROPHY			
	HIV drugs implicated	**Drug-induced effect**	**Cellular response**
↓ Adipocyte differentiation*	PIs, NRTIs	Defect in lamin A/C processing and/or RXR-PPAR-γ heterodimer activation decreases function of SREBP-1c & other downstream transcription factors	↓ Production of new mature fat cells → ↓ fat cell number
↑ Adipocyte apoptosis+	PIs, NRTIs	↑ TNF-α signaling (as well as mechanism described above for ↓ differentiation)	↑ Fat cell death → ↓ fat cell number
↑ Lipolysis*	PIs, NRTIs	↓ Expression of perilipin	↑ Release of stored TGs as FFAs and glycerol into circulation →↓ fat cell size
↓ Lipogenesis	PIs, NRTIs	↓ Expression and function of lipogenic SREBP-1c	↓ FFA uptake by adipocytes → ↓ fat cell size
Mitochondrial toxicity	NRTIs	Inhibition of mitochondrial DNA polymerase-γ	↑ Catabolic pathways (lipolysis), altered production of hormones and cytokines (↓ adiponectin, ↑ TNF-α), ↓ adipocyte differentiation, ↑ adipocyte apoptosis

*Also represent sequelae of mitochondrial toxicity.

Table 101.6 Mechanisms of antiretroviral therapy (ART)-associated lipoatrophy. FFA, free fatty acids; HIV, human immunodeficiency virus; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; PPAR-γ, peroxisome proliferator-activated receptor-γ; RXR, retinoid X receptor; SREBP-1c, sterol regulatory element-binding protein-1c; TG, triglycerides; TNF, tumor necrosis factor. *From refs. 60–62,64,65.*

gain compared to PIs and NNRTIs[72]. Amongst the NRTIs, tenofovir alafenamide led to more weight gain than did tenofovir disoproxil fumarate, abacavir, or zidovudine[72]. With regard to lipoatrophy, NRTIs, especially stavudine, were more likely to result in peripheral fat wasting. Of note, older NRTIs are associated with multiple complications related to mitochondrial toxicity, including myopathy, polyneuropathy, liver steatosis, pancreatitis, hyperlactatemia, bone marrow toxicity and a Fanconi-like syndrome.

Similar to inherited lipodystrophy syndromes, fat redistribution in HIV/ART-associated lipodystrophy may precede the development of metabolic complications. These include insulin resistance, diabetes, dyslipidemia, and bone disorders such as osteopenia, osteoporosis, and avascular necrosis. The insulin resistance may arise via either the direct effects of PIs on insulin-mediated whole-body glucose uptake or the indirect effects of dyslipidemia, mitochondrial toxicity, and changes in body fat composition. Adipocytokines, in particular leptin and adiponectin, affect insulin sensitivity, and low levels of both factors have been observed in HIV/ART-associated lipodystrophy[5,9,73]. Genetic variation in resistin production by adipose tissue is also implicated in HIV/ART-associated obesity and insulin resistance[74]. In HIV-infected patients receiving ART, the prevalence of metabolic syndrome has been reported to be 15%–25%, resulting in an increased risk for cardiovascular disease[40]. For example, the Data Collection on Adverse Events of Anti-HIV Drugs (DAD) study found an ~25% increase in the rate of myocardial infarctions per year during the first 4–6 years of ART exposure[75].

Immune Checkpoint Inhibitor-Associated Lipodystrophy

Two anti-PD-1 antibodies, nivolumab and pembrolizumab, have been associated with the development of lipodystrophy[76]. Following at least 10 months of administration, generalized lipoatrophy developed in

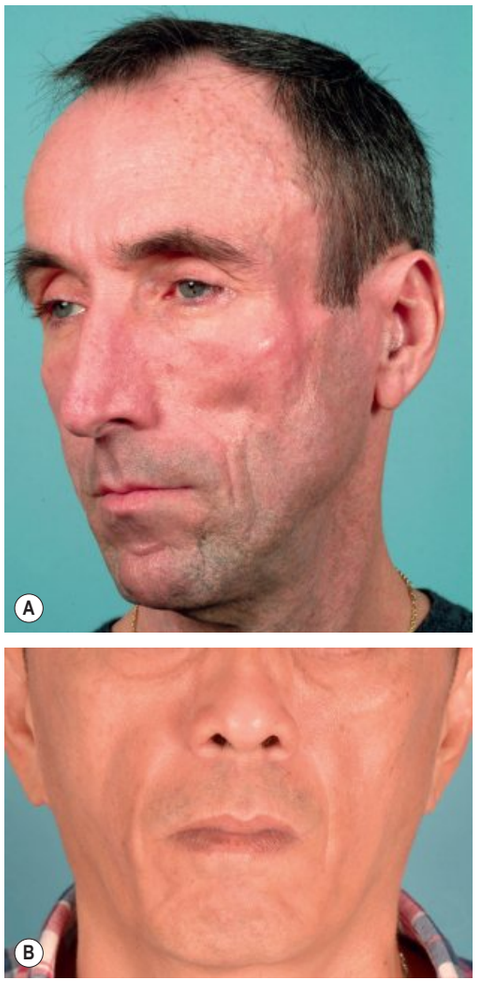

Fig. 101.15 HIV/ART-associated lipoatrophy. A The side view highlights the loss of temporal fat. **B** There is symmetric loss of buccal and parotid fat, resulting in prominent zygomata and a cachectic appearance, in a second patient. *A, Courtesy Ken Katz, MD; B, Courtesy National Skin Centre, Singapore.*

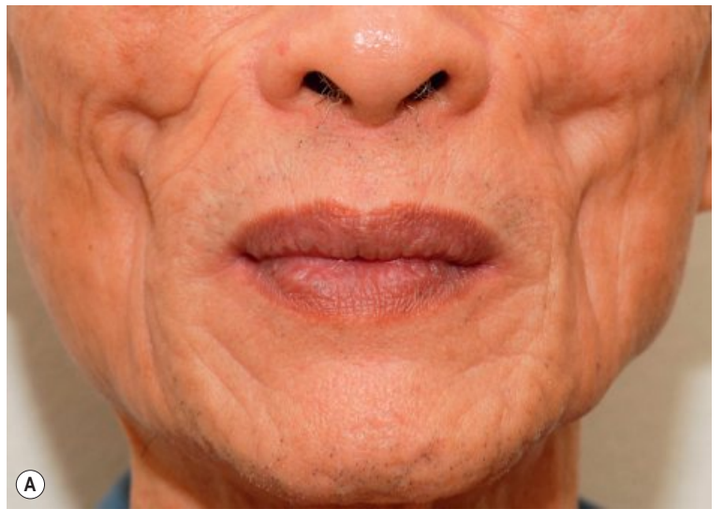

Fig. 101.16 HIV/ART-associated lipoatrophy. A Marked indentation of the medial cheeks in an older patient, with redundant melolabial folds. **B** Lower extremities with prominent veins and defined musculature. *A, Courtesy Priya Sen, MD.*

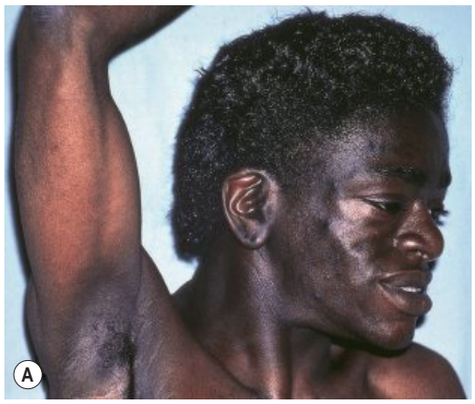
association with diabetes mellitus, insulin resistance, hypertriglyceridemia, and central obesity. These clinical manifestations persisted despite discontinuation of the medication.

POEMS Syndrome

Acquired partial lipodystrophy that preferentially affects the face is one of the more recently recognized cutaneous manifestations of POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes). Symmetric lipoatrophy of the face has been noted in up to half of patients[77]. Treatment of the underlying paraproteinemia usually arrests its progression but does not lead to reversal.

Allogeneic Hematopoietic Stem Cell Transplantation-Associated Lipodystrophy



Acquired partial lipodystrophy and associated metabolic abnormalities have been observed following allogeneic hematopoietic stem cell transplantation, primarily in children[78]. The cutaneous findings resemble those of FPLD with lipoatrophy of the gluteal region and extremities and retention of fat in the face and abdomen. It may reflect a graft-versus-host (GVHD) reaction at the adipocyte level.

Chapter Contents

Structure and Function of Cutaneous Blood Vessels *1790*
Vascular Development *1791*
Structure and Function of the Cutaneous Lymphatic Vascular System *1796*
Angiogenesis- and Lymphangiogenesis-Related Diseases *1798*
Antiangiogenic Therapies *1798*

Key features

- Cutaneous blood vessels and lymphatic vessels play essential roles in skin inflammation, wound healing, and tumor progression
- Vascular endothelial growth factor-A (VEGF-A) and placental growth factor (PlGF) are major skin angiogenesis factors
- The expression of VEGF and PlGF by keratinocytes is upregulated in psoriasis, healing wounds, and cutaneous squamous cell carcinomas
- VEGF-C and VEGF-D induce skin lymphangiogenesis via interaction with VEGF receptor-3 on lymphatic endothelium
- Mutations in several genes including *FLT4*, which encodes VEGF receptor-3, have been identified in congenital lymphedema
- Therapeutic modulation of angiogenesis is of increasing interest for anti-cancer, anti-inflammatory, and chronic wound therapies

STRUCTURE AND FUNCTION OF CUTANEOUS BLOOD VESSELS

Blood vessels are essential for supplying sufficient oxygen and nutrients, maintaining normal tissue homeostasis and function, and meeting the increased nutritional needs in various pathologic conditions. Blood flows from arteries and arterioles through capillary loops to postcapillary venules and veins. For practical and didactic purposes, the vascular system of the skin has been divided into a superficial and a deep vascular plexus (Fig. 102.1), with additional vascular networks surrounding sweat glands and hair follicles.

The architecture of the cutaneous vascular system varies in different areas of the body. In the presence of pronounced epidermal rete ridges, such as in the skin overlying the extensor aspects of the joints or on the palms and soles, straight capillary loops extend into the elongated dermal papillae. In contrast, rete ridge formation and papillary loop formation are less pronounced in sites such as abdominal skin. The shape of the papillary microvessels reflects the three-dimensional architecture of the epidermal rete ridges, typically with one or two loops within each dermal papilla[1]. The inner diameter of papillary blood vessels averages between 5 and 10 microns. In contrast to the idealized architectural model of the cutaneous vascular system, vascular perfusion studies (Fig. 102.2) and light-sheet fluorescence microscopy studies (Fig. 102.3) revealed a rather continuous, sometimes irregular meshwork of interconnecting cutaneous blood vessels. Consistently, blood vessels are found immediately below the non-vascularized epidermis.

Anagen hair follicles are highly vascularized. The often single blood vessel within the mesenchymal hair papilla is derived from the lower vascular plexus, whereas the dense vascular network surrounding the hair follicle is predominantly derived from the upper vascular plexus (Fig. 102.4). The relatively small blood vessels found in the telogen resting phase elongate and enlarge during the anagen growth phase and then extend towards the subcutis together with the growing hair follicle[2]. In the catagen phase, hair follicle involution is associated with regression of perifollicular blood vessels and with increased rates of endothelial cell apoptosis. The extent of perifollicular vascularization may directly influence the size of the hair follicles[2].

The cutaneous vasculature also plays a systemic role in regulating body temperature and blood pressure. Arterioles have precapillary muscular sphincters that, upon contraction, shunt the blood via arteriovenous anastomoses directly to venules, thereby bypassing the capillary networks. Arteriovenous anastomoses are frequently found in the fingertips, where they form the glomi or glomus bodies[1]. Glomi have autonomous innervation and control peripheral blood flow via modulation of their muscular contraction levels.

In the extremities, venous blood vessels have valves that consist of thin, half-moon-shaped folds composed primarily of collagen and covered on both sides by endothelium. These valves are required for the efficient return of blood proximally and ensure unidirectional flow. Initially, it was thought that venous valves were limited to larger veins. However, a series of investigations revealed that (micro)valves are also present in small postcapillary venous networks in the skin, down to a vessel diameter of just less than 100 microns. These valves prevent venous reflux from postcapillary venules into the capillary bed and arteriovenous anastomoses[3].

All blood vessels contain a continuous inner monolayer of flat endothelial cells that are surrounded, on the external side, by a continuous basement membrane. Smaller vessels have a second, sometimes discontinuous, layer of perivascular cells called pericytes, which are surrounded

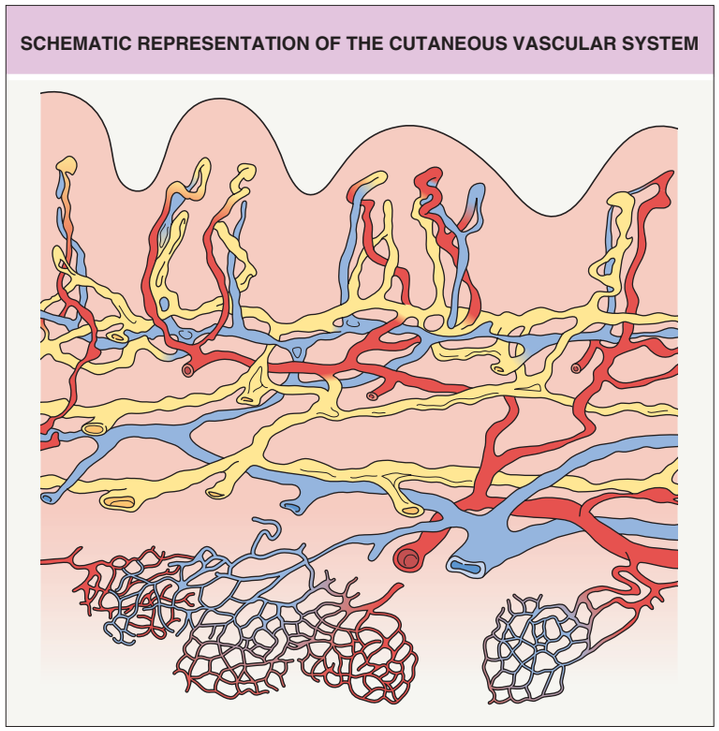

Fig. 102.1 Schematic representation of the cutaneous vascular system. The superficial vascular plexus feeds vessels in the dermal papillae; arteries (red) and veins (blue) are closely associated with lymphatic vessels (yellow). The capillary networks of the subcutaneous adipose tissue are depicted at the base of the schematic.

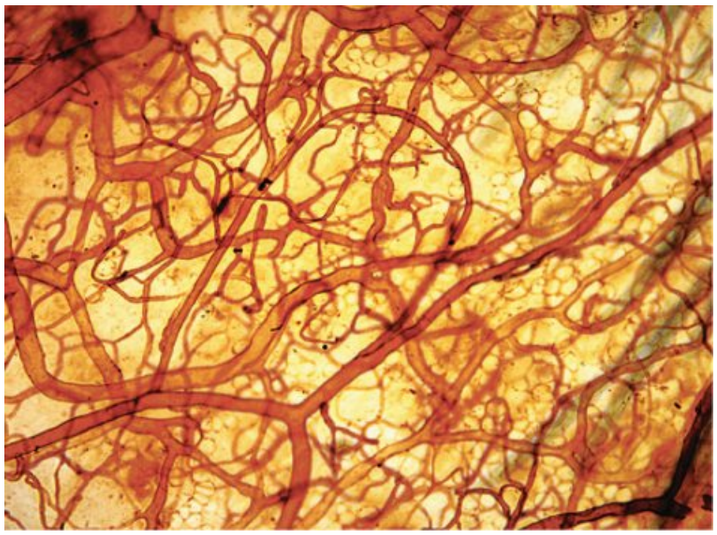

Fig. 102.2 Intravascular perfusion of murine skin with the lectin *Lycopersicon esculentum*. The perfusion highlights dense irregular vascular networks.

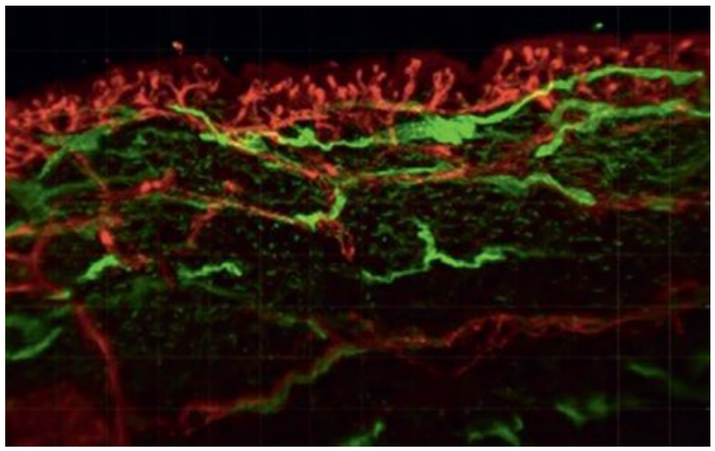

Fig. 102.3 Light-sheet fluorescent microscopy depicting distinct staining of cutaneous blood vessels and lymphatic vessels in human skin. The blood vessels stain positively for von Willebrand factor (red) while the lymphatic vessels stain positively for LYVE-1 (green). Multiple capillary loops are seen in the dermal papillae (top).

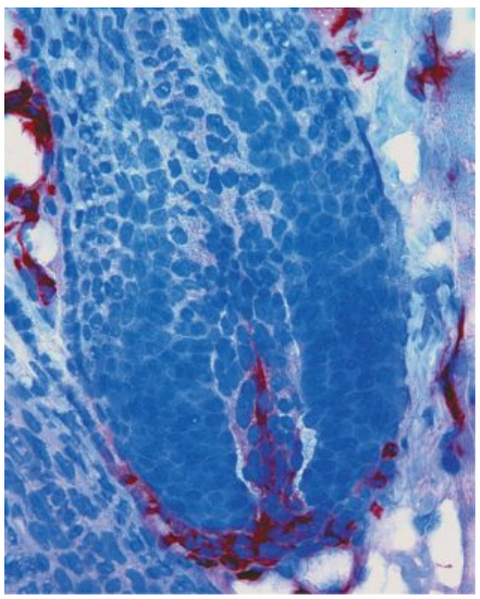

Fig. 102.4 Blood supply of the hair follicle. A single vascular loop extends into the dermal papilla of the hair follicle, while a mesh of blood vessels surrounds the anagen hair follicle (CD31 immunohistochemical stain).

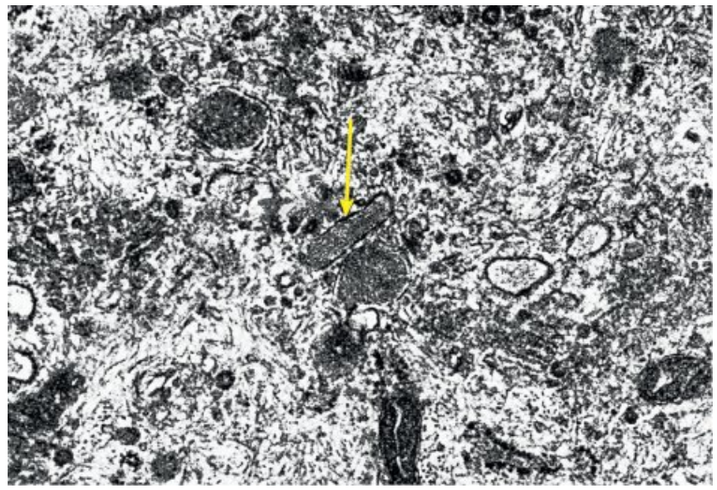

Fig. 102.5 Ultrastructural visualization of a rod-shaped Weibel–Palade body (WPB; arrow) within the cytoplasm of a human endothelial cell.

by a basement membrane that is continuous with the endothelial basement membrane. Pericytes play an important role in maintaining mature blood vessels, and detachment of pericytes from endothelial cells is an early event during sprouting angiogenesis (outgrowth of new capillaries from pre-existing blood vessels). Pericytes also surround arterioles and venules, and they can be visualized by staining for platelet-derived growth factor receptor-β (PDGFR-β), NG2 (chondroitin sulfate proteoglycan 4), α-smooth muscle actin, and desmin. The walls of most arterioles, larger venules, and veins contain contractile smooth muscle cells surrounded by a basement membrane. Vascular basement membranes contain collagen types IV, XV and XVIII, laminin, fibronectin, and other extracellular matrix proteins (see Ch. 95).

At the ultrastructural level, endothelial cells are characterized by tight junctions between adjacent cells and by specialized organelles, the rod-shaped Weibel–Palade bodies (Fig. 102.5). These Weibel–Palade bodies are storage organelles for the coagulation factor von Willebrand factor (also known as factor VIII-related antigen); they also contain P-selectin, angiopoietin-2, and endothelin-1. Activation of endothelial cells by proinflammatory cytokines or pro-angiogenic factors leads to translocation of Weibel–Palade bodies to the cell membrane, with consecutive enhanced membrane expression of P-selectin and release of von Willebrand factor. Other characteristic ultrastructural features include caveolae (minute invaginations of the membrane surface), pinocytotic vesicles, and the formation of vesiculo-vacuolar organelles (VVOs)[4]. Circulating macromolecules cross the endothelium through interendothelial cell gaps and transendothelial cell pores, some of which arise from VVOs. Endothelial cell fenestrations, areas with direct apposition of the endothelial cell membranes without intervening cytoplasm, are rarely seen in normal skin except in angiogenic perifollicular blood vessels during the growth phase of the hair follicle. However, fenestrated endothelial cells are frequently seen in skin diseases with pronounced angiogenesis and vascular hyperpermeability, including psoriasis.

Several markers are utilized for immunohistochemical staining of blood vascular endothelial cells (Table 102.1). In normal human skin, the most specific markers for cutaneous *blood vessels* appear to be von Willebrand factor (see Fig. 102.3), CD34, and PV-1 (plasmalemma vesicle-associated protein-1); the latter is recognized by the PAL-E (Pathologische Anatomie Leiden-Endothelium) antibody. Double immunofluorescence stains for the pan-endothelial cell marker CD31 (PECAM-1) plus the lymphatic vessel endothelial hyaluronan receptor-1 (LYVE-1) or the glycoprotein podoplanin (recognized by the widely used D2-40 antibody) also allow for the selective visualization of LYVE-1-negative (or podoplanin-negative), CD31-positive blood vessels in the skin. As a result, blood vessels can be distinguished from lymphatic vessels (see Fig. 102.15).

VASCULAR DEVELOPMENT

During embryogenesis, the first blood vessels are formed through *vasculogenesis*, defined as the differentiation of undifferentiated angioblasts into endothelial cells that form a primitive vascular network.

IMMUNOHISTOCHEMICAL MARKERS FOR LYMPHATICS AND FOR BLOOD VESSELS		
Marker	**Lymphatics**	**Blood vessels**
CD31 (PECAM-1)	+	++
CD34	–	++
von Willebrand factor	–	+
PV-1 (PAL-E antibody)	–	+
VEGFR-3	+	–
Podoplanin (D2-40 antibody)	++	–
LYVE-1	++	–
Prox1	++	–

Table 102.1 Immunohistochemical markers for lymphatics and for blood vessels. The medium shading and the dark shading highlight markers that distinguish blood vessels and lymphatics, respectively. LYVE-1, lymphatic vessel endothelial hyaluronan receptor-1; PAL-E, Pathologische Anatomie Leiden-Endothelium; PECAM-1, platelet-endothelial cell adhesion molecule-1; Prox1, prospero-related homeobox 1; PV-1, plasmalemma vesicle-associated protein-1; VEGFR, vascular endothelial growth factor receptor.

Angioblasts originate from blood islands in the extraembryonic mesoderm of the yolk sac. Blood islands are clusters of epithelioid cells; the outer cells differentiate into angioblasts, whereas the inner cells differentiate into primitive hematopoietic cells, suggesting that both cell types originate from a common embryonic precursor cell, the hemangioblast[5] (Fig. 102.6). Hemangioblasts are derived from earlier precursor cells under the influence of fibroblast growth factors (FGFs), and they already express the high-affinity receptor for vascular endothelial growth factor-A (VEGF-A) – vascular endothelial growth factor receptor-2 (VEGFR-2; KDR [human]; Flk-1 [murine]).

Angioblasts develop under the influence of stimulation by VEGF-A and express several vascular endothelial cell markers, including the Tie-1 and Tie-2 receptors, vascular endothelial (VE)-cadherin, and the high-affinity VEGF receptors 1 (Flt-1), 2 (KDR), and 3 (Flt-4). Within the embryo, angioblasts that appear along the anterior intestinal portal and the lateral edges of the somites coalesce to form the dorsal aorta and the large vessel primordia of the body. Angioblasts are highly migratory "prevascular" endothelial cells and are found throughout the embryo with the exception of tissues such as cartilage and epithelia.

When angioblasts form a lumen, they become endothelial cells with a polarized phenotype and production of a basal lamina. Interaction of integrin receptors on the endothelial surface with the basement membrane is critical for the formation of the primordial vascular plexus, while vascular endothelial (VE)-cadherin is required for the formation of interendothelial adherence junctions. The early vascular system consists of sinusoidal capillaries arranged in a polygonal honeycomb pattern (see Fig. 102.6). This primordial vascular plexus then becomes surrounded by mesenchymal cells that give rise to pericytes and vascular smooth muscle cells. In a next step, profound remodeling of the primordial vascular plexus takes place under the influence of VEGF-A, angiopoietins, and ephrins (see below). Remodeling involves both the formation and regression of blood vessels as well as apoptosis of vascular endothelial cells.

Angiogenesis, the sprouting of new blood vessels from existing primordial vessels, represents the major mechanism for new blood vessel formation[6]. During this process, specialized endothelial cells, so-called tip cells, extend filopodia and sense the environment for guidance cues such as VEGF-A (Fig. 102.7). Tip cells are followed by stalk cells which extend the sprout by proliferation and form a lumen[6,7]. Tip cells can connect with neighboring tip cells to form new vascular branches[8]. The specification of tip and stalk cells is regulated by Notch signaling. Activation of VEGFR-2 on tip cells by VEGF-A results in increased expression of the Notch ligand Delta-like 4 (Dll4), which binds to Notch expressed on neighboring stalk cells. Notch signaling in stalk cells leads to reduced VEGFR-2 expression, rendering these cells less responsive to VEGF-A (see Fig. 102.7). This is a highly dynamic process in which endothelial cells compete for the tip cell position[6,7]. In addition, glycolysis plays a vital role in the regulation of vascular sprouting, in parallel with genetic cues[9].

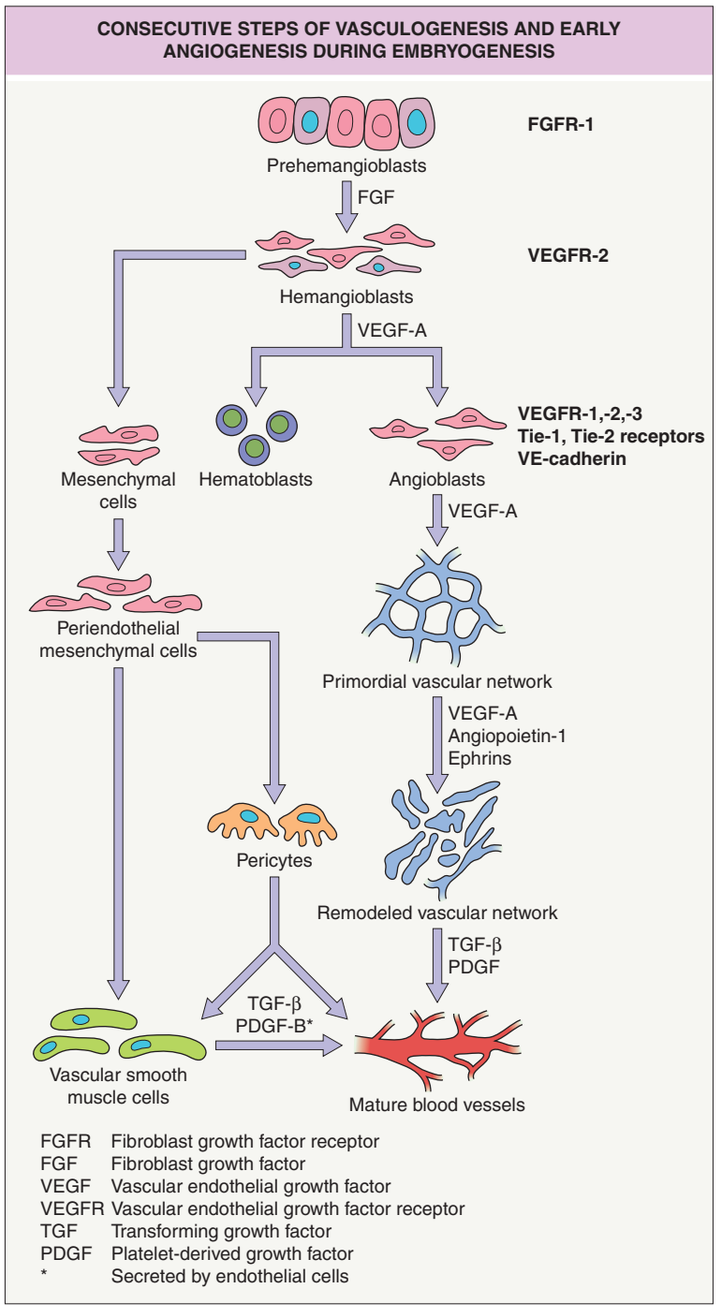

Fig. 102.6 Consecutive steps of vasculogenesis and early angiogenesis during embryogenesis: formation and remodeling of primordial vascular networks.

The Tie-2 receptor tyrosine kinase present on endothelial cells also plays a crucial role in vascular sprouting and remodeling during early embryonic angiogenesis. Pericyte-derived angiopoietin-1 (Ang-1) activates the Tie-2 receptor, whereas Ang-2 can act as an inhibitor of Ang-1 under angiogenic conditions (Fig. 102.8). In addition, Eph–ephrin receptor interactions, via bidirectional signaling, play an important role in vascular remodeling and in the determination of vascular identity. Ephrin B2 is specifically expressed by arterial endothelium, whereas its receptor, Eph-B4, is expressed by venous endothelium. Both molecules are involved in the definition of boundaries between arterial and venous endothelial cells.

Additional molecules are involved in the control of embryonic angiogenesis and vascular remodeling, including semaphorins, transforming growth factor-β (TGF-β), endoglin (the low-affinity receptor for TGF-β), and activin receptor-like kinase-1. Dysfunction of the latter two proteins is seen in hereditary hemorrhagic telangiectasia (see below). Platelet-derived growth factor subunit B (PDGF-B), secreted by endothelial cells, plays a critical role in the recruitment and differentiation of pericytes and periendothelial smooth muscle cells that contribute to the stability of mature blood vessels[6].

Regulation of Skin Angiogenesis

Angiogenesis is a common feature of developing skin during embryogenesis. In contrast, the blood vessels in healthy adult skin are predominantly quiescent, except for the expansion and involution of perifollicular blood vessels during the hair cycle[2]. However, adult skin retains the capacity for brisk initiation of angiogenesis in the setting of wound healing, inflammation, and neoplastic growth. Angiogenesis occurs as: (1) the sprouting outgrowth of new capillaries from pre-existing postcapillary venules; or (2) non-sprouting remodeling of pre-existing blood vessels either through circumferential growth/vascular enlargement or through the formation of intravascular endothelial cell pillars (intussusception). Angiogenesis is a multistep process that often involves as a first step the induction of microvascular hyperpermeability, i.e. increased vascular leakage, leading to extravasation of plasma proteins such as fibrinogen and prothrombin (Table 102.2). Fibrinogen is then further processed to fibrin and serves as a provisional matrix for migrating endothelial cells, whereas the generation of thrombin acts as an initiator of the extrinsic coagulation cascade, leading to cleavage and activation of several matrix proteins[10]. Together, these processes lead to the generation of a highly angiogenic stroma.

A major function of pericytes appears to be the maintenance of mature and quiescent blood vessels (a function which is interrupted during angiogenesis). In normal adult skin, pericytes secrete Ang-1, which leads to phosphorylation of the Tie-2 receptor (a receptor exclusively expressed on endothelial cells) and maintenance of the mature vascular architecture with low vascular permeability (see Fig. 102.8). In turn, endothelial cells secrete growth factors that mediate the recruitment of pericytes, including PDGFB that binds to the PDGFR-β on pericytes. During angiogenesis, endothelial cells express high amounts of Ang-2, a functional antagonist of Ang-1 in activated endothelium, thereby blocking the maturation-inducing effect of Ang-1 and leading to detachment of pericytes from vascular endothelial cells[11]. In the presence of VEGF-A, endothelial cells then undergo the consecutive steps of angiogenesis, whereas in the absence of VEGF-A, vascular endothelial cells undergo apoptosis (see Fig. 102.8). Both VEGF-A and Ang-2 expression are upregulated in angiogenic skin diseases, including psoriasis, and keratinocyte-derived VEGF-A and placental growth factor (PlGF; see below) both potently induce the expression of Ang-2 in dermal microvascular endothelial cells. Bone marrow-derived progenitor cells also contribute to the angiogenic response, with most of these cells differentiating into perivascular macrophages that secrete angiogenic factors, including VEGF-A.

The vascular basement membrane serves as a natural barrier that prevents sprouting of endothelial cells from quiescent vessels, with pericytes assisting in the maintenance of the quiescent state. An early step in the angiogenic response involves the degradation of vascular basement membrane components such as collagen type IV by the concerted action of activated proteases, including matrix metalloproteinase (MMP)-2 and MMP-9[7]. Integrin receptors on the surface of activated endothelial cells, in particular the $\alpha_1\beta_1$, $\alpha_2\beta_1$, and $\alpha_v\beta_3$ integrins, then interact with either native or degraded matrix molecules (e.g. collagen type I, fibronectin) to facilitate endothelial cell migration[12]. The migration of endothelial cells is directed towards a gradient of angiogenesis factors that are usually produced by the epidermis, but may also be secreted by macrophages and other stromal cells. Endothelial cells then undergo a series of cell divisions, promoted by potent angiogenesis factors such as VEGF-A and basic fibroblast growth factor (bFGF). Finally, the endothelial cells form vascular lumina and mature new blood vessels with basement membranes and pericytes.

In normal skin, vascular quiescence is maintained by the dominant influence of potent endogenous angiogenesis inhibitors over angiogenic stimuli. Angiogenesis is induced by increased secretion of angiogenic

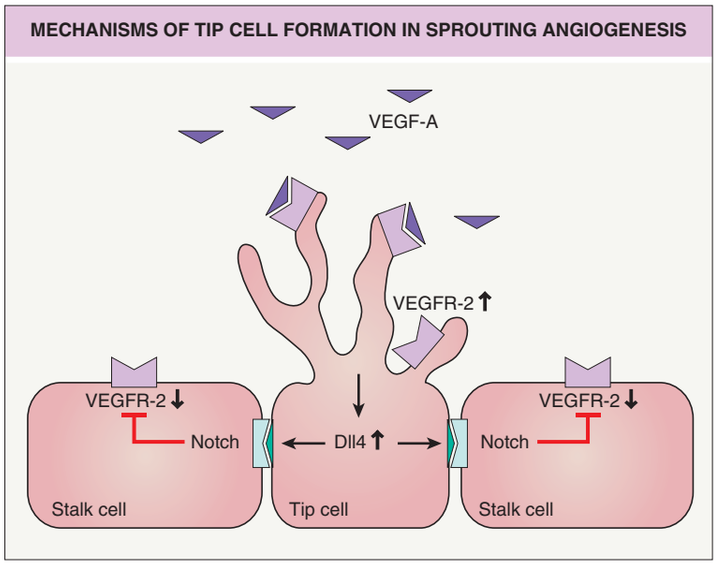

Fig. 102.7 Mechanisms of tip cell formation in sprouting angiogenesis. Activation of VEGFR-2 by VEGF-A in vascular tip cells promotes filopodia formation and increased expression of the Notch ligand Delta-like 4 (Dll4). Dll4 activates Notch signaling in neighboring stalk cells, leading to reduced VEGFR-2 expression and diminished sensitivity to VEGF-A.

THE STEPWISE INDUCTION OF ANGIOGENESIS
1. Induction of microvascular hyperpermeability
2. Enzymatic degradation of vascular basement membrane and interstitial matrix
3. Endothelial cell migration
4. Endothelial cell proliferation
5. Formation of mature blood vessels

Table 102.2 The stepwise induction of angiogenesis.

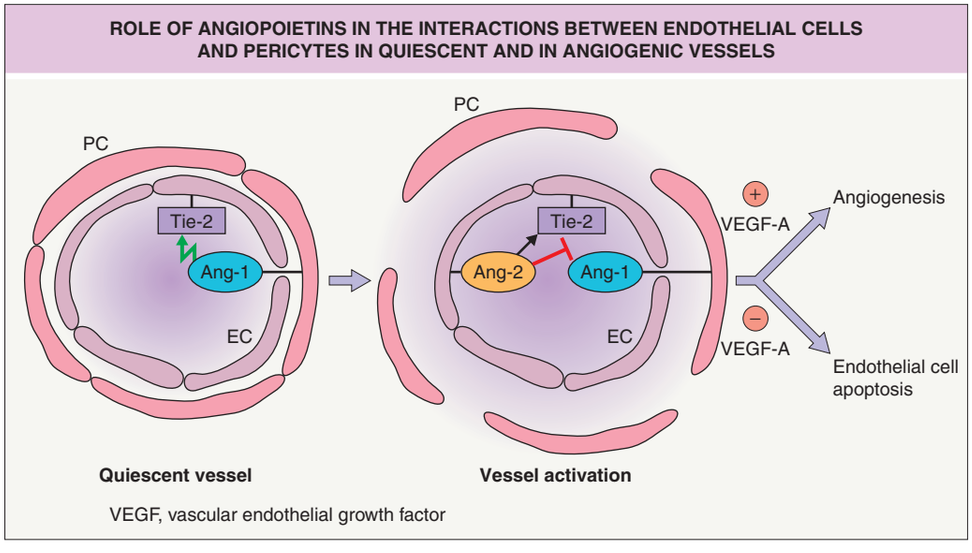

Fig. 102.8 Role of angiopoietins in the interactions between endothelial cells and pericytes in quiescent and in angiogenic vessels. Activation of the endothelial Tie-2 receptor by pericyte (PC)-derived angiopoietin-1 (Ang-1) maintains vessel maturation. Upregulation of angiopoietin-2 (Ang-2) in angiogenic endothelial cells (EC) blocks the vessel-stabilizing effect of pericyte-derived Ang-1 via the endothelial Tie-2 receptor. Both VEGF-A and Ang-2 expression are upregulated in angiogenic skin diseases, including psoriasis.

factors and/or by downregulation of angiogenesis inhibitors. The major skin angiogenesis factor, VEGF-A, was originally discovered as vascular permeability factor (VPF) due to the activity of tumor cell-conditioned media to induce accumulation of ascites fluid[13]. VEGF-A is a homodimeric, heparin-binding glycoprotein with at least four isoforms of 121, 165, 189, and 201 amino acids (due to alternative splicing) found in human skin. VEGF-A binds to two type III tyrosine kinase receptors that are expressed predominantly on vascular endothelial cells: Flt-1/VEGF receptor-1 (VEGFR-1) and KDR/Flk-1/VEGFR-2 (Fig. 102.9). In addition, VEGF-A165 also binds to the neuropilin-1 receptor on endothelial and other cells.

In vitro, VEGF-A acts as a specific mitogen for human dermal microvascular endothelial cells and induces endothelial cell migration. *In vivo*, VEGF-A enhances microvascular permeability and angiogenesis. VEGF-A is expressed at low levels in normal epidermis, whereas in healing wounds and in skin diseases associated with angiogenesis and vascular hyperpermeability, particularly psoriasis, VEGF-A expression by epidermal keratinocytes is markedly increased[14]. The expression and biologic activity of VEGF-A are controlled by several distinct molecular mechanisms. Hypoxia results in transcriptional activation (via hypoxia-inducible factors) and stabilization of VEGF-A mRNA. In the skin, hypoxia leads to upregulation of VEGF-A expression by epidermal keratinocytes, dermal fibroblasts, and dermal endothelial cells. This mechanism is likely important for the induction of epidermal VEGF-A expression during wound healing and in hypoxic areas of skin cancers.

Keratinocyte VEGF-A expression is also induced by growth factors that mediate epidermal hyperplasia. In psoriasis, healing wounds, and squamous cell carcinomas (SCCs), TGF-α and other ligands of the epidermal growth factor receptor (EGFR) are released by suprabasal keratinocytes. In an autocrine loop, these growth factors induce hyperplasia of the epidermis. Simultaneously, they induce VEGF-A gene expression and protein secretion by epidermal keratinocytes, which leads to paracrine induction of angiogenesis via interaction with VEGF receptors on cutaneous microvessels (see Fig. 102.9). This mechanism links epidermal hyperplasia with increased vascularization, thereby providing enhanced vascular support to meet the enhanced nutritional needs of proliferating keratinocytes[14]. Several other growth factors that stimulate keratinocyte proliferation, including keratinocyte growth factor (KGF), bFGF, and hepatocyte growth factor (HGF), can also promote VEGF-A production by epidermal keratinocytes.

The biologic importance of epidermis-derived VEGF-A for cutaneous angiogenesis *in vivo* has been confirmed in genetic mouse models designed to have overexpression of VEGF-A in epidermal keratinocytes. VEGF-A transgenic mice are characterized by elongated and tortuous dermal blood vessels that are hyperpermeable to circulating plasma proteins. These mice are unable to downregulate experimentally induced cutaneous inflammation and develop chronic inflammatory skin lesions that closely resemble those of human psoriasis[15]. Many human cancers are characterized by increased expression of VEGF-A by tumor cells and by increased expression of VEGF receptors by tumor-associated blood vessels. VEGF-A also promotes skin carcinogenesis, in that selective transgenic overexpression of VEGF-A in epidermal keratinocytes resulted in enhanced tumor development and metastasis[16].

Placental growth factor (PlGF) is a member of the VEGF family and two isoforms, PlGF-1 (149 amino acids) and PlGF-2 (170 amino acids), are expressed in human skin. Similar to VEGF-A, PlGF expression is upregulated in cutaneous SCCs, epidermal keratinocytes at the advancing wound edge, and hyperplastic psoriatic epidermis. In contrast to VEGF, PlGF does not activate VEGFR-2 (KDR) but selectively binds to VEGFR-1 (see Fig. 102.9). In addition, the heparin-binding isoform PlGF-2 binds to the neuropilin-1 receptor. Evidence from genetic mouse models indicates that PlGF and VEGF-A act in synergy to induce both angiogenesis and vascular leakage and that PlGF exerts proinflammatory effects[17]. A number of additional pro-angiogenic molecules are upregulated in angiogenic skin conditions, including interleukin-8, PDGF, bFGF, and several angiogenic chemokines[18].

Thrombospondin (TSP)-1 and TSP-2 are major inhibitors of cutaneous angiogenesis that are expressed in normal human skin. These matricellular proteins mediate interactions between extracellular matrix molecules and cellular integrin receptors. TSP-1 inhibits endothelial cell proliferation *in vitro* and angiogenesis *in vivo*. In normal human skin, TSP-1 is expressed by dermal cells and by epidermal keratinocytes. It is deposited within the dermal–epidermal basement membrane zone, contributing to the barrier that prevents ingrowth of blood vessels into the epidermis. TSP-1 expression is downregulated in cutaneous SCCs, and reintroduction of *TSP-1* into SCCs inhibits tumor growth in mice, in association with inhibition of tumor angiogenesis and enhanced tumor cell death[19]. Overexpression of TSP-1 in the skin of transgenic mice results in impaired granulation tissue formation and wound vascularization, delayed and reduced skin carcinogenesis, and diminished photodamage from chronic UVB irradiation. Interestingly, UVB irradiation of human skin results in an angiogenic switch with upregulation of VEGF-A and downregulation of TSP-1[20]. The mechanisms by which TSP-1 inhibits skin angiogenesis include the induction of endothelial cell apoptosis through specific interactions with the endothelial CD36 receptor, the activation of latent TGF-β, and the inhibition of matrix metalloproteinase activity.

TSP-2 also acts as an endogenous inhibitor of angiogenesis. Mice deficient in TSP-2 show increased skin vascularization, enhanced and prolonged inflammatory reactions, and increased skin carcinogenesis, confirming the important role of endogenous TSP-2 in controlling skin angiogenesis. Accordingly, targeted overexpression of TSP-2 within murine epidermis protects from skin cancer development and inhibits the growth of established skin cancers[21]. Antiangiogenic activity has also been reported for several cleavage products of molecules that are expressed in the vascular basement membrane, including fragments of collagens type IV (tumstatin), XV, and XVIII (endostatin).

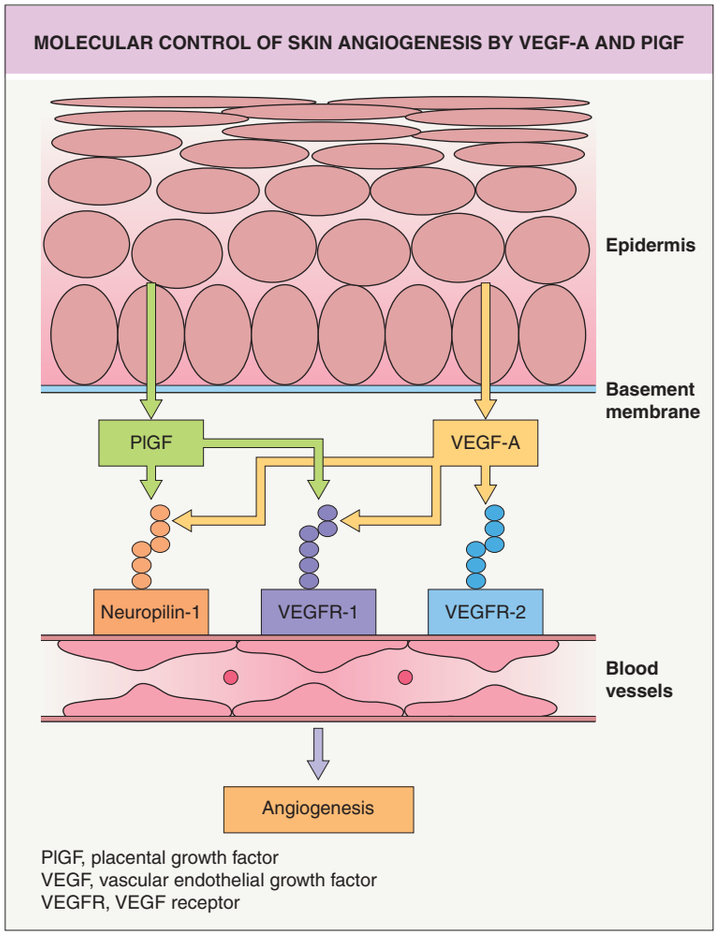

Fig. 102.9 Molecular control of skin angiogenesis by vascular endothelial growth factor-A (VEGF-A) and placental growth factor (PlGF).

Angiogenesis and Wound Healing

Capillary growth from pre-existing vasculature is an essential component of the proliferative phase of cutaneous wound healing (see Fig. 141.3). After exposure to thrombin, endothelial cells release matrix metalloproteinase-2 (gelatinase-A), which causes local dissolution of the basement membrane and extracellular matrix (ECM), allowing endothelial cells

to migrate through the basement membrane. Capillary sprouts then invade the ECM and the fibrin clot in the wound bed, and within a few days, a new stroma forms. This so-called granulation tissue is characterized by the proliferation of blood vessels, fibroblast migration, and collagen synthesis. In this neostroma, the angiogenic sprouts organize into a dense microvascular network, thereby supporting cells with nutrition and oxygen.

The process of vascular sprouting within the premature wound matrix is controlled by several factors including hypoxia (due to microvascular damage) as well as various growth factors and cytokines released from platelets or produced by neutrophils, macrophages, fibroblasts, and keratinocytes during the inflammatory stage of wound healing (Fig. 102.10)[22]. The low oxygen gradient between injured and healthy tissues induces the transcriptional activator hypoxia-inducible factor-1 (HIF-1) which promotes angiogenesis via multiple mechanisms. The latter include: (1) upregulation of a large number of proangiogenic target genes; and (2) production of pro-angiogenic growth factors such as VEGF-A and stromal cell derived factor-1 (SDF-1 or CXCL12; see Fig. 102.10). In addition to hypoxia, cellular disruption also initiates angiogenesis via release of fibroblast growth factors (FGF-1/2). Endothelial progenitor cells are also recruited to the wound site, where they differentiate into mature endothelial cells.

During these initial phases of wound healing, the pro-angiogenic environment creates an immature microvascular network characterized by high vessel tortuosity, often resulting in dead-end flow pathways. The newly formed microvascular network has a density of blood vessels that exceeds that of normal skin. However, after this maximum density of blood vessels during the initial phases, microvascular regression is observed due to the release of several antiangiogenic factors including pigment epithelium-derived factor (PEDF), IFN-γ-inducible protein-10 (CXCL10), or Sprouty-2[23].

At the same time, vascular interstitial cells, including smooth muscle cells and pericytes, stabilize the newly formed microvascular capillaries. The major growth factor that supports the stabilization of this new vascular network is PDGF-B which stimulates pericyte differentiation and has been used therapeutically in the treatment of diabetic wounds. Furthermore, the angiopoietins Ang-1 and Ang-2, together with their receptor Tie-2, regulate the angiogenic response throughout cutaneous wound healing. Additional soluble factors that have been reported to be involved in the orchestration of the angiogenic phase of cutaneous wound repair are depicted in Fig. 102.10. Defects in cutaneous angiogenesis impair the formation of granulation tissue and delay healing, leading to the development of a non-healing environment in several types of chronic cutaneous wounds[24].

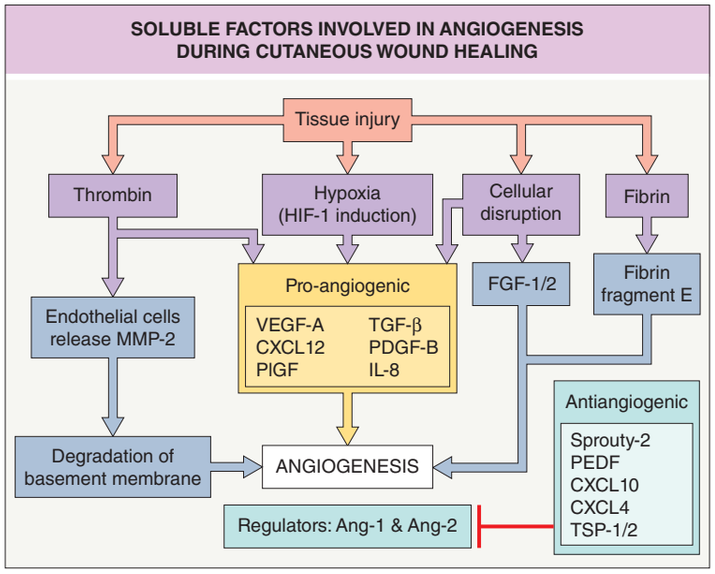

Fig. 102.10 Soluble factors involved in angiogenesis during cutaneous wound healing. Following tissue injury, multiple pro-angiogenic as well as antiangiogenic factors modulate cutaneous wound healing. Ang-1/2, angiopoietin-1/2; CXCL4/10/12, C-X-C motif chemokine ligand 4/10/12; FGF-1/2, fibroblast growth factor-1/2; HIF-1, hypoxia-inducible factor-1; IL-8, interleukin-8; MMP-2, matrix metalloproteinase-2; PEDF, pigment epithelium-derived factor; PlGF, placental growth factor; PDGF-B, platelet-derived growth factor-B; TSP-1/2, thrombospondin-1/2; TGF-β, transforming growth factor-β; VEGF-A, vascular endothelial growth factor A. Stromal cell derived factor-1 (SDF-1) is also known as CXCL12.

Regulation of Leukocyte–Endothelial Cell Interactions

Accumulation of leukocytes is a prominent feature of acute and chronic inflammatory skin diseases and represents a rate-limiting step in the inflammatory response. Leukocyte recruitment is a multistep process controlled by the sequential activation of a number of adhesion molecules on both leukocytes and vascular endothelial cells, as well as by several inflammatory cytokines and chemokines. Leukocyte extravasation occurs primarily in the postcapillary venules of the skin as they are particularly sensitive to the induction of adhesion molecules. The specific cell-type expression, ligands, and function of the major adhesion molecules involved in leukocyte–endothelial cell interactions are summarized in Table 102.3.

MAJOR ADHESION MOLECULES INVOLVED IN LEUKOCYTE–ENDOTHELIAL CELL INTERACTIONS: CELL-TYPE SPECIFIC EXPRESSION, LIGANDS, AND FUNCTION

Adhesion molecule	Cell type	Ligands	Function
Integrin family			
LFA-1 (CD11a/CD18)	Leukocytes	ICAM-1, ICAM-2, JAM-A	Adhesion, crawling, transmigration
Mac-1 (CD11b/CD18)	Granulocytes, monocytes	ICAM-1, ICAM-2, JAM-C	Adhesion, crawling, transmigration
VLA-4 (CD49d/CD29)	Lymphocytes, monocytes, eosinophils, basophils	VCAM-1, JAM-B	Adhesion, crawling, transmigration
Selectin family			
E-selectin (CD62E)	Endothelial cells	ESL-1, PSGL-1, CD44	Capture, rolling
P-selectin (CD62P)	Endothelial cells	PSGL-1	Capture, rolling
L-selectin (CD62L)	Leukocytes	CD34, GlyCAM-1, MAdCAM, PSGL-1	Capture, rolling
Ig supergene family			
ICAM-1 (CD54)	Endothelial cells, monocytes	LFA-1, Mac-1, CD43	Adhesion, crawling
ICAM-2 (CD102)	Endothelial cells	LFA-1, Mac-1	Adhesion, crawling, transmigration
VCAM-1 (CD106)	Endothelial cells	VLA-4	Adhesion, crawling
PECAM-1 (CD31)	Endothelial cells	PECAM-1	Adhesion, transmigration
Junctional adhesion molecules			
JAM-A	Endothelial cells	LFA-1	Adhesion, crawling
JAM-B	Endothelial cells	VLA-4	Adhesion, crawling, transmigration
JAM-C	Endothelial cells	Mac-1	Adhesion, crawling

Table 102.3 Major adhesion molecules involved in leukocyte–endothelial cell interactions: cell-type specific expression, ligands, and function. CLA, cutaneous lymphocyte-associated antigen; ESL, E-selectin ligand; GlyCAM, glycosylation-dependent cell adhesion molecule; ICAM, intercellular adhesion molecule; JAM, junctional adhesion molecule; LFA, lymphocyte function-associated antigen; Mac-1, macrophage-1 antigen; MAdCAM, mucosal addressin cell adhesion molecule; PECAM, platelet–endothelial cell adhesion molecule; PSGL, P-selectin glycoprotein ligand; VCAM, vascular cell adhesion molecule; VLA, very late activation antigen.

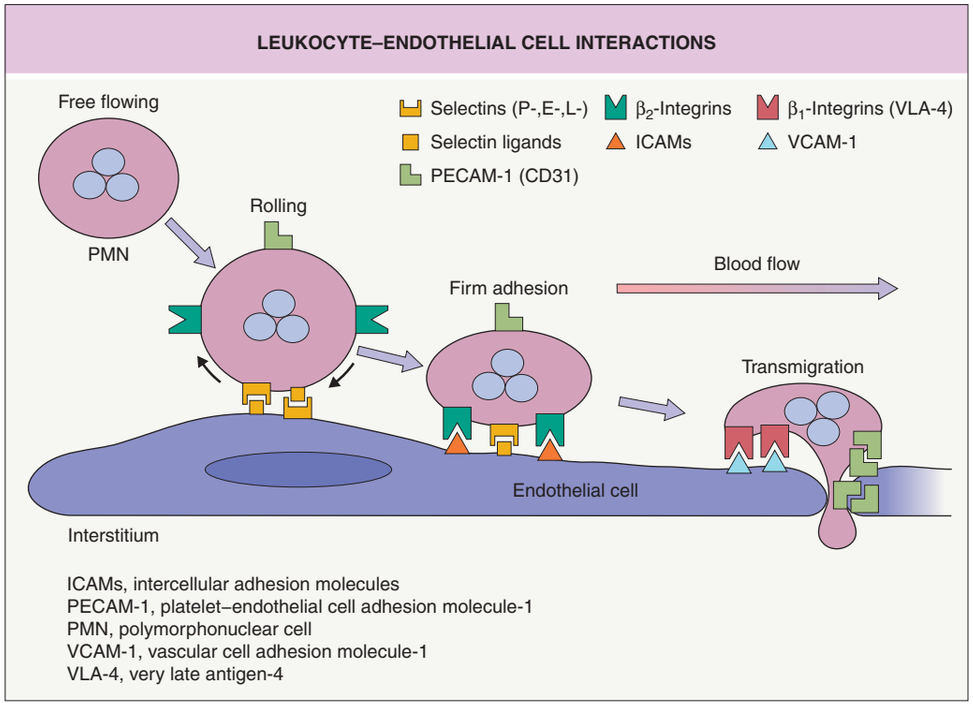

Fig. 102.11 The multistep process of leukocyte–endothelial cell interactions that leads to leukocyte recruitment into inflamed skin. Leukocyte extravasation involves tethering and rolling, largely mediated by selectins and their ligands. This is followed by firm adhesion and transmigration, largely mediated by adhesion molecules and their integrin ligands. Selectin ligands on leukocytes include E-selectin ligand-1 (ESL-1) and P-selectin glycoprotein ligand (PSGL-1).

As the first step in leukocyte extravasation, relatively weak adhesive interactions between leukocytes and endothelial cells, involving distinct selectins and their ligands, lead to tethering and rolling of leukocytes on the vessel wall (Fig. 102.11). In a second step, leukocytes become firmly attached to the vessel wall, which is mainly mediated by the interaction of adhesion molecules of the immunoglobulin superfamily and their ligands. The switch from the rolling phase to firm luminal adhesion and crawling requires activation of integrins, in which they switch from a low-affinity to a high-affinity conformation. This activation is mediated by signaling via chemokines that are either expressed by endothelial cells themselves and presented on their surface or expressed by perivascular cells and transcytosed by the endothelium.

Finally, leukocytes migrate into the dermis through spaces between adjacent endothelial cells. Junctions between endothelial cells are usually very tight due to interactions of vascular endothelial (VE)-cadherin, junctional adhesion molecules (JAMs), and others, and they need to be opened transiently for leukocytes to be able to transmigrate. During this process, vascular endothelial-protein-tyrosine phosphatase (VE-PTP) plays a major role. VE-PTP is normally associated with VE-cadherin but becomes transiently separated from it during leukocyte transmigration[25].

STRUCTURE AND FUNCTION OF THE CUTANEOUS LYMPHATIC VASCULAR SYSTEM

The cutaneous lymphatic system develops in parallel with the blood vascular system through a process termed lymphangiogenesis, and lymphatic vessels are not present in avascular structures such as epidermis, hair, and nails[26]. The lymphatic system is composed of a vascular network of thin-walled capillaries that drain protein-rich lymph from the extracellular space and play a crucial role in maintaining normal tissue pressure. Lymphatic vessels also play an essential role in mediating the transport of immune cells from the skin to the regional lymph nodes. The lymphatic system also plays a role in the metastatic spread of cutaneous malignancies, with anti-lymphangiogenic therapy representing a potential strategy for some cancer types[27].

Lymphatic capillaries are lined by a continuous single-cell layer of overlapping endothelial cells and lack a continuous basement membrane. In the initial lymphatic vessels, overlapping flaps at the borders of oak leaf-shaped endothelial cells lack junctions at their tips but are anchored on the sides by discontinuous button-like junctions; the latter differ from the conventional, continuous, zipper-like junctions found in larger collecting lymphatics and blood vessels[28]. Lymph returns to the venous circulation via larger lymphatic collecting vessels that contain a muscular and adventitial layer as well as numerous valves. The thoracic duct and right lymphatic duct are connected via lymphovenous valves to the subclavian veins.

The lymphatic vessels of the skin form two horizontal plexuses. The superficial plexus collects lymph from lymphatic capillaries and is located in close vicinity to the superficial cutaneous arterial plexus. Vertical lymphatic vessels connect the superficial plexus with the larger collecting vessels in the lower dermis and upper subcutis, whereas few lymphatics are found within the subcutis (see Fig. 102.1). The deep lymphatic vessels are located below the deep arterial system and contain valves to ensure unidirectional fluid transport.

The structure of the cutaneous lymphatics is dependent on the structure of the skin at a particular site and can vary significantly. Lymphatic vessels have a regular, uniform shape where the skin is firm and thick, whereas the shapes are more variable in regions where the skin is thin and loose. Certain areas, such as the fingers, genitalia, and palms and soles, appear to have a more abundant lymphatic network.

Lymphatic capillaries respond to increased tissue fluid content by widening their lumina (Fig. 102.12), an action mediated by anchoring filaments that connect the lymphatic endothelial cells with the surrounding interstitium. In normal skin, the majority of lymphatic vessels are collapsed. Whereas elevation of the interstitial pressure up to +2 mmHg results in both distention of lymphatic vessels and increased lymph flow, higher interstitial fluid pressure results in edema formation. The detection of enlarged lymphatics in the skin, however, does not allow predictions about their function because overextended lymphatics can be dysfunctional, as in some types of lymphedema[29]. Increased fluid load in the tissue is thought to activate lymphatic drainage via mechanosensors in lymphatic endothelium[30].

The peripheral lymphatic system is thought to originate from primary lymph sacs which arise from endothelial cells that bud from veins during early development. They then spread by endothelial sprouting into the surrounding tissues and organs. Non-venous progenitor cells may also contribute to the formation of cutaneous lymphatic vessels[31]. The homeobox gene *Prox1* is a specific marker for lymphatic endothelial cells. *Prox1* is first expressed during embryonic development in a polarized manner by a subset of venous endothelial cells. The latter bud off from the cardinal veins, migrate through the tissues, and finally form lymphatic vessels (Fig. 102.13). In adults, specific expression of Prox1 is maintained by cutaneous lymphatic endothelial cells and – together with podoplanin – appears to be the most specific marker for lymphatic vascular differentiation in the skin (see Table 102.1)[32]. Of note, Prox1 deficiency results in complete absence of a lymphatic

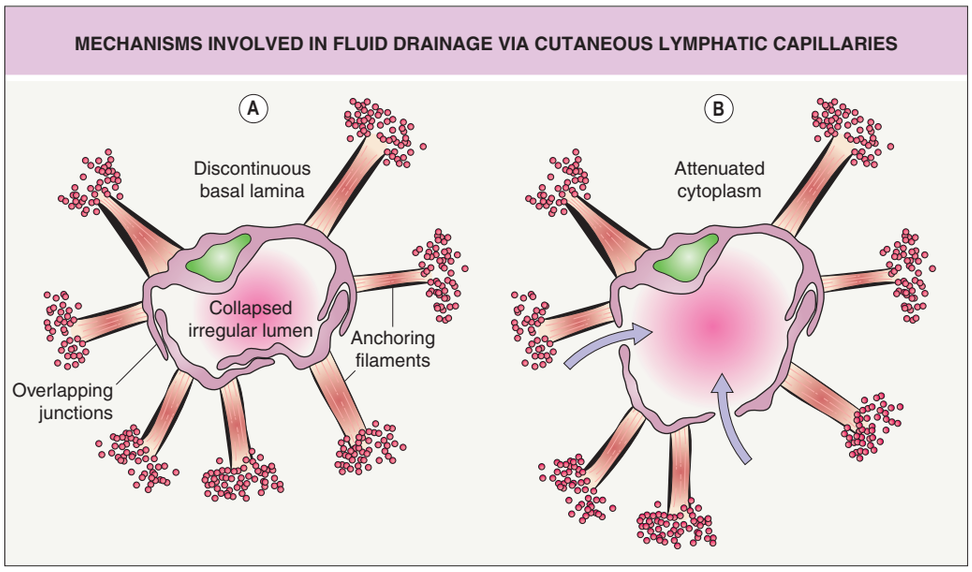

Fig. 102.12 Mechanisms involved in fluid drainage via cutaneous lymphatic capillaries. A Normal skin. **B** Skin with increased interstitial fluid content.

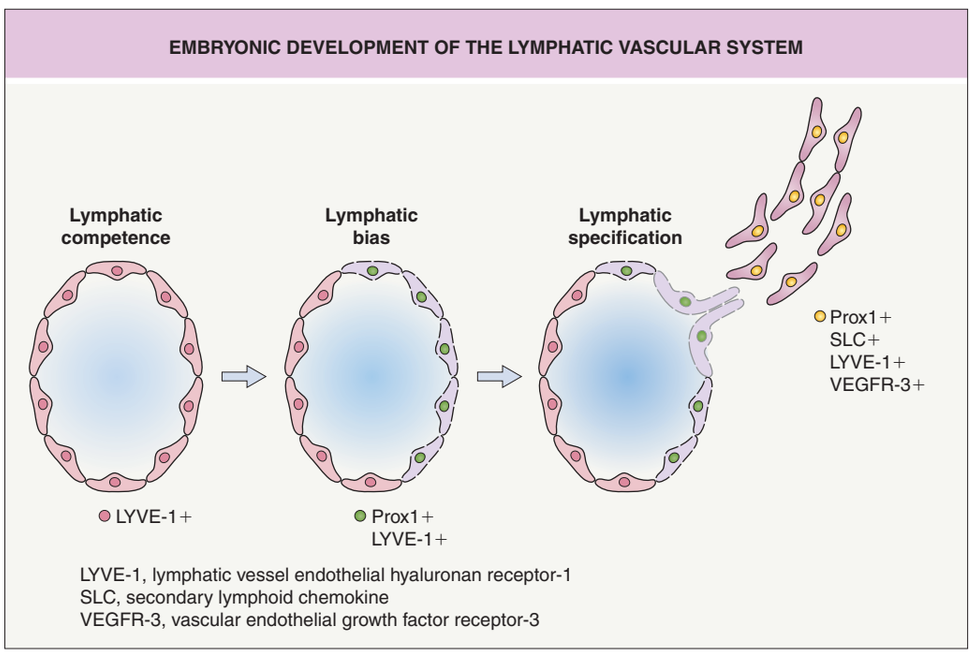

Fig. 102.13 Embryonic development of the lymphatic vascular system.

system in mice, among other defects, and Prox1 activity is needed to maintain the lymphatic vessel phenotype after birth[33].

Other markers, in addition to Prox1, have been identified that are predominantly or exclusively expressed by lymphatic endothelial cells in the skin (see Table 102.1). *VEGFR-3* (vascular endothelial growth factor receptor-3, Flt-4) is expressed on lymphatic vessels in normal skin and serves as a receptor for the lymphangiogenesis factors VEGF-C and VEGF-D[34] (Fig. 102.14). *Podoplanin*, a transmembrane glycoprotein, is a specific marker for the cutaneous lymphatic vasculature. The antibody D2-40 recognizes podoplanin and specifically stains lymphatic vessels (but not blood vessels) in normal and diseased human skin[35]. Of note, podoplanin plays an important role in the separation of the lymphatic and blood vascular systems by inducing platelet aggregation via its receptor CLEC2 on platelets; this prevents the influx of blood into the lymphatic vascular system. Indeed, either specific podoplanin deficiency in the lymphatic vessels of mice or the absence of CLEC2 in platelets results in blood filling of the lymphatic vascular system[36,37].

The *lymphatic vessel endothelial hyaluronan receptor-1* (LYVE-1), a CD44 homolog, has been identified as a specific cell surface protein of lymphatic endothelial cells. Although some specialized blood vascular endothelial cells that are involved in hyaluronic acid metabolism (e.g. sinusoidal endothelial cells in the liver, vascular endothelium in the lung) also express LYVE-1, its expression is specific for lymphatics in most organs, including the skin (Fig. 102.15; see Fig. 102.3). The expression of LYVE-1 is stronger in lymphatic capillaries than in larger lymphatic collecting vessels. Some of the markers discussed here, including VEGFR-3 and LYVE-1, can also be expressed by distinct subsets of leukocytes such as macrophages, particularly under inflammatory conditions. Thus, double staining with markers such as LYVE-1 plus the endothelial marker PECAM-1 (platelet–endothelial cell adhesion molecule-1, CD31), which is expressed by both blood vessel and lymphatic endothelial cells, is recommended for the unequivocal identification of lymphatic vessels (see Table 102.1).

Several molecules have been discovered that regulate the growth and function of lymphatic vessels. Both VEGF-C and VEGF-D activate the receptor tyrosine kinase VEGFR-3 (Flt-4) on lymphatic endothelial cells and, after proteolytic cleavage, the receptor tyrosine kinase VEGFR-2 (KDR) on blood vessels and lymphatic endothelium[34] (see Fig. 102.14). Transgenic mice with targeted overexpression of either VEGF-C or VEGF-D within the skin exhibited hyperplastic cutaneous lymphatic vessels, whereas no major abnormalities of blood vessels were found. Conversely, blockade of both VEGF-C and VEGF-D by transgenic overexpression of a soluble VEGFR-3 in the skin results in the absence of a cutaneous lymphatic system and development of lymphedema[38].

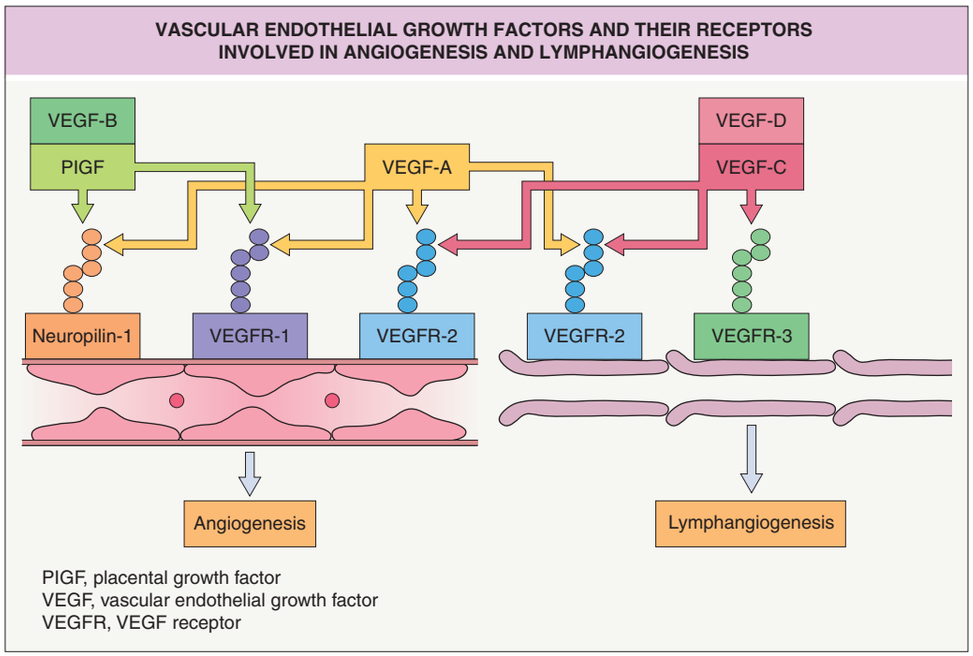

Fig. 102.14 Vascular endothelial growth factors and their receptors involved in angiogenesis and lymphangiogenesis. Heterozygous inactivating missense mutations of the gene encoding VEGFR-3, the receptor for the lymphangiogenesis factors VEGF-C and VEGF-D, have been found in families affected by primary lymphedema/lymphatic malformation 1, which is characterized by chronic swelling of the extremities.

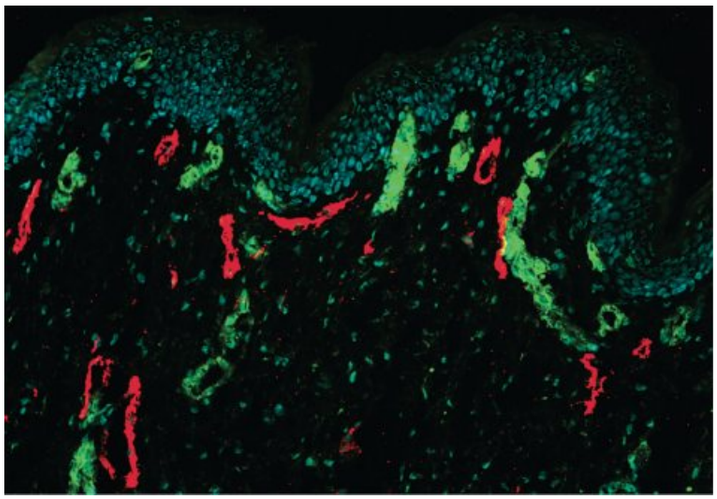

Fig. 102.15 Specific immunofluorescence staining of CD31-positive blood vessels (green) that are LYVE-1-negative and of CD31-positive/LYVE-1-positive lymphatic vessels (red) in human foreskin. Nuclei are stained blue.

Additional lymphangiogenesis factors have been identified, including VEGF-A, angiopoietin-1, bFGF, HGF, and sphingosine-1-phosphate[32].

ANGIOGENESIS- AND LYMPHANGIOGENESIS-RELATED DISEASES

Angiogenesis is a characteristic feature of tissue repair as well as numerous diseases, including inflammatory skin disorders (e.g. psoriasis, contact dermatitis), cutaneous neoplasias (e.g. SCC, melanoma, Kaposi sarcoma, infantile hemangiomas), and chronic wounds. Moreover, several other diseases are characterized by prominent visible blood vessels, including rosacea and basal cell carcinomas (BCCs). Genetic mutations that lead to dysfunction of the vascular Tie-2 receptor have been associated with vascular malformations[39] (see Ch. 104), and mutations in the genes that encode the low-affinity TGF-β receptor endoglin and activin receptor-like kinase (ALK)-1 lead to the formation of vascular malformations in patients with hereditary hemorrhagic telangiectasia types I and II, respectively[40].

Impairment of lymphatic function leads to the development of several diseases, most prominently to lymphedema with its associated impaired immune function, impaired wound healing, and fibrotic changes[41]. Heterozygous inactivating missense mutations of the gene encoding VEGFR-3 have been found in families affected by primary lymphedema/lymphatic malformation 1 characterized by chronic swelling of the extremities (see Table 105.7)[42]. In lymphedema–distichiasis, lymphatic vessel function fails due to mutations in the gene that encodes the forkhead transcription factor FOXC2[43]. Recessive and dominant forms of hypotrichosis–lymphedema–telangiectasia are also caused by dysfunction of a transcription factor, SOX18[44]. Additional gene mutations involved in lymphatic anomalies include *CCBE1*, *FAT4*, or *ADAMTS3* (Hennekam lymphangiectasia–lymphedema syndrome), *GJC2* (hereditary lymphatic malformation 3), *PTPN11* (Noonan syndrome), and *GATA2* (primary lymphedema with myelodysplasia [Emberger syndrome])[45].

Insufficient angiogenesis has also been shown to play a fundamental role in chronic wounds, particularly in patients with diabetes mellitus. In diabetic wounds, VEGF-A levels and the Ang-1 : Ang-2 ratio are decreased, while systemic PEDF levels are increased[46]. This results in a significant impairment of angiogenesis and wound healing.

Tumor-induced lymphangiogenesis promotes sentinel lymph node metastasis and reduces overall survival in patients with melanomas and various types of carcinomas[27,47]. Finally, impaired function of lymphatic vessels has been identified in chronic inflammation, and activation of lymphatic vessel function has shown promising results in the treatment of chronic inflammatory diseases including experimental skin inflammation and arthritis[32,48].

ANTIANGIOGENIC THERAPIES

Because induction of angiogenesis is essential for tumor progression, inhibition of tumor angiogenesis has become a target for cancer therapy[49]. Despite the identification of several distinct tumor angiogenesis factors, including interleukin-8 and bFGF, the majority of approved anti-tumor angiogenesis therapies rely on targeting VEGF-A. The latter is generally considered to represent the major angiogenic factor in the majority of solid tumors.

The anti-VEGF-A humanized monoclonal antibody *bevacizumab* was the first FDA-approved angiogenesis inhibitor (Fig. 102.16). Beneficial effects were observed in patients with metastatic colon cancer when bevacizumab was combined with chemotherapy[7]. Subsequently, bevacizumab has been approved for the treatment of other solid tumors including metastatic breast cancer, non-small-cell lung cancer (NSCLC), ovarian cancer, and cervical cancer as well as glioblastoma and renal cell carcinoma[50]. *Ramucirumab*, a monoclonal antibody that targets human VEGFR-2, has been approved for advanced gastric cancer, hepatocellular carcinoma, and metastatic forms of NSCLC and colorectal cancer. *Afilbercept*, a soluble VEGF receptor fusion protein ("VEGF trap"), is approved for both colorectal cancer and wet macular degeneration. In

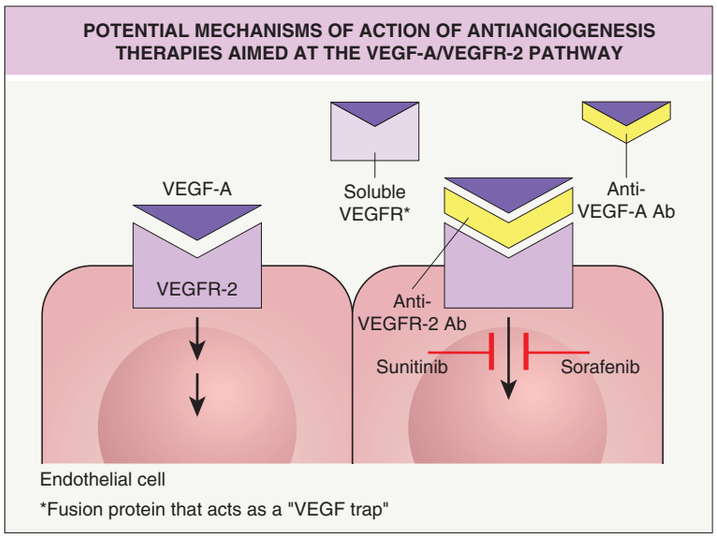

Fig. 102.16 Mechanisms of action of antiangiogenesis therapies aimed at the VEGF-A/VEGFR-2 pathway. Examples of anti-VEGF-A antibodies are bevacizumab and ranibizumab and an example of an anti-VEGFR-2 antibody is ramucirumab. Aflibercept acts as a soluble VEGF receptor fusion protein ("VEGF trap"). Tyrosine kinase inhibitors that block the VEGFR signaling pathway include cabozantinib, lenvatinib, pazopanib, and regorafenib as well as sorafenib and sunitinib.

addition, several tyrosine kinase inhibitors (e.g. cabozantinib, lenvatinib, pazopanib, regorafenib, sorafenib, sunitinib) have been approved, primarily for renal cell carcinoma, but also for thyroid, hepatocellular, and colorectal carcinomas (see Fig. 102.16). However, these inhibitors are not specific for VEGFR tyrosine kinases but also inhibit other tyrosine kinases (see Table 21.16). In addition, the mTOR inhibitor everolimus, a moderate angiogenesis inhibitor, is approved for several solid organ carcinomas.

Although anti-VEGF-A therapies have been beneficial in a range of carcinomas, as a monotherapy they have been ineffective due to the development of resistance. However, combined inhibition of VEGF-A plus other pro-angiogenic signaling pathways has resulted in improved response rates. For example, *vanucizumab*, a humanized anti-VEGF/Ang-2 bi-specific monoclonal antibody, has been shown in initial studies to suppress revascularization and tumor progression in solid tumors. Combined inhibition of both FGF and VEGF pathways has also led to greater efficacy. In addition to their antiangiogenic effects, VEGF-A inhibitors may also increase response rates to immunotherapy – an approach that is currently under investigation for various cancer types, including melanoma[51].

Although it has been proposed that inhibition of tumor angiogenesis leads to normalization of blood vessels and increased tumor delivery of chemotherapeutic drugs, antiangiogenic cancer therapy has not been as successful as originally envisioned. Mechanisms mediating primary or secondary tumor resistance to antiangiogenic approaches include[52]: (1) upregulation of additional angiogenesis factors (e.g. FGFs, HGF) and activation of alternative angiogenic signaling pathways; (2) recruitment of bone marrow-derived progenitor cells and other cell types with proinflammatory/pro-angiogenic phenotypes; (3) hypoxia-driven cancer cell invasion and metastasis; (4) co-opting of existing vessels by tumor cells; and (5) the formation of perfused vessels by tumor cells themselves, called "vascular mimicry".

Non-malignant skin diseases have also emerged as potential targets for treatments aimed at vascular endothelium. The mechanisms by which propranolol, a non-selective β-adrenergic receptor blocker, induces regression of hemangiomas are not fully understood, but it may induce endothelial cell apoptosis and interfere with the VEGF-A/VEGFR signaling pathway as well as reduce plasma renin levels (see Ch. 103). Sirolimus (rapamycin), an mTOR inhibitor, has been successfully used to treat patients with tufted angiomas/kaposiform hemangioendotheliomas who develop Kasabach–Merritt phenomenon as well as lymphatic malformations and kaposiform lymphangiomatosis.

In addition to these potential dermatologic applications, antiangiogenesis has become a promising new therapeutic approach in ophthalmology. Diabetes mellitus is frequently associated with intraocular neovascularization, and new blood vessel growth is the principal cause of visual loss in the wet form of age-related macular degeneration, the most common cause of blindness in Western countries. Nowadays, intravitreal injection of VEGF-A inhibitors (e.g. ranibizumab, aflibercept) are used to prevent progression of this disease and can even improve vision.

Infantile Hemangiomas 103

Anita N. Haggstrom, Sheilagh M. Maguiness and Maria C. Garzon

Synonyms: ■ Hemangioma of infancy ■ Hemangioma

Key features

- The most common benign soft tissue tumor of infancy
- Characteristic growth pattern with early proliferation followed by gradual, spontaneous involution and variable residual skin changes
- Distinct histopathologic and immunohistochemical features that differentiate them from other vascular anomalies in children
- May be associated with extracutaneous findings when occurring at certain anatomic sites (e.g. the face, neck, lumbosacral area), especially when lesions have a segmental pattern
- Management is tailored to each patient as suggested in published guidelines
- Systemic β-blockers are first-line therapy for most children with complicated hemangiomas

INTRODUCTION

Infantile hemangiomas (IHs) are benign proliferations of endothelial cells and their supporting tissues and they represent the most common tumors arising in the neonatal period. IHs are characterized by significant growth during the first several months of life, followed by slow spontaneous involution over the ensuing years. This natural history differentiates them from vascular malformations (Table 103.1). Studies highlighting the potential roles of specific IH stem cells and hypoxia have provided new insights into their pathophysiology.

HISTORY

The terms "infantile hemangioma" and "hemangioma of infancy" describe a specific group of vascular tumors that arise during infancy and demonstrate characteristic clinical and histologic features. IHs have been recognized in the medical literature for centuries, and they have been given various names such as *strawberry nevus* and *capillary hemangioma*. Despite early attempts to make distinctions among different types of vascular lesions, the term "hemangioma" was applied to a wide variety of congenital and acquired vascular anomalies including vascular malformations, without consideration of differences in their biologic behavior.

One of the important developments in the study of vascular "birthmarks", including lesions that become apparent during early infancy, was the acceptance of a biologic classification scheme. In 1982, Mulliken and Glowacki[1] first proposed that vascular birthmarks should be categorized according to their biologic and clinical behavior. The International Society for the Study of Vascular Anomalies has modified and periodically updated this classification to reflect new insights, including the genetic bases of multiple types of vascular anomalies (Table 103.2)[2].

Under this organization scheme, vascular birthmarks are divided into three categories: *vascular tumors*, *vascular malformations*, and a smaller group of "*provisionally unclassified*" lesions. Vascular tumors are characterized by cellular proliferation and include IH, pyogenic granuloma, and less common neoplasms such as tufted angioma and kaposiform hemangioendothelioma (see Table 103.2 and Ch. 114). Vascular malformations, on the other hand, are believed to represent errors in vascular morphogenesis. They are frequently noted during the neonatal period, but, unlike IHs, they do not rapidly proliferate in the first year of life nor do they resolve spontaneously (see Table 103.1; see Fig. 104.1). Vascular malformations are characterized by the type of anomalous vessels they contain and by their flow properties (see Ch. 104).

The biologic classification includes histopathologic, immunohistochemical, and genetic features that aid in distinguishing IHs from other vascular anomalies as well as predicting the clinical behavior and prognosis of these vascular lesions. The current classification serves as a framework for understanding vascular birthmarks but is evolving as new insights emerge.

EPIDEMIOLOGY

IHs arise during the first year of life and are the most common tumor of infancy. They develop in 4%–5% of infants, with lesions usually noted within the first several weeks of life[3]. IHs may occur more commonly in White infants than in other racial groups. A female : male ratio of 2–5 : 1 has been noted in multiple retrospective studies as well as prospective studies conducted in dermatology practices; however, a hospital-based prospective birth-cohort study found no female predominance among infants who developed an IH[3]. A higher female : male ratio of 7–9 : 1 has been reported for patients with severe, complicated IHs.

IHs also develop more frequently in premature infants. Low birth weight represents an independent IH risk factor, and IHs affect 25%–30% of infants with a birth weight <1000 g and 15% of those with a birth weight between 1000 and 1500 g[4]. Factors associated with placental insufficiency (e.g. preeclampsia, placenta previa) are also associated with IH development, while prematurity and multiple gestation pregnancies are linked with the development of multifocal IHs[3,5–7]. One study found a threefold increased incidence in infants born following chorionic villus sampling compared to those born following amniocentesis or without a history of prenatal instrumentation[8]. A higher maternal age has also been associated with hemangioma development[6,7].

IHs typically arise sporadically, although a family history has been reported in up to a third of patients[9]. The frequent occurrence of hemangiomas in the general population makes it difficult to assess the true familial incidence, and no specific genes have been consistently implicated.

PATHOGENESIS

IHs represent localized or regional areas of abnormal vascular development and proliferation. Their development involves *de novo* formation of vessels from multipotent hemangioma-derived stem cells (HemSCs) and endothelial progenitor cells (vasculogenesis) as well as formation of new vessels from existing ones (angiogenesis)[10,11]. Other cell types in the hemangioma's environment, including monocytes, fibroblasts, pericytes, mesenchymal cells, adipocytes and mast cells, can influence endothelial cell proliferation and may have a role in hemangioma formation and/or involution.

The overlapping immunohistochemical phenotype of hemangioma cells and human placental endothelium has led to the suggestion that hemangioma cells may be of placental origin or undergo differentiation toward a placental microvascular phenotype. North and co-workers[12,13] reported that glucose transporter protein-1 (GLUT1) is expressed by IHs during all phases of their development (proliferating, involuting, involuted) as well as by the placenta, but not by other vascular tumors or malformations. Additional placenta-associated vascular antigens, including merosin, FcγRII, and Lewis Y antigen, are present in hemangioma specimens and placental chorionic villi but absent in microvessels of the normal skin and subcutis[13]. However, hemangiomas do not express placental *trophoblastic* markers (e.g. human placental lactogen)[14] and are not thought to represent placental emboli.

DIFFERENCES BETWEEN INFANTILE HEMANGIOMAS AND VASCULAR MALFORMATIONS		
	Infantile hemangioma	**Vascular malformation**
Clinical	• Usually absent at birth or subtle precursor lesion present; only occasionally well formed • Rapid proliferation in first 2–5 months of life • Spontaneous involution over years	• Usually evident at birth • Slower expansion, with increase in area proportionate to the child's growth • Persists into adulthood
Epidemiology	More common in: • Girls (2–5 : 1) • Premature and/or low-birth-weight infants • Infants whose mothers were older, underwent chorionic villus sampling, or had preeclampsia	No sex or gestation predilection
Pathology	**Proliferating**: endothelial cell hyperplasia, lobule formation, mast cells, prominent basement membrane **Involuting**: fibrofatty tissue replacement, decreased mast cells when fully involuted	Dependent upon type, often irregular vascular channels
Immunohistochemistry	Positive for GLUT1, Lewis Y antigen, merosin, and FcγRII, Wilms tumor protein 1 (WT1)	Negative for GLUT1, Lewis Y antigen, merosin, and FcγRII, WT1

Table 103.1 Differences between infantile hemangiomas and vascular malformations.

BIOLOGIC CLASSIFICATION OF VASCULAR BIRTHMARKS
Vascular tumors
Benign • Infantile hemangioma • Congenital hemangioma (rapidly involuting, non-involuting, partially involuting) • Tufted angioma • Pyogenic granuloma • Spindle cell hemangioma • Others Locally aggressive or borderline • Kaposiform hemangioendothelioma • Others, e.g. retiform or composite hemangioendothelioma
Vascular malformations

Simple
• Capillary malformations (CMs)
• Venous malformations (VMs)
  • Common, glomuvenous, others
• Lymphatic malformations (LMs)
  • Common: macrocystic, microcystic, mixed; others
• Arteriovenous malformations, arteriovenous fistula (AVMs, AVFs; high flow)
Combined
• CVM, CLM, LVM, CAVM, CLAVM, others
Of major named vessels
Associated with other anomalies
• Sturge–Weber syndrome, Klippel–Trenaunay syndrome, others

Provisionally unclassified
• Angiokeratomas • Multifocal lymphangioendotheliomatosis with thrombocytopenia • Others

Table 103.2 Biologic classification of vascular birthmarks. Updated based on the International Society for the Study of Vascular Anomalies (ISSVA) Classification of Vascular Anomalies[2]. Vascular malformations are discussed in Chapter 104 and other vascular tumors in Chapter 114. CAVM, capillary–arteriovenous malformation; CLAVM, capillary–lymphatic–arteriovenous malformation; CLM, capillary–lymphatic malformation; CVM, capillary–venous malformation; LVM, lymphatic–venous malformation

Role of Hypoxia

The role of hypoxia in the pathogenesis of IHs is supported by their association with hypoxic placental changes, prematurity/low birth weight (often caused by placental insufficiency), retinopathy of prematurity (GLUT1-positive, hypoxia-induced neovascularization), and regional arterial insufficiency in PHACE(S) and LUMBAR syndromes (see below)[15,16]. Hypoxia upregulates expression of GLUT1 and vascular endothelial growth factor (VEGF), leading to mobilization of endothelial progenitor cells. Moreover, the combination of hypoxia and estrogen has a synergistic effect on hemangioma endothelial cell proliferation *in vitro*[15], potentially explaining the predilection of IHs for female infants. Investigators have also found that hypoxia inducible factor (HIF)-1α and its downstream effectors are upregulated in IHs during their proliferative phase[17].

Signaling Pathways

Several signaling pathways play a role in IH development. Studies have confirmed the importance of VEGF (also known as VEGF-A) signaling, with a shift from expression of VEGF receptor 1 (VEGFR-1), which binds VEGF with high affinity but transmits a very weak signal, to VEGFR-2, which strongly stimulates endothelial cell proliferation upon VEGF binding[18]. VEGFR-2 signaling activates the phosphatidylinositol 3-kinase (PI3K)-mechanistic target of rapamycin (mTOR) pathway, leading to upregulation of HIF-1α and increased levels of VEGF. Accordingly, treatment of hemangioma endothelial cells *in vitro* with the mTOR inhibitor sirolimus (rapamycin) results in reduced proliferation[19].

Hemangiomas also have increased expression of the endothelial cell-specific Tie-2 tyrosine kinase receptor and dysregulated production of angiopoietin-2, which may promote angiogenesis and inhibit vessel maturation (see Ch. 102)[20]. The Notch pathway is thought to mediate differentiation of HemSCs into pericytes/vascular smooth muscle cells[21], and the latter appear to have pro-angiogenic properties and support IH development[22]. The renin–angiotensin system (RAS) has also been implicated in IH proliferation via activation of angiotensin II receptor 2[23], and treatment of IH with β-blockers reduces plasma renin levels[24].

Genetic Factors

A variety of genetic factors may be involved in the development of IH. There have been reports of *somatic* mutations in genes that encode proteins involved in VEGF signaling (e.g. VEGFRs) and other pathways that affect vascular development within hemangioma tissue[25]. Heterozygous *germline* mutations in *VEGFR2* and *ANTXR1* (anthrax toxin receptor 1), which encodes an integrin-like endothelial cell receptor, have been identified in a small subset of IH patients and may represent hemangioma predisposition factors[18].

Factors Influencing Natural History

Hemangiomas have been studied during different phases of their clinical course to gain insights into the mechanisms that govern their growth and involution. In the proliferative phase, hemangiomas express markers of proliferation such as proliferating cell nuclear antigen (PCNA) and increased levels of pro-angiogenic molecules such as VEGF and basic fibroblast growth factor (bFGF)[26–28]. In addition, other angiogenesis mediators, proteins found within the perivascular extracellular matrix, and enzymes involved in matrix remodeling are produced at higher levels during proliferation (Table 103.3)[26,29–32].

The factors that govern the transition of hemangiomas from proliferation to involution and the mechanisms of the associated decrease in

MARKERS OF PROLIFERATING AND INVOLUTING HEMANGIOMAS
Proliferative phase
• General markers of proliferation, e.g. proliferating cell nuclear antigen (PCNA)
• Vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF)*,†
• Monocyte chemoattractant protein-1†
• Adhesion molecules on endothelial cells – E-selectin, ICAM-3†
• Matrix metalloproteinase-2 and -9 (extracellular matrix remodeling)‡
• Vitronectin (found in the perivascular extracellular matrix)
• Indoleamine 2,3-dioxygenase (inhibits T cell activation)
• Apoptosis inhibitors
Involution
• Interferon-regulated gene products (interferons are known to inhibit angiogenesis)
• bFGF (early in involution)
• Increased mast cells (early in involution)
• Tissue inhibitor of matrix metalloproteinases-1 (inhibits angiogenesis)
• Apoptosis promoters
*VEGF and bFGF, but not the angiogenesis inhibitor interferon-β, are also expressed by the hyperplastic epidermis overlying proliferating hemangiomas. †Angiogenesis mediators. ‡Increased levels also found in blood and urine.

Table 103.3 Markers of proliferating and involuting hemangiomas. Lymphatic vessel endothelial hyaluronan receptor (LYVE)-1 has been identified in perivascular dendritic cells in hemangiomas of various stages. ICAM, intercellular adhesion molecule.

pro-angiogenic factors are not fully understood[26,30]. Increased expression of angiogenesis inhibitors and apoptosis promoters has been observed in involuting hemangiomas (see Table 103.3)[26,33]. Depending on the extracellular environment, mesenchymal stem cells may contribute to endothelial cell proliferation during the hemangioma growth phase or differentiate into adipocytes contributing to fibrofatty residua in involuting hemangiomas[34].

CLINICAL FEATURES

Presentation

Most IHs have a typical presentation and growth pattern. Lesions usually become apparent during the first few weeks of life, although the proportion of hemangiomas that are "congenital" in published series has ranged from 15% to 60%[35]. IHs evident at birth most often appear as precursor lesions, which are apparent in up to 65% of IHs[35], but occasionally they present as relatively well-formed typical IHs that subsequently demonstrate variable proliferation then slow involution. Precursor IH lesions include telangiectasias surrounded by a vasoconstricted halo, areas of pallor, pink macules, and blue bruise-like patches (Fig. 103.1). Pink macules and patches may mimic a capillary malformation, and repeat examination over the ensuing weeks is essential to determine the diagnosis (Fig. 103.2). Rapidly involuting, partially involuting, and non-involuting *congenital hemangiomas* (RICH/PICH/NICH) represent distinct entities that are discussed below.

Occasionally, an area of ulceration in the diaper area, in other skin folds, or on the lip may herald the onset of an IH[36], and in a newborn infant these lesions may be confused with bacterial or viral infections. Continued observation usually clarifies the diagnosis. With dermoscopy, the characteristic findings of red lacunae separated by white septae in superficial IHs and violaceous to blue lacunae in deeper IHs may be helpful when the diagnosis is not clear[37].

Hemangiomas may occur anywhere on the skin and mucosal surfaces. Although overall they most commonly develop on the trunk[3], ~50% of the IHs that present to a pediatric dermatologist are located on the head and neck[7]. The clinical appearance of an IH is influenced by its location within the skin and subcutaneous tissues. *Superficial* hemangiomas are situated in the upper dermis and are bright red in color during their proliferating phase. The surface is finely lobulated, and the term "strawberry hemangioma" has been used to describe them[1] (Fig. 103.3).

Deep hemangiomas are located in the deep dermis and/or subcutis. They usually are not apparent in the immediate newborn period, often

Fig. 103.2 Segmental superficial infantile hemangioma mimicking a port-wine birthmark. This 3-week-old girl is at risk of PHACE(S) syndrome. *Courtesy Julie V. Schaffer, MD.*

becoming evident a few weeks or even months after birth. They present as warm, ill-defined, light blue–purple masses with minimal or no overlying skin changes, making them more difficult to diagnose than superficial or mixed hemangiomas (Fig. 103.4). The presence of dilated veins or telangiectasias overlying a deep hemangioma provides a clue that the lesion is of vascular origin. Larger deep hemangiomas often have significant arterial blood supply during the proliferative phase, and detection of high flow by Doppler ultrasonography can help to confirm the diagnosis. Mixed hemangiomas have both superficial and deep components, often presenting during the proliferative phase as a well-delineated red vascular plaque overlying a larger, poorly circumscribed violaceous or light blue nodule.

Superficial hemangiomas are the most common type, accounting for ~50%–60% of IHs. An additional 25%–35% of hemangiomas are mixed and 15% are deep[38]. Approximately 25% of patients have multiple

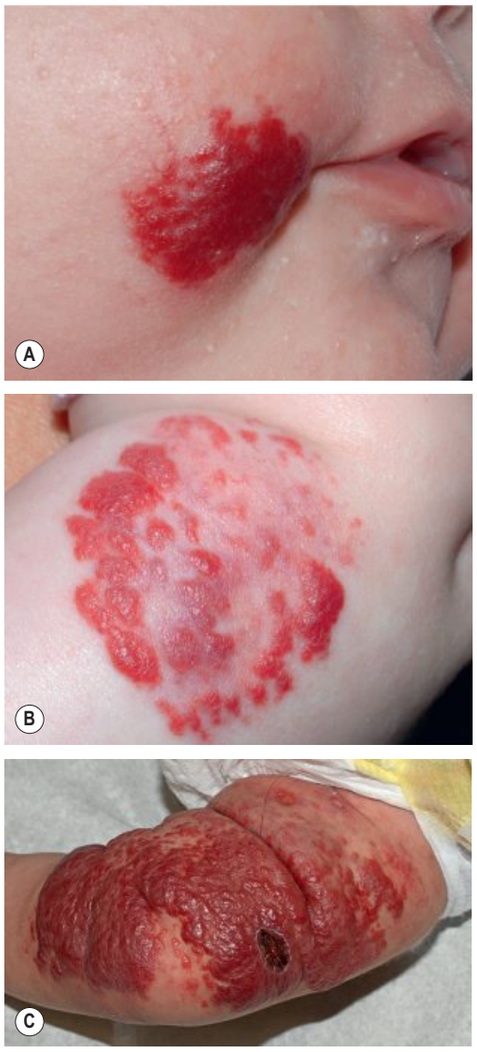

Fig. 103.3 Superficial infantile hemangiomas. Lesions can be focal (**A**,**B**) or have a broader segmental distribution (**C**). Note the bright red color and finely lobulated surface, irrespective of size. Involvement may be diffuse or discontiguous. *Courtesy Julie V. Schaffer, MD.*

A Skin-colored deep hemangioma with overlying telangiectasias and alopecia on the scalp. **B** Mixed hemangioma composed of a well-demarcated, bright red superficial plaque plus a broader, ill-defined underlying deep nodule with a subtle light blue–purple hue (arrow) and scattered telangiectasias. *B, Courtesy Julie V. Schaffer, MD.*

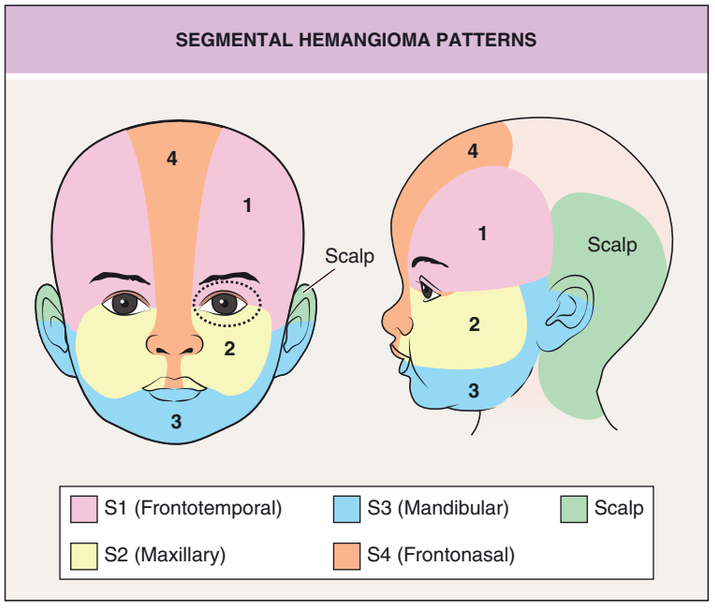

Fig. 103.5 Segmental hemangioma patterns. Based upon a prospective study (n = 165) of image analyses of hemangiomas. *Adapted with permission from Endicott AA, Chamlin SL, Drolet BA, et al. Mapping of segmental and partial segmental infantile hemangiomas of the face and scalp. JAMA Dermatol 2021;157:1328–34.*

lesions, which are occasionally associated with hemangiomas in the liver or other internal organs (see below).

IHs can also be categorized based upon the pattern of involvement, which may help to predict prognosis[39–41]. The two main pattern subtypes are: (1) *focal* – arising from a single localized nidus (see Fig. 103.3A,B); and (2) *segmental* – covering a broad area or developmental unit in a "plaque-like" manner (see Fig. 103.3C). Lesions that are difficult to classify are designated as *indeterminate* and may represent *partial segmental* lesions that respect anatomic boundaries similar to their larger segmental counterparts[42]. The majority of IHs are focal lesions, and those on the face may show predilection for embryonic fusion lines[39]. The distribution patterns of segmental hemangiomas on the face resemble classic embryonic facial prominences, differing the most on the upper face. Investigators have identified four primary segments for facial hemangiomas, S1 to S4 (Fig. 103.5)[43]. Involvement of these segments may be incomplete, and some hemangiomas encompass more than one segment. A C-shaped pattern extending from the posterior auricular area to the posterolateral scalp has also been observed[42].

Segmental hemangiomas often begin as broad patches of confluent or reticulated erythema and/or telangiectasias. Within a few weeks, bright red papules and plaques arise within this "field". Segmental hemangiomas are more likely to be associated with regional extracutaneous anomalies, including PHACE(S) and LUMBAR syndromes (see below)[40]. On the extremities, smaller segmental hemangiomas typically spare the distal digits in a "biker glove" pattern (Fig. 103.6), while larger lesions that encompass the distal digits are associated with a higher risk of extracutaneous anomalies[44]. Rhabdomyomatous mesenchymal hamartomas presenting as a papule or atrophic plaque in the midline anterior neck/trunk or sacrum in association with segmental hemangiomas have also been described[45].

Natural History

Studies have documented the typical growth pattern of IHs. The phases include *early proliferation* with a rapid increase in size, *late proliferation* with continued growth at a slower rate, *plateau* (existence as a distinct phase debated), and *involution*[41]. Hemangiomas tend to "mark out their territory" early on, subsequently undergoing primarily volumetric rather than centrifugal growth[35,41]. During the proliferative phase, hemangiomas frequently become warmer and firmer in texture, and the surface of superficial hemangiomas may appear tense. Mixed and deep hemangiomas in the proliferative phase often feel firmer and look larger when the infant is crying or active. Deep hemangiomas tend to

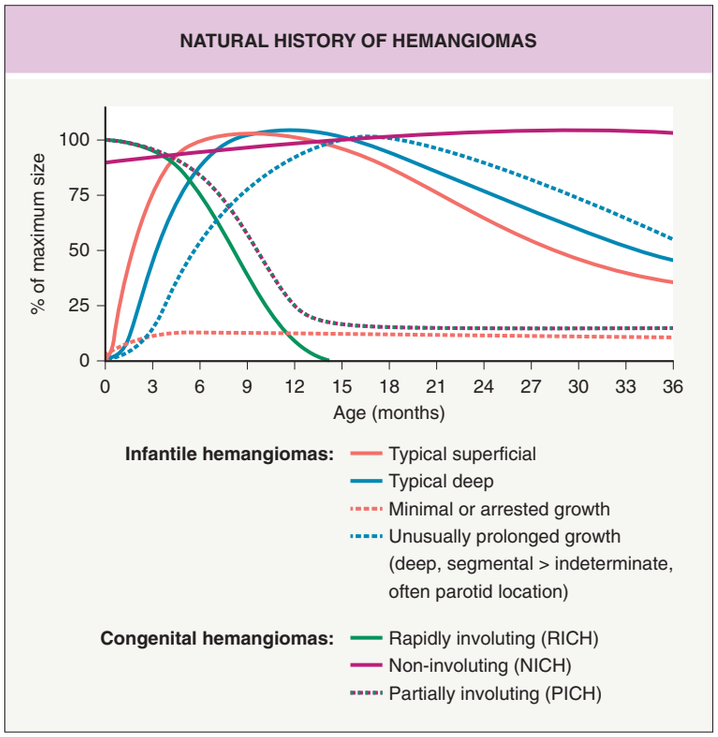

Fig. 103.7 Natural history of infantile and congenital hemangiomas.

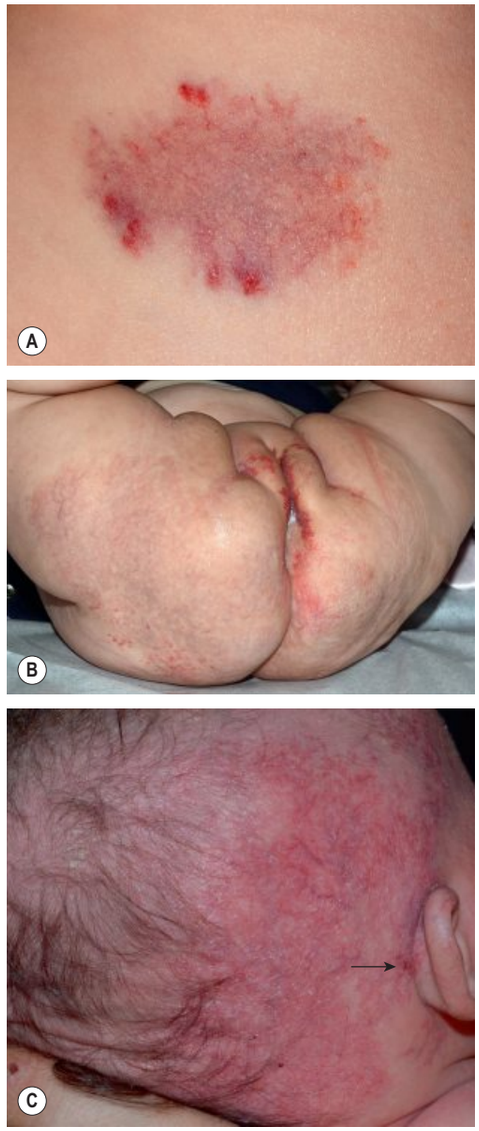

Fig. 103.8 Infantile hemangiomas with minimal or arrested growth (IH-MAG). Telangiectasias and larger ectatic vessels are evident. Focal small bright red papules cover <25% of the surface area and are evident at the periphery (**A**); on the vulva and upper buttock (**B**); and behind the ear (**C**, arrow). Presence of these papules (which may be subtle or absent), reticulated erythema, and characteristic fine to coarse telangiectasias help to distinguish these lesions from capillary–venous malformations. *Courtesy Julie V. Schaffer, MD.*

proliferate for a longer period of time than do superficial hemangiomas, and the deep component of mixed lesions often continues to grow even after the superficial component has plateaued (Fig. 103.7).

The majority of hemangiomas reach 80% of their final size by the end of the early proliferative phase, which occurs at a mean age of 3 months, and growth is usually most rapid from 5 to 8 weeks of age[35,41]. The small minority of hemangiomas that grow after 9 months of age (rarely as late as ≥3 years of age) tend to have a deep component and/or segmental morphology, and IHs in the parotid gland area are particularly prone to this behavior[41,46,47].

A subset of hemangiomas referred to as *IH with minimal or arrested growth (IH-MAG)* (previously described as "*abortive*" or "*reticular*") display little or no growth beyond patches of reticulated erythema with coarse and/or fine telangiectasias, often superimposed on a background of pallor (Fig. 103.8)[48,49]. If present, the proliferative component involves <25% of the surface area, often presenting as small red papules at the periphery[48]. Development of eczematous dermatitis localized to a IH-MAG has been described[50]. These hemangiomas favor the lower body and may develop recalcitrant ulceration or (if larger and segmental) be associated with LUMBAR or PHACE(S) syndrome (see below)[51]. They are GLUT1-positive and involute at a pace similar to classic IHs, although larger ectatic vessels may persist.

Involution of IHs may begin as early as the first year of life and continues for several years. A color change from bright red to gray–purple (Fig. 103.9) and flattening of the surface are often the earliest signs of involution in superficial lesions. As the tumor involutes, deeper lesions become less firm[52].

Classic studies on the natural history of untreated hemangiomas demonstrated that 30% of lesions involute fully by 3 years of age, 50% by 5 years, 70% by 7 years, and >90% by 9 years[52]. However, more recent studies have concluded that the median age of completed involution is 36 months, with >90% of children showing no further improvement after 4 years of age[53]. Some hemangiomas involute completely, while others leave residual telangiectasias, atrophy/anetoderma, fibrofatty tissue, redundant skin, or (if previously ulcerated) scarring (Fig. 103.10). Predicting whether the residual lesion will be significant is a challenging aspect of hemangioma management. Risk factors for more prominent sequelae include an abrupt "step" border, "cobblestoned" surface, and mixed IH subtype[54].

Complications

The majority of hemangiomas are small lesions that require little or no intervention. However, some hemangiomas are problematic due to their size, location, or association with other anomalies. The age of the patient and the growth pattern of the hemangioma are additional factors that help to determine the risk of complications and need for systemic therapy[55] (see Table 103.7).

Ulceration

Ulceration occurs in up to 10% of all IHs and represents the most common complication[56]. Although hemangiomas in any location can be affected, those on the lip and in the anogenital region or other skin folds (e.g. the neck) have the greatest tendency to ulcerate (Fig. 103.11). Ulceration develops more commonly within large, mixed (superficial and deep), or segmental hemangiomas[56]. For example, ulceration occurs in up to 30% of segmental extremity lesions (see Fig. 103.3C)[44]. In addition, IHs-MAG are prone to ulceration, which may be recalcitrant.

Ulceration of IHs occurs most commonly during the proliferative phase, with most ulcers developing within the first 6 months of life[57]. Whitish discoloration of hemangiomas in infants younger than 3 months of age may be a sign of impending ulceration[58]. In addition to causing pain, ulcers increase the risk of infection and result in scarring. Bleeding rarely occurs and can usually be controlled with firm pressure. The management of ulcerated hemangiomas may be challenging (see below)[57,59]. Large hemangioma size, segmental morphology, and ulceration extending over a greater surface area are associated with longer healing times[57].

Fig. 103.9 Infantile hemangioma during involution. Note the patchy lightening in surface color and softening.

Disfigurement and interference with function related to IH size and/or location

Large hemangiomas can distort tissues, interfere with function, and lead to significant long-term sequelae. In addition, regional extracutaneous abnormalities may occur, primarily in association with segmental hemangiomas (see below). High-output congestive heart failure represents a rare complication that occurs primarily in patients with extensive hepatic hemangiomas.

Even small IHs may cause complications if they arise in vulnerable locations. *Periocular* hemangiomas can result in ophthalmologic complications (Fig. 103.12). Most commonly, periocular hemangiomas cause astigmatism by compressing the globe and deforming the cornea, which results in asymmetric refractive errors. They may also cause visual abnormalities by obstructing the visual axis or by invading the orbital musculature, which can lead to light-deprivation amblyopia and strabismus, respectively. Proptosis is a rare presentation of an orbital hemangioma, potentially leading to corneal exposure; the diagnosis of hemangioma may be difficult clinically when a cutaneous lesion is not present. Infants with periocular hemangiomas should be evaluated by an ophthalmologist at baseline with appropriate follow-up during the proliferative stage.

Hemangiomas on the *nasal tip* are particularly challenging (Fig. 103.13A). Deep and mixed hemangiomas can distort the underlying cartilage and leave significant fibrofatty residua upon involution. The resultant "Cyrano-nose" deformity may require reconstructive surgery. In rare cases, superficial hemangiomas located along the *columella* may ulcerate and lead to destruction of underlying cartilage, which may be heralded by the appearance of a horizontal crease in the inferior columella.

Fig. 103.10 Residua of infantile hemangiomas. Hemangioma with ulcer (**A**), which involuted leaving minimal hypopigmentation (arrows) and a circular scar at site of ulceration in the same patient 20 years later (**B**); **C, D** telangiectasias; and **E** atrophy and fibrofatty changes. *A, B, Courtesy Ronald P. Rapini, MD; D, Courtesy Jean L. Bolognia, MD.*

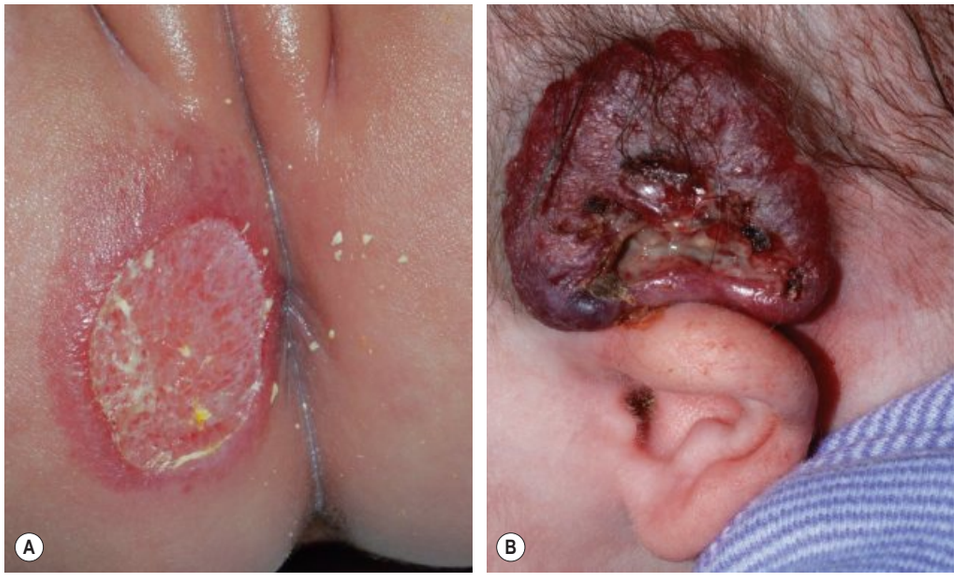

Fig. 103.11 Ulcerated hemangiomas. A Ulcerated early superficial hemangioma on the buttock. Because the hemangioma component may not be obvious, this diagnosis should be considered when an infant presents with an ulcer in the diaper area. **B** Ulcerated thick superficial hemangioma above the ear. Fig. 103.13 Infantile hemangiomas in facial sites with increased risk of disfigurement. A Nasal deformity can result from mixed or deep hemangiomas on the nasal tip. **B** The lip is a sensitive site, especially when lesions cross the vermilion border or involve the philtrum, and hemangiomas in this location are prone to ulceration. *Courtesy Julie V. Schaffer, MD.*

Lip hemangiomas are often superficial or mixed lesions; painful ulceration is common as they proliferate, which leads to feeding difficulties. Local factors, including friction and moisture, may contribute to ulceration. Distortion of the vermilion border or lengthening of the lip can result in significant cosmetic residua, eventually requiring surgical correction (Fig. 103.13B)[60].

Hemangiomas located on the *pinna* may ulcerate and become infected, increasing the risk of scarring and distortion of normal structures. Conductive hearing loss can result from obstruction of the external auditory canal by a hemangioma.

Hemangiomas located on the *breast* pose a particular challenge in girls. These lesions may affect the underlying breast bud, and residual masses may lead to the appearance of breast asymmetry. Early surgical intervention is not advised, as it may ultimately affect normal breast development.

Anogenital hemangiomas are often complicated by painful ulceration, and wound care may be difficult in this region. Large hemangiomas of the *limbs* may also ulcerate, and residual excess tissue and rarely limb-length discrepancy can remain upon involution.

Extracutaneous involvement

Large hemangiomas on the head and neck, most commonly segmental lesions >5 cm in diameter, can pose challenges beyond the complications noted above. In particular, they are often associated with extracutaneous anomalies[61]. These hemangiomas may present as segmental telangiectatic patches (e.g. IH-MAG), plaques, or deep masses. A relationship between facial hemangiomas and structural or vascular CNS anomalies was recognized >45 years ago[62]. Since then, other associated congenital anomalies have been identified. In 1996[63], the acronym *PHACE(S) syndrome* was coined for this spectrum of findings: *P, p*osterior fossa and other structural brain malformations; *H, h*emangioma; *A, a*rterial anomalies of cervical and cerebral vessels; *C, c*ardiac defects (especially *c*oarctation of the aorta); *E, e*ye anomalies; and *S, s*ternal defects and *s*upraumbilical raphe (Fig. 103.14). Impaired hearing, dysphagia, speech/language delay, dental anomalies, and endocrine abnormalities such as hypopituitarism and hypothyroidism are additional less commonly observed features[64,65]. Diagnostic criteria for PHACE(S) syndrome were established by a multidisciplinary group of specialists in 2009 and updated in 2016[66] (Table 103.4).

In a prospective study of 108 infants (age <1 year) with large facial hemangiomas (≥22 cm^2), 31% had PHACE(S) syndrome. The vast majority (91%) of affected individuals had more than one extracutaneous manifestation (major ± minor criteria), and the most common findings were cerebrovascular (91%), cardiovascular (67%), and structural brain (52%) anomalies[61]. The cerebrovascular anomalies typically occur ipsilateral to the hemangioma and most commonly involve the internal carotid artery, highlighting the need for both head and neck imaging[67]. Of note, in other studies, the prevalence of PHACE(S) in infants with segmental IHs of the head and neck was as high as 58%[68].

An approach to the evaluation of infants at risk for PHACE(S) syndrome is presented in Fig. 103.15, and there are consensus-derived recommendations for evaluation and ongoing care[66]. Cerebrovascular and cardiovascular changes may be progressive, with potential complications including ischemic stroke and neurovascular sequelae in adulthood (e.g. atypical migraines, hearing loss)[69,70]. Affected individuals should be followed by specialists as clinically appropriate.

Lower facial or "beard" hemangiomas often serve as markers of airway hemangiomas, which typically involve the subglottis. The risk of airway hemangiomas can be estimated by the extent of cutaneous involvement in this region (Fig. 103.16)[71], but occasionally they are associated with segmental hemangiomas that primarily involve the upper face or small hemangiomas in the "beard" area[72]. The onset of respiratory symptoms such as noisy breathing or biphasic stridor ranges from weeks to months of age[71]. Infants with lower facial hemangiomas of concern should be referred for otolaryngologic evaluation.

Hemangiomas located in the *midline lumbosacral area* (Fig. 103.17) are a marker for occult spinal dysraphism. The risk of spinal dysraphism in an infant or child with an isolated midline lumbosacral hemangioma or residuum of an involuted hemangioma >2.5 cm in diameter is ~35%[73]. Factors that further increase the risk include a larger or ulcerated hemangioma and the presence of additional cutaneous markers such as a deviated gluteal cleft, lipoma, or skin appendage (see Ch. 64)[73].

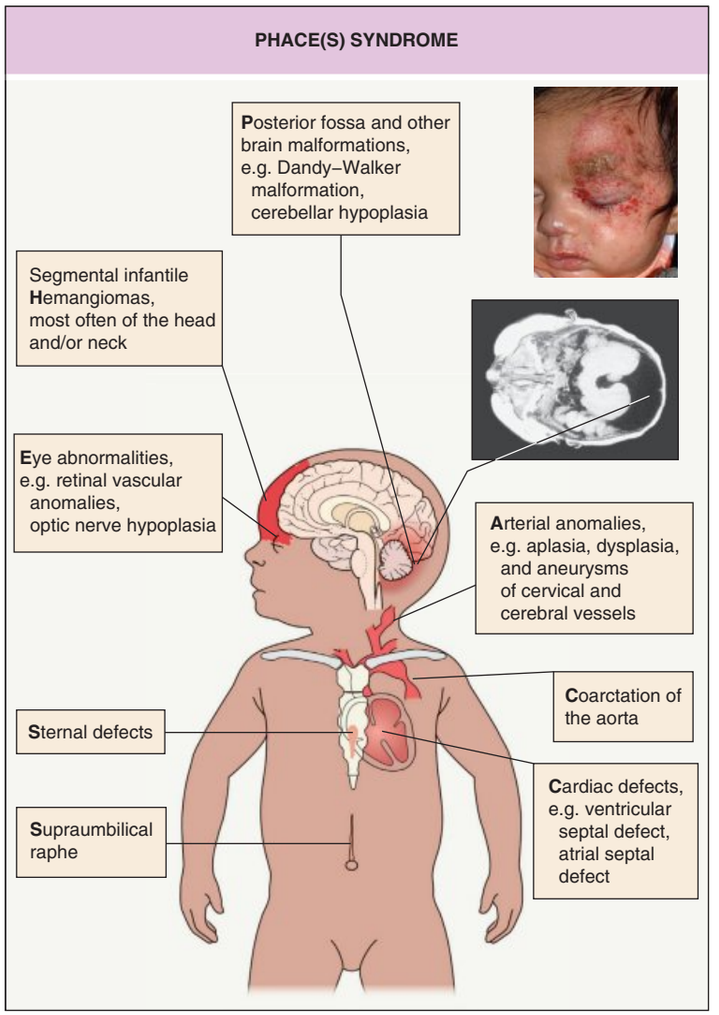

Fig. 103.14 PHACE(S) syndrome. Major clinical features are illustrated. Additional possible associated features include hearing impairment, dysphagia, speech/language delay, dental anomalies, and endocrine abnormalities such as hypopituitarism and hypothyroidism. *Inset, courtesy Julie V. Schaffer, MD.*

Large hemangiomas on the lower body, especially extensive segmental IHs, are associated with a broad spectrum of regional extracutaneous abnormalities, analogous to those of the upper body in PHACE(S) syndrome. Several acronyms have been proposed for this group of findings, and the most inclusive is *LUMBAR syndrome*: *L, l*ower body/*l*umbosacral hemangioma and *l*ipomas or other cutaneous anomalies (e.g. "skin tags"); *U, u*rogenital anomalies and *u*lceration of the hemangioma; *M, m*yelopathy (spinal dysraphism); *B, b*ony deformities; *A, a*norectal and *a*rterial anomalies; and *R, r*enal anomalies[74] (Fig. 103.18). Recommendations for evaluation of infants with hemangiomas in a midline lumbosacral location and/or a segmental distribution on the lower body are summarized in Fig. 103.15.

Multifocal lesions are found in 10%–25% of infants with hemangiomas and may be associated with visceral involvement[75]. Most infants with both internal and skin involvement have many small, superficial cutaneous hemangiomas that range from a few millimeters to a few centimeters in diameter (Fig. 103.19). Historically, the terms *"diffuse"* and *"benign" neonatal hemangiomatosis* were used for infants who had multiple cutaneous hemangiomas with or without visceral lesions, respectively. However, some cases reported as diffuse neonatal hemangiomatosis actually represented other vascular anomalies (e.g. multifocal lymphangiomatosis with thrombocytopenia; see Ch. 114)[76]. To avoid confusion, *multifocal infantile hemangiomas with or without extracutaneous hemangiomas* is now the preferred term.

The liver is by far the most common site of internal hemangiomas in patients with multifocal IHs (Fig. 103.20). Because a larger number of cutaneous IHs increases the risk of hepatic involvement, evaluation

DIAGNOSTIC CRITERIA FOR PHACE(S) SYNDROME		
Definite PHACE(S):		
• Hemangioma >5 cm in diameter of the head including scalp PLUS 1 major criterion or 2 minor criteria • Hemangioma of the neck, upper trunk, or trunk and proximal upper extremity PLUS 2 major criteria		
Possible PHACE(S):		
• Hemangioma >5 cm in diameter of the head including scalp PLUS 1 minor criterion • Hemangioma of the neck, upper trunk, or trunk and proximal upper extremity PLUS 1 major criterion or 2 minor criteria • No hemangioma PLUS 2 major criteria		
Organ system	**Major criteria**	**Minor criteria**
Arterial	• Anomalies of major cerebral or cervical arteries* – dysplasia†, hypoplasia, stenosis/occlusion, aberrant origin/course • Persistent carotid–vertebrobasilar anastomosis (e.g. proatlantal segmental, hypoglossal, otic, trigeminal arteries)	• Aneurysm of cerebral arteries
Structural brain	• Posterior fossa anomalies – Dandy–Walker complex, other hypoplasia/dysplasia of the mid or hind brain	• Midline anomalies • Malformation of cortical development
Cardiovascular	• Aortic arch anomalies • Aberrant origin of subclavian artery ± vascular ring	• Ventricular septal defect • Right/double aortic arch • Systemic venous anomalies
Ocular	• Posterior segment anomalies – persistent hyperplastic primary vitreous/persistent fetal vasculature, retinal vascular anomalies, optic nerve hypoplasia, morning glory disc anomaly	• Anterior segment anomalies, e.g. sclerocornea, cataract, coloboma, microphthalmia
Ventral or midline	• Sternal defect/pit/cleft • Supraumbilical raphe	• Hypopituitarism • Ectopic thyroid • Midline sternal papule/hamartoma
*Includes internal carotid artery; middle, anterior, or posterior cerebral artery; and vertebrobasilar system. †Includes kinking, looping, tortuosity, and/or dolichoectasia.		

Table 103.4 Diagnostic criteria for PHACE(S) syndrome[66].

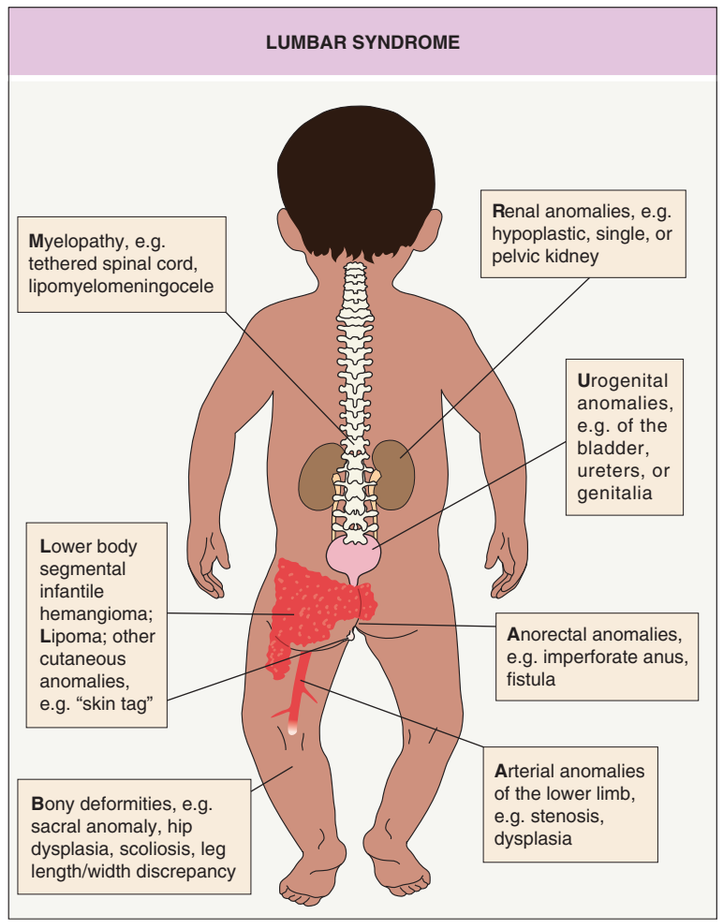

Fig. 103.18 LUMBAR syndrome. Major clinical features are illustrated. The segmental hemangioma is often ulcerated.

with abdominal ultrasonography is recommended when ≥5 skin lesions are present (see Fig. 103.15)[77,78]. Rarely, infants with a large IH or fewer than 5 small IHs have liver involvement.

Liver hemangiomas are classified as focal, multifocal, or diffuse. Focal hepatic hemangiomas are likely distinct from IHs, undergoing early involution similar to rapidly involuting congenital hemangiomas (RICH; see below)[79]. Multifocal and especially diffuse hepatic hemangiomas are associated with a risk of high-output cardiac failure due to arteriovenous or arterioportal shunts, as well as hypothyroidism (see below) and abdominal compartment syndrome due to massive hepatomegaly[79]. Management of patients with hepatic hemangiomas requires interdisciplinary care, which typically includes serial ultrasounds, clinical assessments and laboratory evaluation, with treatment as indicated[79].

Extracutaneous hemangiomas occasionally occur in infants with a single large cutaneous hemangioma, usually a segmental facial lesion, with or without associated PHACE(S). For example, segmental cutaneous hemangiomas may be associated with segmental hemangiomas in the gastrointestinal tract, most often in the distribution of the superior mesenteric artery and potentially complicated by bleeding[80]. IHs within the CNS are very rare and typically represent intracranial or intraspinal extension of an overlying IH, which may be a segmental lesion. Associated hydrocephalus has been reported, but invasion into the CNS parenchyma does not typically occur[81]. Additional sites of internal involvement rarely observed in association with segmental hemangiomas of the skin include the mediastinum and lungs.

Fig. 103.19 Multifocal infantile hemangiomas with extracutaneous hemangiomas. In this child, many small, superficial skin lesions were present in a miliary pattern and hemangiomas were present in the liver. Historically, this was referred to as "diffuse neonatal hemangiomatosis". *Courtesy Julie V. Schaffer, MD.*

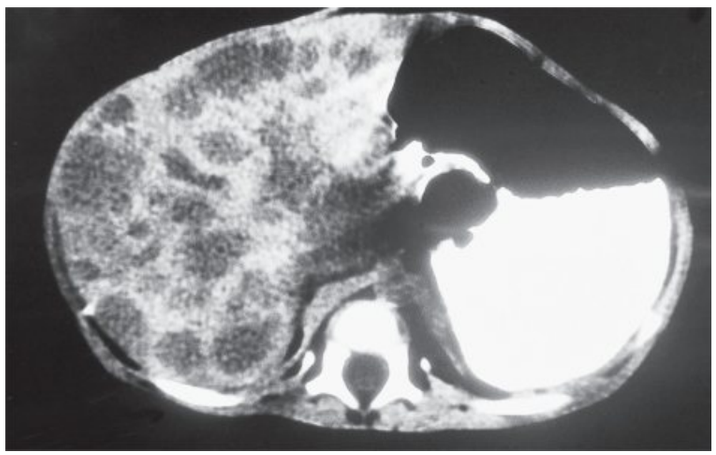

Fig. 103.20 Multifocal hepatic hemangiomas. CT scan demonstrating multiple hepatic hemangiomas in a child with multifocal cutaneous infantile hemangiomas ("diffuse neonatal hemangiomatosis"). *Courtesy Amy Paller, MD.*

Hemangiomas may also develop in a variety of other locations, including mucosal surfaces and the eyes. Extracutaneous hemangiomas may also occur in the absence of skin lesions. Typically, IHs in extracutaneous sites follow the same course of proliferation and involution as cutaneous lesions.

Increased levels of type 3 iodothyronine deiodinase, an enzyme that deactivates thyroid hormone, have been identified in tissue from proliferating hemangiomas. This can lead to hypothyroidism in infants with large-volume proliferative-phase lesions[82]. The consumptive nature of the hypothyroidism often makes it difficult to correct, but it resolves as the tumor regresses. Screening for hypothyroidism in the immediate neonatal period is inadequate, as hemangiomas are typically only beginning to develop at that time. Although consumptive hypothyroidism is usually associated with hepatic hemangiomas, it has been described in patients with large hemangiomas in the parotid area, and type 3 iodothyronine deiodinase activity has been noted in cutaneous hemangiomas[83]. Consequently, it has been recommended that evaluation for hypothyroidism be considered in infants with large cutaneous hemangiomas or hepatic hemangiomas[82].

RADIOLOGIC FEATURES

Most superficial and mixed IHs are diagnosed based upon their clinical features. Ultrasonography or MRI may be helpful in confirming the diagnosis and extent of deep IHs that lack superficial changes. It is important to consider the phase of growth when assessing hemangiomas radiographically, because proliferating hemangiomas demonstrate different characteristics than their involuting and involuted counterparts.

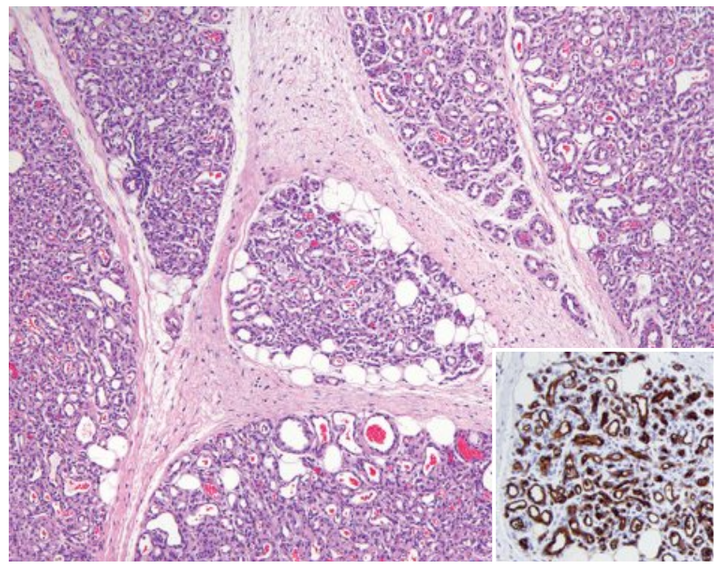

Fig. 103.21 Histologic features of a proliferating infantile hemangioma. Collections of endothelial cells forming vascular lumens, separated by fibrotic septae. The inset shows positive GLUT1 staining of endothelial cells. *Courtesy Matthew Kuhar, MD.*

MRI with contrast is the most useful imaging technique for helping to define the extent and tissue characteristics of vascular anomalies, and the use of contrast can help to differentiate a hemangioma from other tumors. If MRI does not confirm the diagnosis of hemangioma or there are concerns regarding a possible malignancy, histologic examination of the tumor is recommended. MRI and/or MR angiography (MRA) can also be used to determine the presence of hemangiomas within internal organs and to detect other structural abnormalities, including CNS malformations and arterial anomalies.

PATHOLOGY

The histopathologic features of IH correlate with the stage of hemangioma development (see Table 103.1). IHs may extend from the superficial dermis to the deep subcutaneous tissue; in some locations, there may be involvement of surrounding tissues such as salivary glands and muscle. Biopsy specimens of proliferating hemangiomas demonstrate well-defined non-encapsulated masses composed of proliferating plump endothelial cells and pericytes. Small vascular lumens may be noted focally throughout the tumor, but lumen formation may be more difficult to appreciate in early proliferating lesions.

Later in the proliferating stage, lobules of endothelial masses separated by fibrous septae become more prominent (Fig. 103.21). Larger feeding and draining vessels are noted within the septae, and mitotic figures and apoptotic bodies may be present within the tumor mass. Although abnormal mitotic figures are not typical of proliferating hemangiomas, some authors have noted that mitotic activity and mild nuclear pleomorphism may be present in IHs and should not be a cause for concern if other typical histopathologic features are also present. An increased number of mast cells is often present within proliferating hemangiomas, and some studies have found even higher numbers of mast cells during early involution[31].

The involution phase is marked by flattening of the endothelium and reduced numbers of mitotic figures. Eventually, the vessels decrease in number and lose their tightly packed appearance, with fibrous and fatty tissue separating the vessels within and between lobules. The feeding and draining vessels within the septae may persist. Fully involuted lesions display fibrofatty tissue and a few persistent vessels at sites where tumor lobules and septae previously existed.

Immunohistochemical analysis is useful for confirming the diagnosis of IH. A high level of GLUT1 immunoreactivity is present in the endothelia within IHs of all phases (see Fig. 103.21). GLUT1 staining is

absent in most other types of vascular tumors and vascular malformations. Wilms tumor 1 (WT1) expression is also observed in IH but not vascular malformations, with the exception of arteriovenous malformations. In addition, other placenta-associated vascular proteins, including FcγRII, merosin and Lewis Y antigen, are present in IHs but absent in vascular malformations and pyogenic granulomas. These placental markers are also absent in normal vessels of the skin and subcutis[12,31].

DIFFERENTIAL DIAGNOSIS

Superficial and mixed hemangiomas are usually diagnosed based upon their characteristic clinical features. Hemangioma precursors and early proliferating lesions may sometimes be misdiagnosed as capillary malformations or telangiectasias. Pyogenic granulomas (PGs) occur commonly in children and may mimic a superficial hemangioma; however, PGs usually arise after the first few months of life, are typically pedunculated, and tend to bleed. Other vascular lesions of infancy that may be in the differential diagnosis of superficial hemangioma include tufted angioma, multifocal lymphangioendotheliomatosis with thrombocytopenia, infantile hemangiopericytoma, spindle cell hemangioma, verrucous venulocapillary malformation ("verrucous hemangioma"), and eccrine angiomatous hamartoma.

Deep hemangiomas provide a greater diagnostic challenge, and radiographic evaluation may be helpful. Other vascular anomalies that may be considered in the differential diagnosis of a deep hemangioma include a venous, lymphatic, or combined venous–lymphatic malformation (see Ch. 104) as well as a congenital hemangioma (see below; Table 103.5) or kaposiform hemangioendothelioma (see Ch. 114). Kasabach–Merritt phenomenon (KMP), a potentially life-threatening thrombocytopenic coagulopathy, typically presents during the first months to year of life with a rapidly enlarging, ecchymotic mass (see Ch. 114); KMP is now known to be primarily associated with kaposiform hemangioendotheliomas and less often tufted angiomas, but not IHs as historically assumed.

Congenital fibrosarcoma is often firm and blue–purple in color and can have ectatic superficial veins, which may lead to misdiagnosis as a hemangioma. In addition, some patients with this malignancy present with disseminated intravascular coagulation, which further confuses the clinical picture. Rhabdomyosarcoma, neuroblastoma, primitive neuroectodermal tumor, lymphoblastic lymphoma, and dermatofibrosarcoma protuberans are other neoplasms that may have a vascular appearance due to overlying telangiectasias or a blue–red color. Additional entities that may be mistaken for a hemangioma include: infantile myofibromatosis – solitary or multiple red to pink plaques or nodules; lipoblastoma – an enlarging skin-colored or (less often) erythematous mass; and nasal glial heterotopia – classically a congenital blue–red mass on the bridge of the nose. Radiographic studies, especially MRI, may be useful in differentiating these tumors from a hemangioma. However, if the diagnosis is not clarified by clinical and radiographic examinations, or if the lesions are atypical, then histologic examination is indicated.

KEY FEATURES OF INFANTILE AND CONGENITAL HEMANGIOMAS

Infantile hemangioma	Rapidly involuting congenital hemangioma (RICH)	Non-involuting congenital hemangioma (NICH)
Usually absent or precursor lesion at birth	Fully developed at birth	Fully developed at birth
Rapid postnatal proliferation	Intrauterine proliferation	Intrauterine proliferation then proportionate postnatal growth
Slow spontaneous involution	Rapid involution during the first year*	Do not involute spontaneously Tardive growth during childhood in ~10%
More common in girls	Equal prevalence in boys and girls	Equal prevalence or slightly more common in girls
Lobular endothelial proliferation during proliferative phase; fibrous and fatty tissue during involution	Capillary lobules within fibrotic stroma containing thin-walled vessels, hemosiderin	Lobules of small, thin-walled vessels with large central vessel; dilated, dysplastic veins between lobules; "hobnailed" endothelial cells lining intralobular vessels
Positive GLUT1 and Lewis Y antigen	Negative GLUT1 and Lewis Y antigen	Negative GLUT1 and Lewis Y antigen

*Occasionally associated with thrombocytopenia during the neonatal period.

Table 103.5 Key features of infantile and congenital hemangiomas. Partially involuting congenital hemangiomas (PICHs) represent an intermediate form that undergoes incomplete involution.

TREATMENT

IHs manifest with a wide spectrum of clinical severity, and their management needs to be individualized. The Hemangioma Activity Scale and Hemangioma Severity Scale were developed to help objectively assess IHs and their response to therapy[84,85]. Active intervention is recommended for IHs with a greater risk of developing local or systemic complications (Table 103.6)[86]. The major goals of management include: (1) preventing or reversing life- or function-threatening complications; (2) treating ulcerations; (3) preventing permanent disfigurement; (4) minimizing psychosocial distress to patients and their families; and (5) avoiding overly aggressive, potentially scarring procedures for lesions that have a strong probability of involuting without significant residua[87].

Active Non-Intervention

Small, uncomplicated hemangiomas carry an excellent prognosis and are often managed with active non-intervention, especially in extrafacial sites[88]. However, physicians should recognize that even small, seemingly trivial lesions may be troubling to parents and cause significant distress. Active non-intervention includes addressing parental concerns as well as discussing the expected natural history of IHs, indications for treatment, types of therapy, and why such interventions are or are not appropriate for their child. The hemangioma can be followed with periodic clinical assessment and photography. Reviewing photographic examples of the evolution of hemangiomas may be helpful for families. Many parents are fearful of bleeding; therefore, reviewing the care for superficial bleeding, along with reassurance that it is rarely problematic, is worthwhile.

Management of Ulceration

Ulceration is the most frequent complication of IHs (see Fig. 103.11). Management should be directed at healing the ulceration, preventing infection, and reducing pain. Multiple modalities are often used concurrently, with no single therapy proven to be most effective[59]. Components of management include wound care, treatment of infection (relatively uncommon), specific therapies (e.g. topical or systemic β-blockers), and pain control.

Wound care

Many small, superficial ulcerations can be managed with local wound care. Saline solution compresses may be used to gently debride thick

REASONS TO CONSIDER SYSTEMIC THERAPY FOR INFANTILE HEMANGIOMAS

Threatened vital functions
- Vision
- Airway

Increased potential for disfigurement
- Nasal tip/columella
- Lip, especially if the lesion crosses the vermilion border
- Large (≥2 cm)/rapidly growing lesion, especially if on the face (>1 cm if age ≤3 months) or with an abrupt "step" border
- Breast, especially if a larger lesion involves the nipple in a girl

Recalcitrant/severe ulceration

High-output cardiac failure

Table 103.6 Reasons to consider systemic therapy for infantile hemangiomas.

crusts. Although infection is uncommon, topical antibacterial ointments (e.g. mupirocin) can be applied for occlusive as well as antimicrobial effects. If clinical signs of infection develop, a bacterial culture should be obtained. Occlusive dressings (e.g. hydrocolloid, foam, silicone-based) aid in healing and pain control. They can be applied after the topical antibiotic or petrolatum at sites that are amenable (see Ch. 145). Thin hydrocolloid dressings are often favored because of the ease of application over curved surfaces and the ability to leave them in place for a few days. Inexpensive petrolatum-impregnated gauze is another option and it is especially helpful for perineal ulcers, but needs to be changed frequently.

Specific therapy

Modalities that are utilized to treat hemangiomas for other indications (see below) may be helpful in treating ulcerated lesions. Application of topical timolol can aid in healing of small ulcerated IHs, but caution must be taken regarding systemic absorption[89–91] (see below).

Oral propranolol therapy is often useful for ulcers that are extensive or have failed local therapies. In one study of ulcers present for a mean of 7 weeks, the median time to healing after initiating propranolol was 4 weeks and most patients achieved pain relief within 15 days[92]. Although early propranolol therapy may help to prevent ulceration of IHs in high-risk locations, precipitation or worsening of ulceration in such lesions has also been described with propranolol administration[93]. Initiation of propranolol at a low dose with slow escalation is recommended for IHs with ulceration or at high risk of ulceration – a recent retrospective study found that ulcer healing time was shorter with a propranolol dose of ≤1 mg/kg/day compared to higher doses[57,93].

Pulsed dye laser has been used for the treatment of ulcerated hemangiomas, especially in combination with other modalities. Some uncontrolled studies demonstrated healing of ulcerations and resolution of pain after two to three treatments[94]. However, others observed mixed results, with 50% showing improvement and 5% experiencing worsening of the ulceration[59]. Excisional surgery may be considered for small or pedunculated ulcerated lesions.

Pain control

An important consideration in the treatment of ulcerated hemangiomas is pain control. Local wound care, and especially occlusive dressings, can provide some pain relief. Oral acetaminophen and topical lidocaine 2%–5% ointment may also help to alleviate the discomfort. Lidocaine ointment should be used sparingly (e.g. maximum of a pea-sized amount) to prevent systemic lidocaine toxicity. Eutectic mixture of local anesthetics is not recommended for the treatment of ulcerated hemangiomas because it should not be applied to eroded or ulcerated skin[59]. In severe cases, consultation with a pain management specialist may be required.

Local Therapies

Topical β-blockers

Topical application of timolol maleate, a non-selective β-blocker, can be of benefit in the treatment of IHs, especially small superficial lesions that are <1 mm in thickness[91,95] (Fig. 103.22). Timolol is available in several ophthalmic formulations, including 0.5% solution and 0.5% gel-forming solution (GFS; extended-release), with one drop (0.25 mg) twice daily of the latter most commonly utilized to treat IHs. A randomized control study found this dosing of timolol 0.5% GFS to be an effective and safe therapy for small (<2.5 cm), thin, non-ulcerated cutaneous IHs in infants 5–24 weeks of age, with benefit seen after 8–16 weeks of treatment[96].

A pharmacokinetic study found that as hemangiomas with a prominent superficial component increased in thickness, higher plasma concentrations of topically applied timolol were observed[97]. Although topical timolol treatment guidelines have not been established, it is recommended that the dose be limited to a maximum of 2 drops of timolol 0.5% GFS daily or <0.25 mg/kg/day[98,99]. Despite systemic absorption, topical timolol treatment is generally well tolerated and serious adverse events are rare.

Intralesional corticosteroids

Historically, intralesional corticosteroids were commonly used to treat localized IHs; however, this modality is now utilized infrequently considering the efficacy of β-blocker therapy. Intralesional corticosteroids (e.g. triamcinolone <3 mg/kg per treatment session) may be employed for selected small, focal hemangiomas. However, serious complications, including retinal and ophthalmic artery occlusion leading to permanent vision loss, as well as local atrophy and necrosis, have limited the use of this modality in the periorbital area[100].

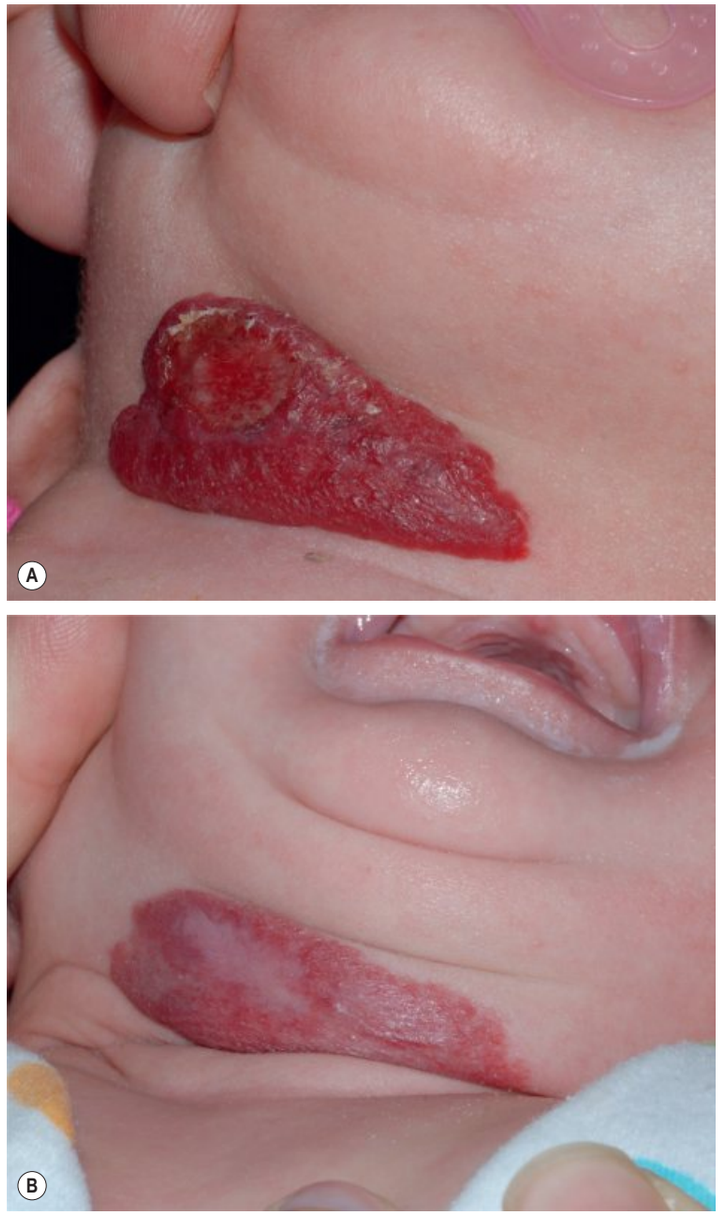

Fig. 103.22 Ulcerated superficial hemangioma treated with topical timolol. **A** An ulcerated superficial infantile hemangioma on the neck of a 10-week-old girl. **B** Four weeks after institution of topical timolol 0.5% gel, with one small drop applied twice daily. Note the healing of the ulcer, which occurred within two weeks, as well as the lighter color and decreased thickness of the hemangioma. *Courtesy Julie V. Schaffer, MD.*

Systemic Therapies

Systemic β-blockers

The serendipitous discovery of the non-selective β-blocker propranolol as a treatment for IH in 2008 has revolutionized the management of this common tumor, and it currently represents the first-line systemic therapy for IHs[101]. In 2014, propranolol (Hemangeol™) became the first FDA-approved treatment for IHs. Oral β-blockers are effective in halting growth and expediting regression of cutaneous, ocular, airway, and hepatic IHs as well as for complications such as ulceration.

The mechanisms of action of propranolol are thought to be multifaceted. The color change from red to purple and softening that are observed within the first few days of treatment are likely related to immediate vasoconstrictive effects via β_2-adrenergic receptors on hemangioma pericyte cells. Subsequent progressive reduction in volume and redness may be due to decreases in serum concentration of VEGF, bFGF, and renin as well as induction of endothelial cell apoptosis[102–105].

Compared to systemic corticosteroids, propranolol has superior efficacy and a more favorable side-effect profile[106]. Potentially serious adverse effects such as hypotension, bradycardia, hypoglycemia, and bronchospasm are uncommon. β-blockers may mask early signs of hypoglycemia, so infants should be fed in conjunction with medication administration[107]. More common side effects include sleep disturbances (e.g. restless sleep, nightmares), cold extremities, diarrhea, and somnolence (especially in the first few days of therapy). There are rare reports of hyperkalemia associated with propranolol treatment of large ulcerated hemangiomas[108,109]. Long-term studies have found no evidence of cognitive, developmental, or growth impairment in 4- to 7-year-old children who received propranolol treatment for hemangiomas during infancy[110,111].

Table 103.7 outlines recommendations for propranolol administration, although clinical practices regarding evaluation, dosing, and monitoring vary[112,113]. Patients at risk of PHACE(S) syndrome should undergo evaluation for cardiovascular and cerebrovascular anomalies that may merit caution given the theoretical risk for hypotension. Most infants with PHACE(S) syndrome can be successfully treated with propranolol[114]. However, depending on their extracutaneous manifestations, these patients may need to be managed together with cardiologists and/or neurologists, proceeding cautiously with dose escalation in individuals at increased risk for complications such as stroke[115]. A history of airway reactivity or asthma may not be an absolute contraindication to propranolol therapy, but such patients require closer monitoring and consultation with a pulmonologist.

Propranolol dosing is weight-based, usually with a target dose of 2–3 mg/kg/day (see Table 103.7). In infants with ulcerated hemangiomas, doses of ≤1 mg/kg/day may reduce healing time[57]. Treatment

ADMINISTRATION OF PROPRANOLOL FOR INFANTILE HEMANGIOMAS (IHs): COUNSELING, RISK ASSESSMENT, DOSING, AND MONITORING

Counseling for parents

- Discuss potential risks of propranolol, including bradycardia, hypotension, hypoglycemia, sleep disturbances, and bronchospasm
- Review signs of hypoglycemia – *early* (may be masked by β-blockade): sweating, rapid heart rate, shakiness, fussiness; *late*: lethargy, poor feeding, hypothermia, seizures
- Emphasize the need to administer propranolol during or immediately after a feeding; twice daily doses should be ≥9 hours apart
- Dose should be lowered or therapy suspended during intercurrent illnesses with decreased oral intake or vomiting
- Provide written anticipatory guidance: https://pedsderm.net/site/assets/files/1028/12_spd_propranolol_color_web-final.pdf

Assessment of risk for complications of β-blocker therapy

Standard risk

- Age ≥5 weeks (using corrected age for premature infants)
- Normal birthweight and weight gain
- IH pattern and distribution does not confer risk of PHACE
- Normal cardiovascular and respiratory examination/history†
- Caregiver is able to understand and adhere to outpatient protocols

Higher risk

- Age <5 weeks (using corrected age for premature infants)
- IH pattern and distribution at risk for PHACE*
- History of recent or persistent hypoglycemia
- Cardiovascular disease, reactive airway disease/bronchospasm†, or brain malformation
- Extensive hepatic hemangiomas
- First degree relative with congenital heart disease, sudden death, or arrhythmia
- Maternal history of connective tissue disorder

Dosing and course

- Initial: usually ~1 mg/kg/day divided into 2 (or 3) doses‡
- Target: 2–3 mg/kg/day divided into 2 (or 3) doses‡; the target dose may be lower (~1 mg/kg/day) for ulcerated lesions, and the FDA-approved maximum is 3.4 mg/kg/day
- For a proliferating IH, treatment is typically continued for 6–12 months, depending on the clinical setting and course¶
  - The dose should be adjusted to account for weight gain to maintain the goal dose/kg
- Taper over 2–4+ weeks before discontinuing, primarily to assess for rebound growth

Monitoring

- Outpatient initiation of therapy
  - FDA recommendations include monitoring heart rate and blood pressure for 2 hours after the initial dose or a significant dose increase§
  - Measure heart rate and blood pressure every 4–8 weeks while on a stable dose
  - Normal ranges for pediatric vital signs are available at: www.emedicinehealth.com/pediatric_vital_signs/article_em.htm
- Consider a brief inpatient stay (e.g. 1–2 days) with telemetry for initiation of treatment if <5 weeks corrected age and/or complications such as cardiovascular or cerebrovascular anomalies

*Hemangioma ≥5 cm in diameter on the head or upper body (see Table 103.4). For at-risk patients, perform MRI/MRA of head/neck and echocardiogram to exclude arterial and cardiovascular anomalies (see Fig. 103.15); if abnormal, consult with a neuroradiologist, neurologist, and/or cardiologist as indicated.

†Contraindications include bradycardia (<80 beats/minute), blood pressure <50/30 mmHg, >1st degree heart block, and decompensated heart failure. Reactive airway disease/bronchospasm is a relative contraindication to propranolol therapy that may require consultation with a pulmonologist.

‡The dose is typically increased in increments of 1 mg/kg/day weekly in an outpatient setting or after 1–3 doses in an inpatient setting, until reaching the target dose; a lower starting/target dose and slower escalation may be required for patients at higher risk of complications. For at-home initiation (e.g. via telemedicine), a starting dose of 0.5 mg/kg/day increased by 0.5 mg/kg/day every 3–4 days until the target dose is reached has been recommended[112].

¶A longer duration of treatment may be required for IHs with prolonged growth or rebound growth after reduction/discontinuation of propranolol.

§A multicenter retrospective study found that in-office monitoring of vital signs upon propranolol initiation and dose escalation rarely changed management and did not predict adverse events[139].

Table 103.7 Administration of propranolol for infantile hemangiomas: recommendations for counseling, risk assessment, dosing, and monitoring. Practices for evaluation, dosing, and monitoring vary widely. The patient's age, hemangioma-related issues, and medical comorbidities affect management. A dosing chart is provided for FDA-approved Hemangeol™ 4.28 mg/ml solution (https://hemangeol.com/physician/dosing-administration/); generic propranolol 20 mg/5 ml (4 mg/ml) solution is also available.

is typically continued for 6–12 months, followed by gradual tapering. Approximately 25% of IHs undergo rebound growth after cessation of propranolol, with a higher risk if the lesion is deep or therapy is discontinued before 9 months of age[116–118].

β-blockers that do not cross the blood–brain barrier because they are hydrophilic (rather than lipophilic like propranolol) may potentially produce less CNS effects such as sleep disturbance. These agents include atenolol (β_1-selective) and nadolol (non-selective), neither of which is currently FDA-approved for IH treatment. Randomized controlled studies of atenolol and nadolol treatment of IH have demonstrated efficacy and safety similar to that of propranolol, with a faster response to nadolol[119–121]. Because nadolol is excreted primarily in the feces, bowel movement frequency should be monitored and the medication held if substantial constipation[122]. A recent study found that the R(+) enantiomers of propranolol and atenolol, which do not have β-blocker activity, inhibited formation of IH-like blood vessels from hemangioma stem cells in a murine xenograft model, suggesting the possibility of these agents' utility for IH treatment[123].

Systemic corticosteroids

Systemic corticosteroids, usually prednisolone or prednisone, were traditionally employed for the treatment of life- or function-threatening hemangiomas (see Table 103.6). Corticosteroids suppress VEGF production by hemangioma-derived stem cells and inhibit vasculogenesis in a murine model[124]. Although no longer a first-line therapy, systemic corticosteroids are still occasionally utilized when β-blocker therapy is contraindicated or in combination with β-blockers, e.g. for airway or diffuse hepatic hemangiomas[106]. Initial doses equivalent to 2–3 mg/kg/day of prednisone are typically administered, with variable duration of therapy, tapering schedules, and monitoring. Adverse effects of systemic corticosteroids include cushingoid facies, irritability, disruption of sleep, gastrointestinal symptoms, hypertension, hypothalamic–pituitary–adrenal (HPA) axis suppression, and increased susceptibility to opportunistic infections (see Ch. 125).

Other systemic therapies

Sirolimus (rapamycin) inhibits the mTOR signaling pathway, which plays an important role in cell growth and proliferation (see Fig. 61.12). Oral sirolimus is emerging as a second-line systemic treatment for recalcitrant life- or function-threatening IHs. There have been reports of its successful use for large facial IHs that failed to respond to β-blocker therapy[125,126]. Potential adverse effects include mucositis, hyperlipidemia, headaches, hepatotoxicity, and neutropenia. Laboratory monitoring is necessary including complete blood counts, serum creatinine, liver function tests and lipid panels, as well as sirolimus serum levels.

Vincristine and recombinant interferon-α (2a and 2b) represent historical therapies for severe, recalcitrant IHs that are no longer used because of potential complications such as peripheral neuropathy and spastic diplegia, respectively[127].

Surgical Therapy

Pulsed dye laser (PDL) therapy (585–600 nm wavelength, usually 0.45–1.5 ms pulse duration) is effective for the treatment of capillary malformations. Although PDL therapy may have some benefit for superficial IHs, there is risk for ulceration when it is used early in the growth phase. Multiple treatment sessions, usually every few weeks, are required during the proliferative phase to produce improvement. Considering the superior efficacy of β-blockers, PDL is currently not a first-line therapy for proliferating IHs. However, PDL therapy is often helpful for residual telangiectasias following propranolol therapy and/or involution of the IH. Potential adverse effects from PDL therapy include pigmentary alteration and atrophic scarring as well as ulceration. The Nd:YAG laser has also been used to treat IHs, either alone or in combination with the PDL; however, the higher risk of scarring limits its utility.

The fractional CO_2 laser has been used to improve the texture of residual atrophy and scarring following IH involution. Multiple treatments are typically required and may not be well tolerated without sedation.

Surgical excision may be employed for involuted or partially involuted lesions to remove fibrofatty tissue and redundant skin. The optimal timing of surgery depends upon multiple factors, including the location, size, and morphology (e.g. pedunculated vs sessile) of the lesion. In a retrospective study of 112 IHs resected by a single surgeon, 87% of the lesions were located on the head or neck, 38% of patients had received other treatments during the proliferative phase, and most excisions were performed at 2–3 years of age[128].

Surgical excision during the proliferative phase is controversial and usually reserved for situations in which: (1) a function-threatening hemangioma, e.g. a periocular lesion blocking the visual axis or lip lesion interfering with feeding or speech, failed to respond to pharmacologic therapy; or (2) pharmacologic therapy is believed to pose a greater risk to the patient than surgical excision. Other settings where early surgery may be appropriate include pedunculated lesions for which resection will be inevitable and small, persistently ulcerated lesions that have failed conservative therapy. The ultimate management goal is to achieve as normal an appearance as possible, considering the expected surgical scar as well as the predicted time course and outcome of involution. Therefore, just as with other treatment modalities, the surgical management of IHs needs to be individualized.

RAPIDLY INVOLUTING AND NON-INVOLUTING CONGENITAL HEMANGIOMAS

Infants are occasionally born with a fully developed hemangioma. These congenital hemangiomas (CHs) have features that are clinically, histologically, immunohistochemically, and genetically distinct from IHs (see Table 103.5). Most notably, CHs are GLUT1-negative and have different natural histories, most commonly rapidly involuting (RICH) or non-involuting (NICH) subtypes[129,130] (see Fig. 103.7). Lesions often have somatic gain-of-function mutations in *GNAQ* or *GNA11*, which encode G protein α-subunits that increase signaling via the MAPK pathway[131].

Rapidly involuting congenital hemangiomas (RICHs) are characterized by intrauterine development, with little, if any, postnatal growth and rapid involution within the first year of life. They are equally common in boys and girls. Intrauterine growth may be noted by prenatal ultrasonography as early as 12 weeks' gestation, and prenatal Doppler ultrasonography may reveal high vascularity and fast flow[129]. This tumor can appear at birth as a raised violaceous mass with prominent radiating veins, a hemispheric nodule with coarse telangiectasias surrounded by a pale rim, or a firm, pink to violaceous plaque that is often located on the lower extremity (Fig. 103.23). Small, firm, violaceous papules may be present on the surface, and superimposed milia or hypertrichosis are occasionally noted. Possible complications include necrosis, ulceration, transient thrombocytopenia, and potentially life-threatening hemorrhage that may be heralded by focal crusting[129,132].

Non-involuting congenital hemangiomas (NICHs) typically grow proportionately with the child and, unlike IHs, do not involute spontaneously[130]. These lesions may have a slight female predominance and most often develop on the trunk and extremities[133]. They typically present at birth as a well-circumscribed, pink to blue–violet plaque or nodule with overlying coarse telangiectasias, surrounded by a pale or bluish rim and often draining veins; a "patch" subtype has a flat surface and minimal induration[133] (Fig. 103.24). NICHs are warm to palpation and may be painful. The diagnosis is often established retrospectively when involution fails to occur. Up to 10% of NICHs undergo tardive (delayed) growth, most often between 2 and 10 years of age; lesions may also develop red papules, overlying pyogenic granulomas, and superficial bleeding[134]. In addition, some CHs that initially show regression soon after birth fail to fully involute and have been termed *partially involuting congenital hemangioma* (PICH)[135].

Although CHs may be recognized by prenatal ultrasonography during the second and third trimesters, misdiagnosis as other vascular anomalies such as lymphatic or arteriovenous malformations is common[136]. Postnatal ultrasonographic evaluation of a RICH or NICH typically reveals dense vascularity with a fast-flow component[137]. Compared to IH, CHs tend to have a more heterogeneous appearance with visible vessels and sometimes (especially in RICH) calcifications[138]. MRI reveals features similar to IHs[130], although CHs may be less well-defined and occasionally demonstrate fat stranding[138].

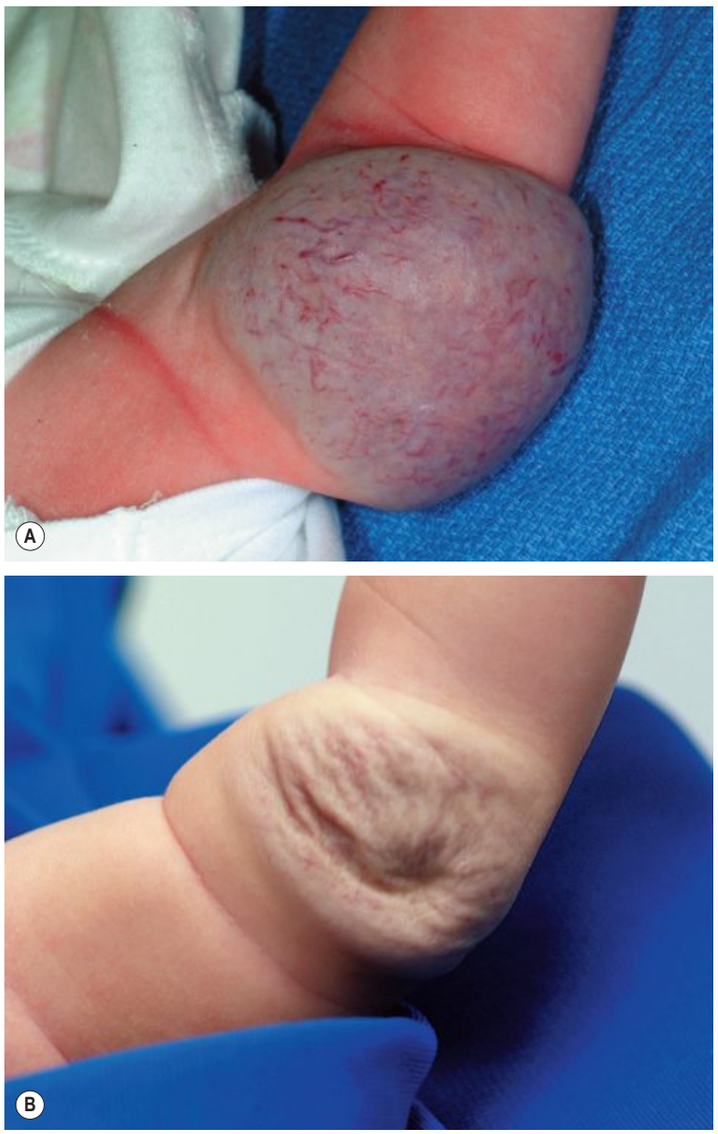

Fig. 103.23 Rapidly involuting congenital hemangioma (RICH). A Violaceous tumor on the upper extremity with surface telangiectasias in a neonate. **B** Spontaneous involution at 5 months of age, with fibrofatty residua. *Courtesy Annette Wagner, MD.*

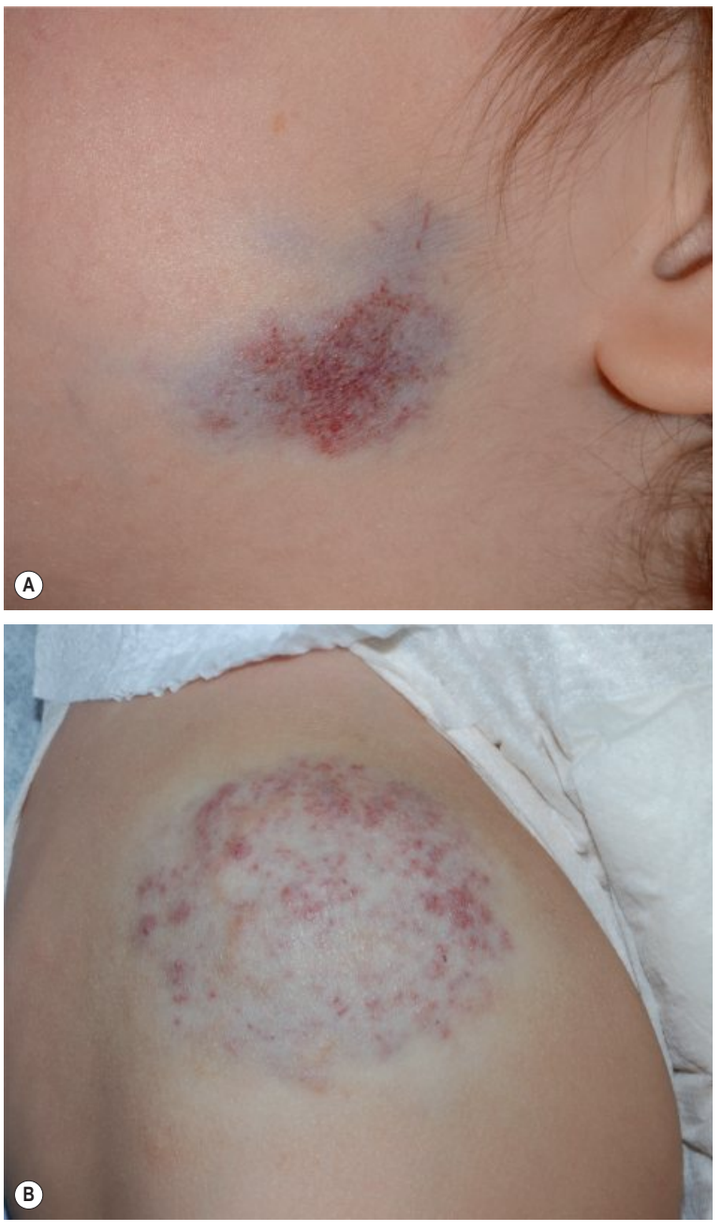

Fig. 103.24 Non-involuting congenital hemangiomas. Light blue–violet vascular plaques with overlying coarse telangiectasias and a pale rim, located on the cheek (**A**) and thigh (**B**). *Courtesy Julie V. Schaffer, MD.*

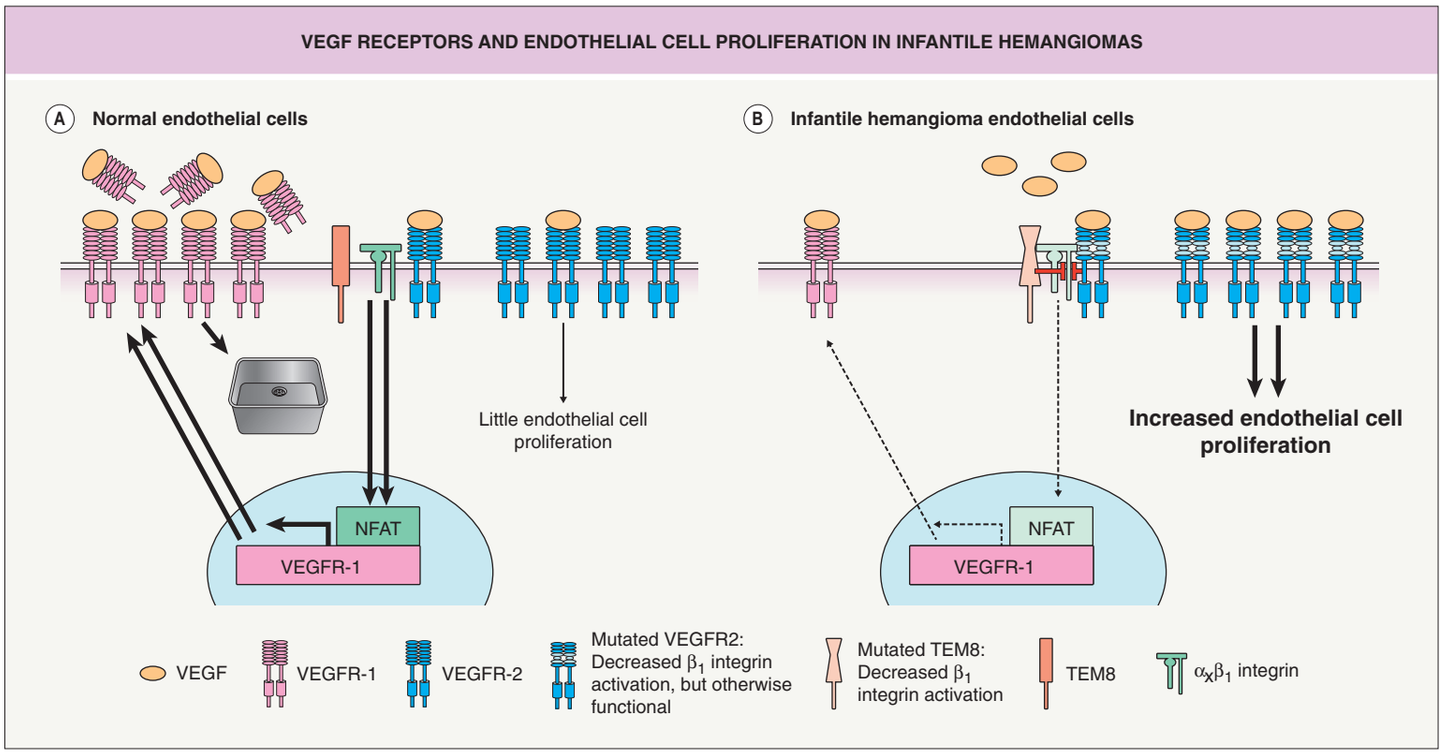
Histologically and immunophenotypically, CHs have several features that are distinct from IHs (see Table 103.5). These include striking lobularity with densely fibrotic stroma, stromal hemosiderin deposits, focal thrombosis and sclerosis of capillary lobules, fewer mast cells, and the coexistence of proliferating vasculature with multiple thin-walled vessels. Moreover, CHs lack immunoreactivity to GLUT1 and Lewis Y antigen. Some tumors do, however, demonstrate zones of involution.

Most CHs do not require treatment, and medical therapies such as propranolol are generally not effective. Surgical excision may be an option for a well-defined NICH, although residual tumor and persistent pain are possible.



Additional figures and a table on Imaging of infantile hemangiomas, available in our eBook (see inside front cover for access code).

eFig. 103.1 VEGF receptors and endothelial cell proliferation in infantile hemangiomas. A In normal endothelial cells, β_1 integrin (which forms a complex with the integrin-like receptor TEM8 and VEGFR-2) increases transcription of VEGFR-1 via activation of NFAT. Binding of VEGF to VEGFR-2 stimulates endothelial cell proliferation, but VEGF binding to VEGFR-1 (which exists in soluble and transmembrane forms) is of higher affinity and does not transmit a signal. VEGFR-1 thereby acts as a VEGF "sink" or decoy receptor that decreases the amount of VEGF available to activate VEGFR-2. **B** Hemangioma endothelial cells have decreased β_1 integrin activity and, consequently, markedly reduced expression of VEGFR-1. This leads to increased VEGF-dependent activation of VEGFR-2 and enhanced endothelial cell proliferation. In a subset of hemangioma patients, the low β_1 integrin activity can be explained by a germline mutation in the *VEGFR2* or *TEM8* gene; such mutations result in increased interactions among β_1 integrin, TEM8, and VEGFR-2 as well as inhibition of β_1 integrin function. NFAT, nuclear factor of activated T cells; VEGF, vascular endothelial growth factor; VEGFR, VEGF receptor; TEM8, tumor endothelial marker 8.

104 Vascular Malformations

Eulalia Baselga

Synonyms: ■ Vascular birthmarks; mature angiomas [misnomer]; angiodysplasias ■ Capillary malformation (CM): port-wine birthmark [preferred], port-wine stain, nevus flammeus ■ Venous malformation (VM): cavernous angioma [misnomer], cavernous hemangioma [misnomer], phlebectasia ■ Lymphatic malformation (LM): lymphangioma, lymphangioma circumscriptum, lymphangioma simplex, cystic hygroma, cavernous lymphangioma [historical terms/misnomers] ■ Arteriovenous malformation (AVM): cirsoid aneurysm, cirsoid hemangioma [misnomer]

Key features

- Although both were once called "angiomas", vascular malformations differ from the vascular tumors seen in infants and children
- In slow-flow malformations, capillaries, veins, and/or lymphatic channels are anomalous; most lesions are either apparent at birth or become evident within the first few months or years of life
- In fast-flow malformations, there is arteriovenous shunting; some lesions are apparent at birth, but the majority become evident later in childhood or adulthood
- Vascular malformations are lifelong and may worsen over time, creating cosmetic consequences and functional impairment
- Vascular malformations are occasionally found together with other abnormalities as a part of a complex syndrome

INTRODUCTION

According to the classification system adopted by the International Society for the Study of Vascular Anomalies (ISSVA), there are two types of vascular anomalies: vascular tumors (most commonly the infantile hemangioma) and vascular malformations[1] (Table 104.1; see Table 103.2). Vascular malformations are localized defects of vascular morphogenesis, likely caused by dysfunction in pathways regulating the formation of vascular channels during embryonic development, including effects on endothelial cell growth and survival. True angiogenesis may occur in some of these lesions, potentially explaining their propensity to thicken and even expand over time. However, in general, vascular malformations do not exhibit the markers of endothelial cell proliferation seen in infantile hemangiomas during their proliferative phase (Fig. 104.1). The suffix "oma" (meaning "tumor") has therefore been deemed inaccurate for vascular malformations, and terms such as "angioma", "lymphangioma", and "hemangioma" should not be used for these lesions.

In the current ISSVA classification system[2,3], which was updated in 2018, vascular malformations are categorized depending on the predominant type(s) of anomalous vessels:

- **capillary** (CM), classically a port-wine birthmark (PWB), but also including telangiectasias, cutis marmorata telangiectatica congenita (CMTC), and nevus simplex
- **venous** (VM): a misnomer for this entity is "cavernous hemangioma", a term with a long history of use to describe deep infantile hemangiomas
- **lymphatic** (LM): this category includes microcystic and macrocystic lesions, which were previously termed lymphangioma and cystic hygroma (respectively), along with more extensive forms with visceral or bone involvement. Central conducting lymphatic anomalies and primary lymphedema are also included in this category.
- **arteriovenous** (AVM): fast-flow lesions characterized by malformed arteries, veins, and capillaries with direct communications that produce arteriovenous shunting.

Vascular malformations are further divided into four groups: (1) *simple* – containing only one type of vessel or an AVM; (2) *combined* – composed of ≥2 types of vessels, e.g. capillary–venous (CVM), capillary–lymphatic (CLM), capillary–lymphatic–venous (CLVM), lymphatic–venous (LVM), capillary–arteriovenous (C-AVM), or capillary–lymphatic–arteriovenous (CL-AVM); (3) *major named vessels* involved; and (4) *associated with other anomalies* as a part of a complex syndrome, which have classically been referred to with eponyms such as Sturge–Weber and Klippel–Trenaunay syndromes (see Table 103.2). In a few scenarios, vascular tumors and malformations occur together, such as spindle cell hemangiomas and VMs in patients with Maffucci syndrome or pyogenic granulomas superimposed on a CM or AVM. Co-segregation of infantile hemangiomas and vascular malformations within families has also been observed.

Vascular malformations may occur in any body part or organ system. They are most easily identified in the skin and mucous membranes, with some of these lesions invading deep into underlying muscles, bones, or joints. Others are found in visceral locations. Vascular malformations can appear as localized lesions of varying sizes, occur within a segmental distribution, or be dispersed as multifocal or disseminated lesions.

Vascular malformations are persistent and some worsen over time if not treated. Categorizing a lesion as a CM, LM, VM, AVM, or combined lesion is important, since diagnostic modalities as well as treatment differ depending on the type(s) of vessels involved[1]. The genetic bases of multiple types of vascular malformations and associated syndromes have been elucidated (Table 104.2, Fig. 104.2). This has been incorporated in the ISSVA classification and provides the foundation for targeted approaches to therapy[4]. In many patients, a multidisciplinary team is required to provide optimal management. Cure is rarely achievable. A realistic aim is improvement and minimization of cosmetic or functional consequences. Many patients require longitudinal care from infancy through adulthood[1].

HISTORY

In the medical literature addressing vascular malformations, lesions and syndromes were originally delineated based on clinical features. Many authors played a major role in their description, including Virchow, Trélat, Monod, Klippel, Trenaunay, Weber, Sturge, Bockenheimer, Maffucci, Bell, and Malan. Unfortunately, pathologists and clinicians did not work together. Consequently, multiple nomenclatures became an obstacle to communication among physicians treating these patients. In 1976, John B. Mulliken (a plastic surgeon in the US), Anthony E. Young (a vascular surgeon in the UK), and Jean-Jaques Merland (a neurointerventional radiologist in France) joined forces to convene the first of many Workshops on Vascular Anomalies. The ISSVA, created in 1992, is dedicated to analyzing the clinical, radiologic, biologic, and pathologic characteristics of vascular lesions and improving diagnosis and treatment via multidisciplinary and international collaboration.

EPIDEMIOLOGY

Little is known regarding the exact prevalence of vascular malformations in the general population. The most common types are CMs, then VMs. The least common are AVMs. Vascular malformations have no sex predilection.

PATHOGENESIS

An initial embryologic process, vasculogenesis, creates the primitive vascular plexus. Then angiogenesis, the secondary sprouting of

DIFFERENCES BETWEEN VASCULAR MALFORMATIONS AND INFANTILE HEMANGIOMAS		
Characteristics	**Vascular malformations**	**Infantile hemangiomas**
Clinical features	CM: red, macular during infancy VM: blue, compressible, fills with dependency LM: vesicles or large cysts AVM: four stages: stage 1 – dormant: red, warm; macular (mimics CM) or slightly infiltrated (mimics involuting infantile hemangioma) stage 2 – expansion: warm mass with thrill/throbbing, dilated draining veins stage 3 – destruction: pain, ulceration; occasional bone lysis and fracture stage 4 – cardiac decompensation; high-output cardiac failure; also signs of stage(s) 2 ± 3	Premonitory markers at birth in 50%: red telangiectatic, bluish bruise-like, or white/anemic macules Superficial hemangioma: bright red, "strawberry"-like papules and plaques (during proliferative phase) Deep hemangioma: warm, rubbery mass under normal-colored or bluish skin
Sex prevalence	Female : male ratio 1 : 1	Female : male ratio 2 : 1 to 5 : 1
Natural history	Usually evident at birth Lifelong persistence, with commensurate growth during childhood and often slow worsening over time AVM: may worsen with puberty, trauma, and pregnancy	Precursor lesion or no evidence at birth Postnatal proliferation over 5–9 months, then slow involution over years Reach stable involuted stage
Radiology	VM or LM (slow flow): hypersignal on MRI T2-weighted sequence VM: thrombi and phleboliths (MRI, CT); gadolinium enhancement on MRI AVM (fast flow): flow voids on MRI T1- and T2-weighted sequences; arteriovenous shunts on Doppler ultrasound	Well-defined mass Some flow voids on MRI T1-weighted sequences (high-flow vessels)
Pathology (see Fig. 104.25)	CM: ectatic capillaries VM or LM: distorted, interconnected malformed channels AVM: AV fistulae and increased capillaries Typically no increase in cellular turnover	Dense lobular proliferation of endothelial cells forming capillaries with tiny lumens Increased cellular turnover in proliferating lesions can be demonstrated by elevated levels of markers of proliferation (PCNA, Ki-67), ECM remodeling (collagenase, urokinase), and vascular growth (bFGF, VEGF)
Immunophenotype	GLUT1-negative	GLUT1-positive
Hematology	VM or LVM: chronic LIC, occasional DIC Treatment of flares with low-molecular-weight heparin Possible benefit of low-dose aspirin as prophylaxis	(Kasabach–Merritt phenomenon is not linked to infantile hemangiomas, but to other vascular tumors such as kaposiform hemangioendotheliomas and tufted angiomas, both of which are GLUT1-negative; see Ch. 114)
Molecular biology	CMs (including SWS): somatic *GNAQ* > *GNA11* mutation Sporadic VMs: somatic *TEK* (~50%) or *PIK3CA* (~25%) mutation LMs: somatic *PIK3CA* mutation AVMs: somatic *MAP2K1, NRAS, KRAS, BRAF* Familial vascular malformations and overgrowth syndromes: see Tables 104.2 and 104.5	Rare families with autosomal dominant inheritance linked to 5q, and *somatic* loss of heterozygosity of 5q in some hemangiomas *Germline* mutation in *VEGFR2* or *TEM8* in some patients *Somatic* mutation in *VEGFR2* or *FLT4*/*VEGFR3* (5q34) in some hemangiomas Clonality in some hemangiomas

Table 104.1 Differences between vascular malformations and infantile hemangiomas. AVM, arteriovenous malformation; bFGF, basic fibroblast growth factor; CM, capillary malformation; CT, computed tomography; DIC, disseminated intravascular coagulation; ECM, extracellular matrix; *FLT4*, fms-related tyrosine kinase 4; *GNAQ/11*, G protein subunit α q or 11; LIC, localized intravascular coagulation; LM, lymphatic malformation; *MAP2K1*, mitogen-activated protein kinase kinase 1; MRI, magnetic resonance imaging; PCNA, proliferating cell nuclear antigen; *PIK3CA*, phosphatidylinositol-4,5-biphosphate 3-kinase catalytic subunit α; SWS, Sturge–Weber syndrome; *TEM8*, tumor endothelial marker 8; VEGF, vascular endothelial growth factor; VM, venous malformation.

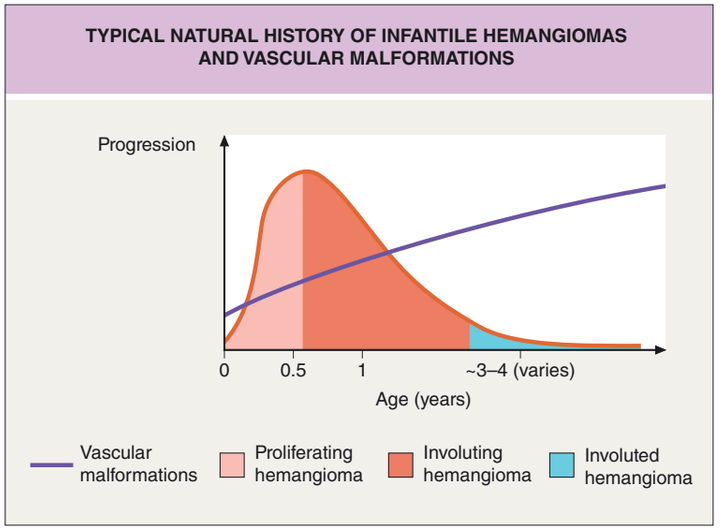

Fig. 104.1 Typical natural history of infantile hemangiomas and vascular malformations.

mesoderm-derived endothelial cells, forms new vessels from existing ones, thereby generating most blood and lymphatic vessels. Endothelial cells differentiate and recruit smooth muscle cell precursors to ensheathe them and build vessel walls. Changes in channel size, morphology, and rheology then create capillaries, veins, and arteries.

Vascular malformations constitute a heterogeneous group of disorders that result from alterations in the formation of blood or lymphatic channels. Dysfunction in signaling processes that regulate migration, differentiation, maturation, adhesion, and survival of the cells of vascular walls is thought to have a pathogenic role. Markers of cellular proliferation are not elevated in vascular malformations. In the cephalic region of the embryo, mural cells associated with endothelial cells come from the neural crest; therefore, a vascular malformation complex involving the head, such as Sturge–Weber syndrome (SWS), is caused by a somatic mutation in the embryo's anterior neural crest or adjacent cephalic mesenchyma. Identification of the genetic defects underlying various types of vascular malformations and the functions of the encoded proteins has provided insights into regulatory pathways critical to vascular morphogenesis (see Table 104.2)[5].

Sporadic vascular malformations may be caused by somatic mutations in the same or different genes than those implicated in the less common familial forms of the same type of malformation. For example, *somatic*

VASCULAR ANOMALIES FOR WHICH THE MOLECULAR BASIS IS KNOWN				
Vascular malformation	**Mode of inheritance**	**Mutated gene(s)**	**Type of mutation**	**Protein and function**
Capillary and/or arteriovenous malformations				
Port-wine birthmark/Sturge–Weber syndrome	Mosaic	*GNAQ* *GNA11*	Gain-of-function	Q-class G protein α-subunits
Port-wine birthmark/phakomatosis pigmentovascularis type II or overgrowth (e.g. of an extremity)		*GNAQ* *GNA11*		
AKT3-associated capillary malformation	Mosaic	*AKT3*	Gain-of-function	Activates AKT/mTOR pathway
Capillary malformation–arteriovenous malformation, including Parkes Weber syndrome	AD	*RASA1* *EPHB4**	Loss-of-function	p120-Ras-GAP protein and EPH receptor B4 in endothelial cells – interact and modulate MAPK signaling
Cerebral cavernous malformation (CCM)†	AD	CCM1: *KRIT1* CCM2: *CCM2* CCM3: *PDCD10*	Loss-of-function	KRIT-1 interacts with KREV-1, RAP-1A and malcavernin (the *CCM2* gene product) – roles in MAPK and integrin signaling
Hereditary hemorrhagic telangiectasia (HHT; Osler–Weber–Rendu)	AD	HHT1: *ENG* HHT2: *ACVRL1/ALK1* HHT5: *GDF2*	Loss-of-function	Endoglin and activin A receptor-like type 1 are two TGF-β receptors with roles in vessel wall integrity, which are activated by GDF2
Juvenile polyposis with HHT	AD	*SMAD4*	Loss-of-function	SMAD4 tumor suppressor protein – role in TGF-β signaling
Microcephaly–capillary malformation syndrome‡	AR	*STAMBP*	Loss-of-function	STAM-binding protein, a deubiquitinating enzyme
Arteriovenous malformations	Mosaic	*MAP2K1* *BRAF* *KRAS* *HRAS*	Gain-of-function	Activate MAPK pathway
Venous malformations				
Cutaneous and mucosal venous malformations (VMCM)	AD	*TEK*	Gain-of-function	TIE-2, an endothelial cell-specific tyrosine kinase receptor that binds angiopoietins
Blue rubber bleb nevus syndrome	Mosaic with double (cis) somatic mutations			
Venous malformations¶	Mosaic, sometimes with double (cis) somatic mutations	*TEK* *PIK3CA*	Gain-of-function	See above for TIE-2; PIK3CA activates AKT/mTOR pathway
Glomuvenous malformations	AD	*GLMN*	Loss-of-function	Glomulin is a component of a multiprotein complex – role in vascular morphogenesis
Verrucous venous malformation	Mosaic	*MAP3K3*	Gain-of-function	Activates MAPK pathway
Lymphatic anomalies				
Lymphatic malformations (microcystic, macrocystic, generalized lymphatic anomalies)	Mosaic	*PIK3CA*	Gain-of-function	Activates AKT/mTOR pathway
Kaposiform lymphangiomatosis	Mosaic	*NRAS*	Gain-of-function	Activates MAPK pathway
Congenital lymphedema (Milroy disease)	AD > AR	*FLT4*	Loss-of-function	VEGFR-3 – a tyrosine kinase receptor in lymphatic vessels
Milroy-like disease	AD	*VEGFC*	Loss-of-function	VEGF-C – a ligand for VEGFR-3
Lymphedema–distichiasis	AD	*FOXC2*	Loss-of-function	Forkhead family transcription factor C2
Hereditary lower extremity lymphedema	AD (female predominance)	*CELSR1*	Loss-of-function	Cadherin involved in lymphatic valve formation
Hypotrichosis–lymphedema–telangiectasia syndrome	AR, AD	*SOX18*	Loss-of-function or dominant-negative	SRY-box 18 transcription factor
Hennekam lymphangiectasia–lymphedema syndrome§	AR	*CCBE1* *FAT4* *ADAMTS3*	Loss-of-function	Collagen & calcium-binding EGF domain-containing protein 1; FAT atypical cadherin 4; protease that cleaves pro-VEGF-C
Generalized lymphatic dysplasia	AR	*PIEZO1*	Loss-of-function	Ion channel involved in lymphatic development

*Mutations in *EPHB4* can also result in nonimmune hydrops fetalis and postnatal lymphatic dysfunction.
†Cutaneous vascular malformations, including hyperkeratotic capillary–venous malformations (associated primarily with *KRIT1* mutations) and venous malformations (less common), occur in ~10% of patients.
‡Features multiple small capillary malformations, hypoplastic distal phalanges, severe intellectual disability, and intractable seizures.
¶Somatic mutations in *GJA4* (gap junction protein alpha 4) encoding connexin 37 have also been reported in cutaneous and hepatic venous malformations.
§Presents with generalized lymphedema, lymphangiectasias (intestinal and pulmonary), facial anomalies (flat face, depressed nasal bridge, hypertelorism), and intellectual disability.

Table 104.2 Vascular malformations for which the molecular basis is known.

Continued

VASCULAR ANOMALIES FOR WHICH THE MOLECULAR BASIS IS KNOWN				
Vascular malformation	**Mode of inheritance**	**Mutated gene(s)**	**Type of mutation**	**Protein and function**
Hereditary lymphedema	AD	*GJC2*	Loss-of-function	Connexin 47 in gap junctions of lymphatic vessels
Oculo-dento-digital dysplasia	AD	*GJA1*	Missense	Connexin 43 in gap junctions
Lymphedema–choanal atresia	AR	*PTPN14*	Loss-of-function	Protein tyrosine phosphatase that may interact with VEGFR-3
Microcephaly, lymphedema, chorio-retinal dysplasia syndrome	AD	*KIF11*	Loss-of -function	Kinesin family member 11
Arteriopathy				
CADASIL	AD	*NOTCH3* *HTRA1*	Loss-of-function	Accumulation of NOTCH-3 protein in vascular smooth muscle cells; serine peptidase dysfunction

Table 104.2 Vascular malformations for which the molecular basis is known. Vascular malformations also occur in patients with the overgrowth syndromes presented in Table 104.5. Lymphedema is a feature of other disorders such as Noonan syndrome/other RASopathies (see Table 61.3), GATA2 deficiency (see Table 60.13), and a subset of hypohidrotic ectodermal dysplasia with immunodeficiency (see Ch. 63). *Aagenaes syndrome* is an autosomal recessive disorder linked to 15q that manifests with infantile cholestasis and childhood-onset lymphedema. Unless otherwise noted, the mosaic conditions above are characterized by a heterozygous somatic mutation in lesional tissue. Some AD conditions (e.g. cutaneous and mucosal venous malformations, glomuvenous malformations) feature a "second hit" mutation in lesional tissue. AD, autosomal dominant; *ADAMTS3*, ADAM metallopeptidase with thrombospondin type 1 motif 3; AR, autosomal recessive; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; *CELSR1*, cadherin EGF LAG seven-pass G-type receptor 1; *FLT4*, fms-related tyrosine kinase 4; *GDF2*, growth differentiation factor 2; *PIK3CA*, phosphatidylinositol-4,5-biphosphate 3-kinase catalytic subunit α; MAPK, mitogen-activated protein kinase; *MAP2K1*, MAPK kinase 1; *MAP3K3*, MAPK kinase kinase kinase 3; mTOR, mechanistic target of rapamycin; *PDCD10*, programmed cell death 10; *PIEZO1*, piezo-type mechanosensitive ion channel component 1; TGF-β, transforming growth factor-β; VEGF(R), vascular endothelial growth factor (receptor); VM, venous malformation.

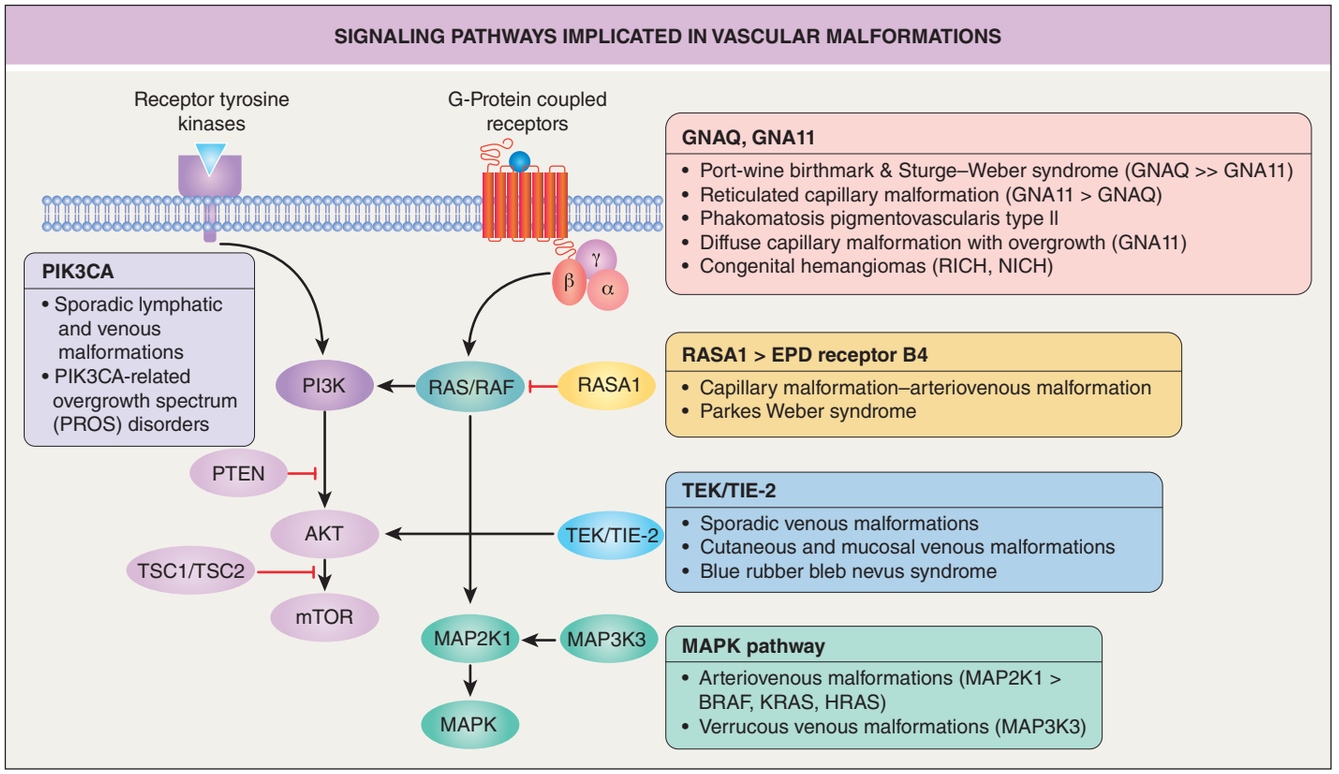

Fig. 104.2 Signaling pathways implicated in vascular malformations. MAPK, mitogen-activated protein kinase; *MAP2K1*, MAPK kinase 1; *MAP3K3*, MAPK kinase kinase kinase 3; mTOR, mechanistic target of rapamycin; *PIK3CA*, phosphatidylinositol-4,5-biphosphate 3-kinase catalytic subunit α.

TEK mutations that cause constitutive activation of the endothelial cell tyrosine kinase receptor TIE-2 are found in lesional tissue (but not the peripheral blood) in approximately half of patients with sporadic VM. Individuals with blue rubber bleb nevus syndrome and a subset of those with sporadic VMs (multifocal > unifocal lesions) have *two somatic* gain-of-function *TEK* mutations within the *same* allele (double [*cis*])[6,7]. While familial cutaneous and mucosal VMs (VMCM) result from a *germline* gain-of-function *TEK* mutation, a second-hit mutation in the same or other *TEK* allele has been documented in a few individuals[6,7]. Advances in our understanding of the pathogenesis of vascular malformations has provided the basis for targeted treatment strategies[4,6–9].

CLINICAL FEATURES

Most vascular malformations can be correctly categorized based on their clinical features. This helps in selection of the most appropriate investigative tools (Table 104.3), avoiding redundant and unnecessary diagnostic imaging procedures. In addition, genetic analysis may be of utility in patients with vascular malformations associated with clinical manifestations that may potentially benefit from targeted systemic therapy as well as those with familial transmission. A sample of affected tissue is typically required for genetic testing in conditions caused by a somatic mutation, and massively parallel/next-generation sequencing

INVESTIGATIVE TOOLS FOR VASCULAR MALFORMATIONS				
Tool	**Vascular lesion**			
	Capillary malformation	**Lymphatic malformation**	**Venous malformation**	**Arteriovenous malformation**
Ultrasonography	+/–	++++	+++	++++
CT with contrast	–	++	++	++
MRI with gadolinium	–*	+++ (no gadolinium enhancement)	++++ (gadolinium enhancement)	+++
3D-angio CT or 3D-angio MRI	–	–	++	++++
Dynamic magnetic resonance lymphangiography (MRL)	–	++++	–	–
Arteriography	–	–	–	++++
Phlebography	–	–	+/–	–
Lymphography (isotopic)	–	+/–	–	–
Biopsy	+/–	+/–	–	–

*See text for recommended imaging to evaluate for possible Sturge–Weber syndrome (SWS).

Table 104.3 Investigative tools for vascular malformations. Multidetector CT and 3-dimensional MR venography may help to determine the extent of involvement in patients with Klippel–Trenaunay syndrome. A larger number of +'s indicates increased utility. CT, computed tomography; MRI, magnetic resonance imaging.

(NGS) panels are available for overgrowth syndromes and lymphedema (see Appendix).

Capillary Malformations

The ISSVA CM category includes nevus simplex, PWBs, reticulate CMs, CMTC, CM of CM-AVM, and telangiectasias[3]; additional clinical variants such as "geographic" and "diffuse" CMs have also been described[10]. Occasionally, CMs represent the most obvious sign of a complex syndrome. An approach to the evaluation of a patient with a presumed CM of the head and neck region is shown in Fig. 104.3.

Nevus simplex

Nevus simplex (salmon patch) is a very common congenital vascular birthmark evident in 30%–80% of neonates[11]. Although classified as a CM by the ISSVA, nevus simplex is thought to represent remnants of the fetal circulation rather than a mosaic condition due to a somatic mutation. These pink-to-red macules and patches with somewhat indistinct borders have characteristic locations on the forehead/glabella in a V-shape ("angel kiss"), eyelids, philtrum, occiput, nape ("stork bite"), and lumbosacral area (Fig. 104.4A,B). They often become more prominent with crying or vigorous activity. The term *nevus simplex complex* has been proposed for extensive lesions[12].

Facial nevus simplex tends to fade spontaneously between 1 and 3 years of age, but extrafacial and some glabellar lesions are more persistent. During infancy, eczematous dermatitis may preferentially or solely develop within a nevus simplex. The vast majority of children with a nevus simplex do not have associated abnormalities; however, a prominent or persistent midfacial nevus simplex is a feature of several syndromes, including Beckwith–Wiedemann and megalencephaly–CM. Although there has been controversy regarding whether a lumbosacral nevus simplex represents a possible sign of occult spinal dysraphism, most authors do not recommend spinal imaging in the absence of additional cutaneous findings (see Ch. 64)[13,14].

Port-wine birthmark (PWB) and variants

A somatic activating mutation in *GNAQ* (Q-class G protein subunit α) or, occasionally, *GNA11* (G protein subunit α 11) in affected skin (especially the blood vessels) ± regional extracutaneous tissues (e.g. brain, eyes) underlies isolated PWBs and Sturge–Weber syndrome (SWS)[15]. These mutations (most often of R183 residues) lead to increased mitogen-activated protein kinase (MAPK) signaling (see Fig. 104.2), which results in increased cell proliferation and decreased apoptosis[16].

PWBs typically present at birth as well-demarcated, bright or deep red macules and patches, with their color resembling that of port wine. Fainter red or pink birthmarks have been termed "*nevus roseus*" because their color resembles that of rosé wine[17]. Some light red–pink birthmarks are not solid but finely reticulated, often with a blotchy appearance and indistinct borders; these *reticulated CMs* are distinct from CMTC, which has a more well-defined, purplish net- or tram track-like pattern and is often associated with cutaneous atrophy. Reticulated CMs can be due to somatic gain-of-function mutations in *GNA11* and, less commonly, *GNAQ* or *PIK3CA*[15,18].

The growth of PWBs is commensurate with the child's growth. They can be localized, have a segmental pattern, or be multifocal and widespread. The distribution patterns of facial PWBs are thought to reflect the prominences that form during embryonic craniofacial development and their associated vasculature. Because these regions resemble the dermatomes of the trigeminal nerve, the following areas were classically recognized: V1 – forehead and upper eyelid; V2 – maxillary region (Fig. 104.4C); and V3 – mandibular region.

Over time, PWBs, especially those in the maxillary and mandibular areas, often develop a deeper red hue, changing from pinkish-red at birth to purplish-red by adulthood. Affected skin may thicken and become nodular (Fig. 104.5), and superimposed pyogenic granulomas occasionally appear. In a study of 173 patients with PWBs, thickening was observed in 11% (median age 32 years), nodularity in 24% (median age 44 years), and both in 6% (median age 45 years)[19]. These changes are rarely observed in the lighter "nevus roseus" or in PWBs located on the trunk and limbs. Overgrowth of the soft tissues and facial bones underlying a PWB can also occur, creating problems such as an open-bite deformity. Affected gums and lips may enlarge, potentially resulting in epulides, gingival bleeding, macrocheilia, and lip incompetence. As with nevus simplex, eczematous dermatitis may have a predilection for areas of skin affected by the PWB.

PWBs are congenital in the vast majority of patients. However, *acquired port wine-like lesions* have been described in adolescents and adults, and onset of such lesions may be precipitated by trauma[20]. Of note, early morphea, especially the linear variant, occasionally presents with a red vascular patch that mimics an acquired *port wine-like lesion*[21].

A CM can be admixed with a network of blanched macules representing a nevus anemicus (*nevus vascularis mixtus*; Fig. 104.6). The association of a CM with dermal melanocytosis (Fig. 104.7) or a nevus spilus (speckled lentiginous nevus) is referred to as *phakomatosis pigmentovascularis (PPV)* (Table 104.4)[22,23]. Patients with PPV type II (*cesioflammea*) have the same activating mutation, either in *GNAQ* or *GNA11*, in both the PWB and dermal melanocytosis. Likewise, mosaic mutations in *PTPN11* (protein tyrosine phosphatase nonreceptor type 11) have been found to underlie both the nevus roseus and nevus spilus in patients with PPV type III[23a]. Hypertension due to renal artery stenosis has been described in patients with extensive PWBs[15].

Sturge–Weber syndrome

SWS is a sporadic neurologic disorder in which a facial PWB is associated with ipsilateral leptomeningeal/brain and ocular vascular anomalies. Although all three components constitute a diagnosis of "complete" SWS, patients with a PWB plus CNS involvement alone are also typically diagnosed as having SWS, whereas those with a facial PWB

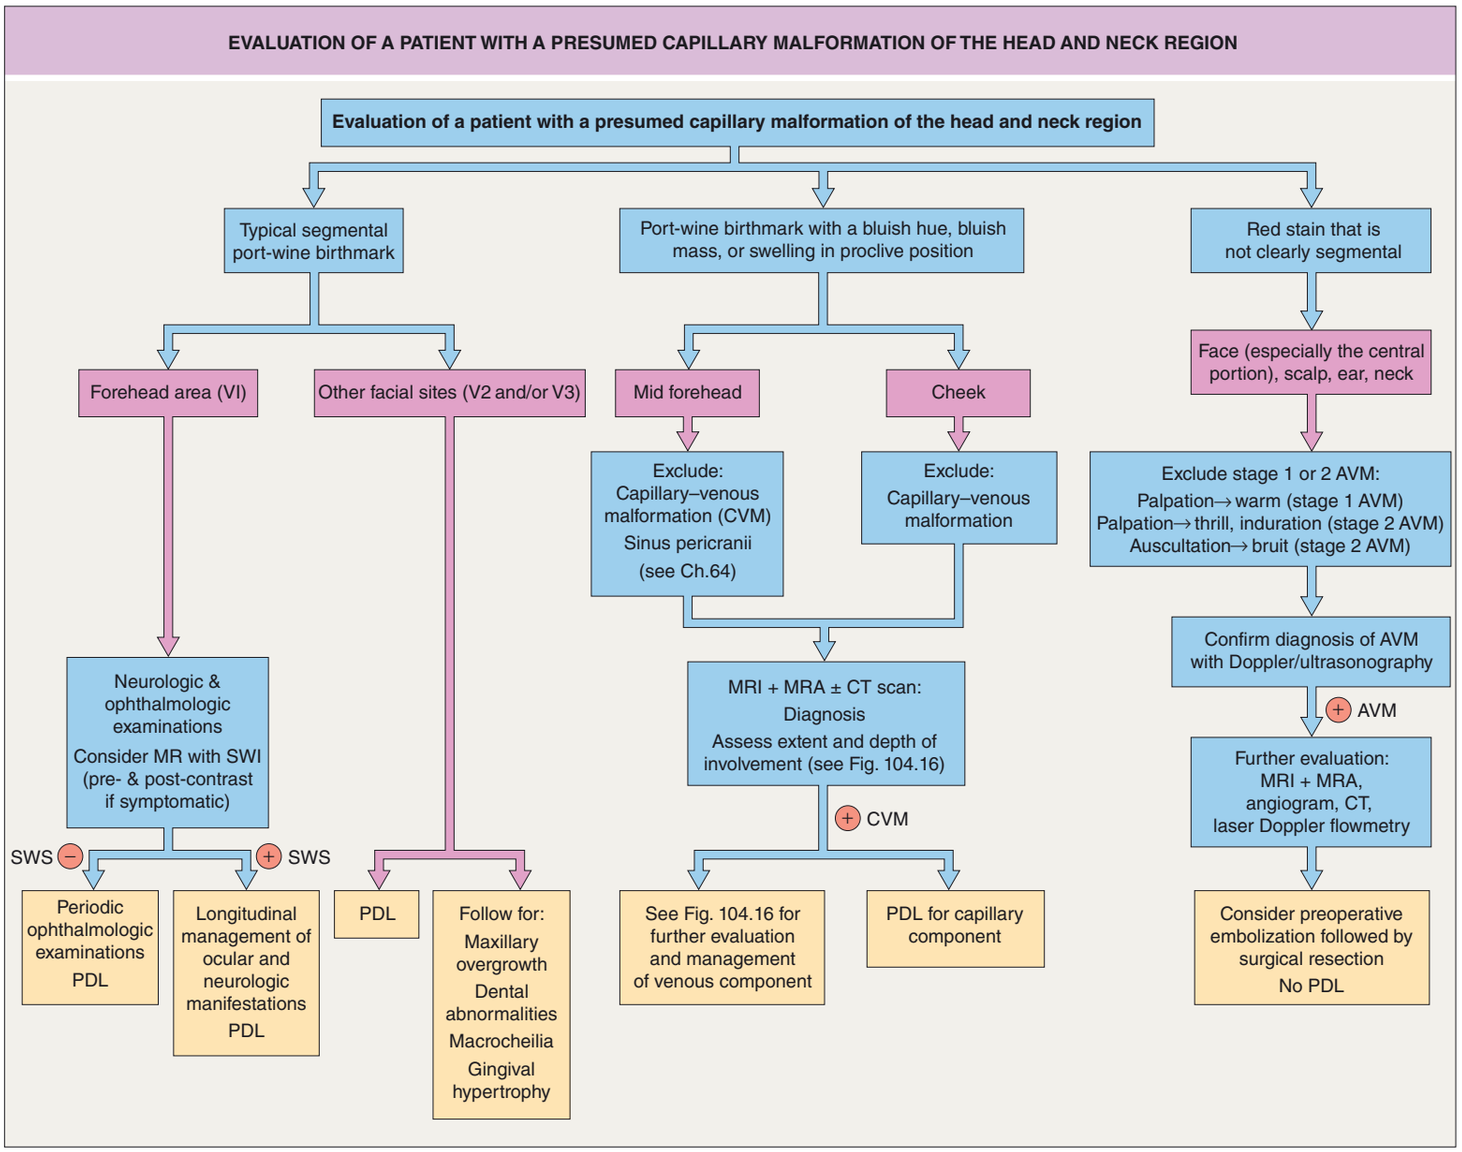

Fig. 104.3 Evaluation of a patient with a presumed capillary malformation of the head and neck region. AVM, arteriovenous malformation; CT, computed tomography; PDL, flashlamp-pumped pulsed dye laser; MRA, magnetic resonance arteriography; MRI, magnetic resonance imaging; SWI, susceptibility-weighted imaging; SWS, Sturge–Weber syndrome.

Fig. 104.4 Nevus simplex versus port-wine birthmark (PWB). A Involvement of the central face in a symmetric pattern is typical of a nevus simplex (salmon patch); such lesions usually fade over the first few years of life but are sometimes misdiagnosed as a PWB. **B** Nevus simplex in the nape area ("stork bites") tend to be more persistent. **C** In this young infant with a PWB in the maxillary region, the affected skin is smooth. This lesion will be persistent. *B, Courtesy Julie V. Schaffer, MD.*

Fig. 104.5 Facial port-wine birthmark in the maxillary region in an adult. Hyperplasia and nodularity are prominent. *Courtesy Pablo Boixeda, MD.*

plus ocular involvement alone are often classified separately. The brain and/or ocular manifestations of SWS rarely occur without an associated PWB. Mosaicism due to a somatic activating mutation in *GNAQ* (or rarely *GNA11*) represents the cause of both SWS and non-syndromic facial PWBs (see above), with the former resulting from a mutation that arises earlier in development and affects the vasculature of the eye and CNS as well as the skin[16].

Facial PWBs associated with SWS were classically considered to involve the V1 region, which includes the forehead and upper eyelid[1], often with extension unilaterally or bilaterally over more of the face (Fig. 104.8). More recent studies have shown that involvement of the "forehead area", which includes the upper eyelid and is delineated inferiorly by a line drawn from the outer canthus to the top of the ear, represents the best clinical predictor for SWS (Fig. 104.9)[24]. This risk area encompasses portions of V2/V3 as well as V1 and is thought to correspond with the embryonic *frontonasal prominence*[25]. The latter includes neural crest-derived vasculature and develops in conjunction with the forebrain, which gives rise to the cerebral cortex and optic vesicles. A somatic *GNAQ* mutation occurring in the frontonasal area prior to migration of embryonic neural crest derivatives, which also include the leptomeninges and choroid, may therefore explain the forehead location of CMs associated with cerebral and ocular vascular malformations. Some SWS patients also have PWBs on the extremities and trunk. In addition, SWS occasionally occurs in the setting of PPV type II (see Table 104.4).

Fig. 104.6 Port-wine birthmark intermingled with a nevus anemicus on the shoulder. This man had phakomatosis pigmentovascularis type IIb, with additional features including an upper facial port-wine birthmark, Sturge–Weber syndrome, and extensive dermal melanocytosis.

Fig. 104.7 Phakomatosis pigmentovascularis type IIa (cesioflammea). A large port-wine birthmark and extensive dermal melanocytosis are seen.

PHAKOMATOSIS PIGMENTOVASCULARIS (PPV)				
Type	**Descriptive name**	**Proportion of reported cases**	**Major cutaneous components**	**Other reported cutaneous components**
Ia/b	*	<5%*	Epidermal nevus + **PWB**	
IIa/b	Phakomatosis cesioflammea	75%	Dermal melanocytosis (aberrant Mongolian spots) + **PWB**	Nevus anemicus, hypotrichosis, lipohypoplasia, hypoplastic nails
IIIa/b	Phakomatosis spilorosea or melanorosea	10%	Nevus spilus (macular type) + **light red–pink CM ("nevus roseus")**	Nevus anemicus, lymphedema, hypotrichosis
IVa/b	Phakomatosis melanovascularis or unclassifiable	10%	Café-au-lait macule + **CM** Variable, sometimes with features of II + III or II + V	Nevus anemicus, nevoid hyper- or hypopigmentation, nevus sebaceus
Va/b	Phakomatosis cesiomarmorata	<5%	Dermal melanocytosis + **cutis marmorata telangiectatica congenita**	

*Existence as a type of PPV has been challenged considering that epidermal nevi are not melanocytic lesions; epidermal nevi can occur together with vascular malformations in Proteus, PTEN hamartoma tumor, and CLOVES syndromes (see Table 104.5), which are not generally considered as PPV.

Table 104.4 Phakomatosis pigmentovascularis (PPV). a = cutaneous abnormalities only; b = cutaneous and extracutaneous abnormalities (e.g. of Sturge–Weber syndrome, Klippel–Trenaunay syndrome, or ocular, as well as nevus of Ota). Vascular lesions are in bold. CM, capillary malformation; PWB, port-wine birthmark.

Fig. 104.8 Infant at risk for Sturge–Weber syndrome (SWS). The port-wine birthmark covers most of the left side of the face.

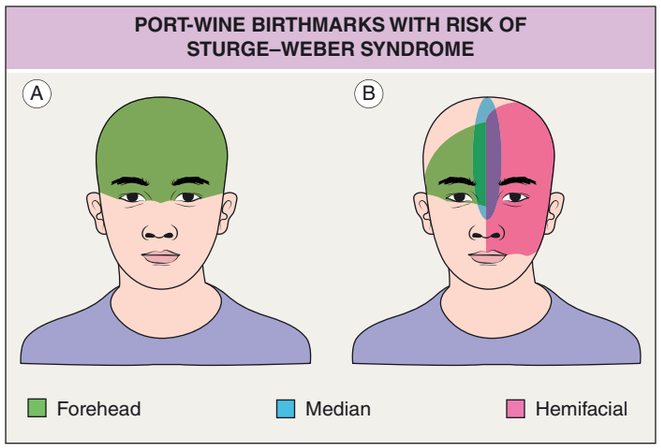

Fig. 104.9 Port-wine birthmarks (PWBs) with risk of Sturge–Weber syndrome (SWS). Involvement of the "forehead area" (**A**), which includes the upper eyelids and is delineated inferiorly by a line drawn from the outer canthus to the top of the ear, is associated with risk of SWS. Hemifacial and median forehead (**B**) as well as bilateral forehead lesions are associated with highest risk.

Ocular involvement in SWS can result in enlarged venous vessels affecting the conjunctiva, episclera, retina, and/or choroid. The most common ocular manifestation is glaucoma, which affects 30%–60% of patients with a PWB on the forehead and/or eyelids; choroidal hemorrhage and retinal detachment are rare complications. Ocular involvement is more frequent when the PWB affects both the V1 and V2 regions. Glaucoma may be detected at birth because of buphthalmos (enlargement of the globe), and acute glaucoma with a cloudy cornea can be an infantile emergency. Usually, however, increased eye pressure develops slowly. As a result, glaucoma may become evident during late childhood, adolescence, or even adulthood. Thus, periodic lifelong assessment of visual function and pressure of both eyes, as contralateral glaucoma occasionally occurs, is mandatory.

Neurologic symptoms can result from hypoperfusion of the ipsilateral brain due to CVMs within the pia mater, absence of superficial cortical veins, and dilated deep draining veins. Over time, chronic hypoxia may lead to cerebral hemiatrophy and calcifications, with the occipital region being the most frequent location. The most common neurologic manifestation is seizures, which are most often focal motor, either affecting the side of the body opposite to the vascular anomaly or generalized. The seizures typically develop in the first two years of life and affect ≥75% of children with SWS[26]; they may be difficult to control with anticonvulsants, especially early on. Additional findings can include stroke-like episodes with contralateral hemiparesis or hemiplegia; developmental delay affecting motor and cognitive skills; emotional and behavioral problems; attention deficit disorder; and migraine headaches. Endocrine dysfunction such as central hypothyroidism and growth hormone deficiency may also occur, even in patients with normal neuroimaging[27].

The risk of ocular and/or neurologic manifestations of SWS is ~25%–50% when a unilateral PWB affects most of the forehead area; it is lower when the PWB involves a smaller portion of this area and higher (>50%) for a hemifacial lesion or a bilateral PWB covering the forehead and both upper eyelids[25,28,29] (see Fig. 104.9). One prospective study also found an increased risk of SWS in patients with PWBs on the median forehead (a distribution reminiscent of nevus simplex), whereas linear PWBs on the forehead were not associated with SWS[25].

A recent consensus statement on the management of SWS recommended referral of any infant or child with a high-risk facial PWB (see above) to a pediatric neurologist and ophthalmologist for baseline evaluation and periodic follow-up (see Fig. 104.3)[30]. In newborns and infants with a high-risk PWB but no history of seizures or neurologic symptoms, neuroimaging should be considered in selected individuals (e.g. with an extensive bilateral facial PWB or if presymptomatic treatment is contemplated) rather than on a routine basis[29]. In such patients, a non-sedated, non-contrast screening MRI including T1 and T2 (± fluid attenuation inversion recovery [FLAIR]) and susceptibility-weighted imaging (SWI) ± diffusion-weighted imaging (DWI) is recommended. These modalities can demonstrate early leptomeningeal changes with enlargement of transmedullary and periventricular veins; although sensitivity in asymptomatic patients is limited in the first few months of life, leptomeningeal involvement can be excluded by ≥1 year of age. In patients with neurologic symptoms, pre- and post-contrast MRI that includes high-resolution volumetric sequences in addition to SWI and post-contrast FLAIR imaging is recommended[29]. Gyriform calcifications and atrophy develop during childhood in SWS patients and are visible by CT scans and other neuroimaging modalities.

Early diagnosis of SWS is important, as prophylactic aspirin administration may reduce the frequency of stroke-like episodes and seizures[31,32]. Some infants and children with SWS have cognitive deficits that are more severe than anticipated based upon their limited cortical involvement on conventional MRI studies. Functional cerebral imaging, e.g. SPECT (single photon emission computed tomography) that evaluates regional cerebral blood flow or PET (positron emission tomography) that demonstrates metabolism of glucose, can provide additional prognostic information. Quantitative electroencephalography (EEG) may also aid in screening for brain involvement in asymptomatic infants at risk of SWS[33].

Capillary malformations associated with overgrowth, including the PIK3CA-related overgrowth spectrum (PROS)

PWBs and reticulated CMs on the trunk and extremities may be associated with regional overgrowth and other syndromic features (Table 104.5)[34]. Mosaicism for mutations that result in activation of the phosphatidylinositol 3-kinase (PI3K)/AKT pathway have been found to underlie several of these conditions (see Figs. 104.2 and 113.1), including those in the *PIK3CA*-related overgrowth spectrum (PROS). The various terms and eponyms used for overgrowth syndromes are likely to be refined as the molecular etiologies are further clarified.

Diffuse capillary malformation with overgrowth

Diffuse CM with overgrowth (DCMO) is a term proposed for a widespread reticulated CM associated with proportional soft tissue and/or bony hypertrophy (Fig. 104.10A)[35]. Unlike Klippel–Trenaunay syndrome (KTS), the overgrowth is not progressive and does not correlate with the location of the CM; in addition, although some DCMO patients have clinically prominent subcutaneous veins, they do not have a true VM or LM. In contrast to megalencephaly–CM, DCMO patients are normocephalic and do not have associated neurologic abnormalities. The pale red–pink, reticulated CM in DCMO involves multiple contiguous anatomic regions, often with a sharp midline demarcation on the anterior trunk, and may lighten over the first few months of life; approximately half of patients have additional areas with a confluent CM, usually in acral sites. Somatic activating mutations in *GNA11* and *PIK3CA* (phosphatidylinositol-4,5-biphosphate 3-kinase catalytic subunit α) have been reported to cause diffuse CM associated with mild and more significant overgrowth, respectively[15,36,37].

†Surveillance with abdominal ultrasound every 3–4 months until 8 years of age is recommended.

Table 104.5 Overgrowth syndromes with vascular malformations. PTEN hamartoma tumor syndrome (PHTS) includes Cowden and Bannayan–Riley–Ruvalcaba syndromes as well as SOLAMEN syndrome – *s*egmental *o*vergrowth, *l*ipomatosis, *a*rteriovenous *m*alformation, and *e*pidermal *n*evus (see Ch. 63). Additional entities in the *PIK3CA*-related overgrowth spectrum that have dermatologic manifestations include hemihyperplasia multiple lipomatosis, fibroadipose hyperplasia, and isolated tissue overgrowth related to a LM, VM, or lipomatosis. CLOVES, *c*ongenital *l*ipomatous *o*vergrowth, *v*ascular anomalies, *e*pidermal nevi, *s*coliosis/*s*keletal abnormalities; DCMO, *d*iffuse *c*apillary *m*alformation with *o*vergrowth; GI, gastrointestinal; KTS, Klippel–Trenaunay syndrome; LM, lymphatic malformation; M-CM, megalencephaly–capillary malformation; *PIK3CA*, phosphatidylinositol-4,5-biphosphate 3-kinase catalytic subunit α; *PTEN*, phosphatase and tensin homolog; VM, venous malformation.

Klippel–Trenaunay syndrome

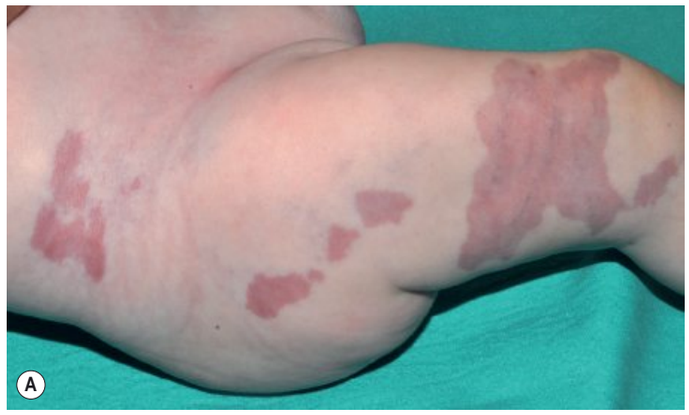
Klippel–Trenaunay syndrome (KTS) is currently defined by the triad of a PWB, anomalous veins (representing a VM), and progressive overgrowth of the affected extremity. However, this eponym has also been erroneously used for any capillary malformation associated with limb hypertrophy. The vascular malformation in KTS is a combined CVM or CLVM, which may be localized or more extensive. Somatic mutations in *PIK3CA* have been identified in CLVMs associated with KTS[38]. In addition, somatic mutations in *PIK3R1* (phosphoinositide-3-kinase regulatory subunit 1) have been identified in patients with C(L)VMs and overgrowth of the affected extremity[39] (see Table 104.5).

A well-demarcated, dark red-to-purple birthmark with irregular borders, referred to as a *geographic CM*, favors the lateral aspect of the thigh and is usually associated with a lymphatic component. Superimposed purple papules or hemorrhagic vesicles frequently develop and, especially if a persistent lateral marginal vein is evident on the outer aspect of the knee, a geographic CM predicts more severe, progressive overgrowth and a higher likelihood of complications such as cellulitis[40,41] (Fig. 104.11A). Other children have pink-to-red, blotchy capillary birthmarks, which are associated with a better prognosis (Fig. 104.11B); in the absence of a VM, these patients may be more appropriately classified as having DCMO (see above) or simply a PWB with associated overgrowth. Foot and hand malformations in KTS are usually associated with deep venous system anomalies[42].

With lower extremity KTS, leg length discrepancy is progressive and requires ongoing orthopedic care. Lymphedema can lead to massive limb overgrowth and cellulitis. Some severely affected individuals have capillary–venous or lymphatic anomalies affecting the anogenital area, bladder, pelvis, retroperitoneum, and gastrointestinal tract that may bleed and result in anemia. A protein-losing enteropathy has also been described.

Like simple VMs (see below), the anomalous venous network in KTS may be associated with a chronic intravascular coagulopathy with high D-dimer and variably low fibrinogen levels. Patients with specific anomalies such as the presence of the lateral marginal vein, insufficient perforator veins, or intramuscular involvement are at higher risk of deep vein thrombosis, chronic thromboembolic pulmonary hypertension, and even life-threatening pulmonary embolism[40,43,44]. Prophylactic anticoagulation should be considered in KTS patients, especially those with evidence of hypercoagulability, when they have additional risk factors for venous thromboembolism such as surgery, trauma, or pregnancy[45]. Periodic echocardiography to assess for pulmonary hypertension has also been recommended by some authors[46].

Duplex ultrasonography is useful in investigating the vascular anomalies underlying KTS (see Table 104.3). Multidetector computed tomography (MDCT) and three-dimensional magnetic resonance venography (MRV) can help to determine the extent of musculoskeletal, thoracic, and abdominopelvic involvement as well as to characterize bone density changes, limb asymmetry, and the presence/patency of the deep venous system. Lymphoscintigraphy is rarely indicated. In patients with GI bleeding, colonoscopy or capsule endoscopy may reveal capillary patches, extensive dilated venous channels, and microcystic LM in the intestines.



CLOVES syndrome

This "Proteus-like" syndrome is characterized by asymmetric, progressive, infiltrative *c*ongenital *l*ipomatous *o*vergrowth that is typically truncal; *v*ascular anomalies; *e*pidermal nevi; *s*coliosis/*s*keletal abnormalities that include broad hands and feet; *s*pinal/paraspinal arteriovenous lesions; and *s*eizures[47,48]. CLOVES syndrome is caused by somatic activating mutations in *PIK3CA*[49], and the clinical findings overlap considerably with those of other forms of PROS, such as KTS and megalencephaly–CM (see Table 104.5)[50]. LMs are often present within the lipomatous truncal mass of CLOVES, with variable extension into the retroperitoneum and mediastinum. Well-demarcated, dark red, geographic CMs/CLMs usually overlie the mass, which is also typically associated with both aberrant superficial veins and phlebectasia of the thoracic or major central veins; the latter result in increased risk of pulmonary embolism, especially when undergoing surgery[51].

Fig. 104.10 Reticulated capillary malformations. A Diffuse capillary malformation with overgrowth. This normocephalic infant has an extensive reticulated capillary malformation involving the trunk, one arm, and both legs. **B** Megalencephaly–capillary malformation syndrome. This boy has hemihypertrophy of the side of the body opposite to the capillary malformation. *Courtesy Julie V. Schaffer, MD.*

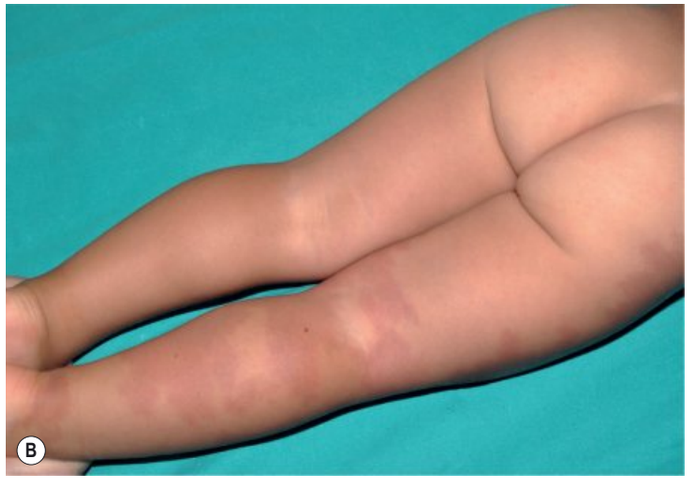


Fig. 104.11 Klippel–Trenaunay syndrome. A Darker red–purple, well-demarcated geographic capillary birthmark on the thigh associated with dilated veins and an enlarged lower limb. **B** Light red, blotchy capillary birthmark associated with enlargement of the lower extremity. Compared to blotchy CMs, geographic CMs are more likely to be associated with lymphatic malformations as well as tissue overgrowth.

Megalencephaly–capillary malformation

Megalencephaly–CM, which was previously known as macrocephaly–CM and macrocephaly–CMTC, features asymmetric overgrowth, progressive (hemi)megalencephaly, and a widespread reticulated CM, often with a characteristic midline demarcation on the abdomen (Fig. 104.10B). Additional features include a persistent midfacial nevus simplex, frontal bossing, neonatal hypotonia, developmental delay, syndactyly (especially 2nd–3rd toes), polydactyly, joint laxity, and hyperelastic skin[52]. Neuroimaging characteristically shows ventriculomegaly, acquired cerebellar tonsillar ectopia ± herniation, polymicrogyria, and cerebral asymmetry. Megalencephaly–CM is caused by postzygotic mutations in *PIK3CA*[53,54].

CLAPO syndrome

CLAPO syndrome features a *C*M of the lower lip and *L*M of the tongue and neck, together with *a*symmetry and *p*artial *o*vergrowth of the face and extremities[55]. The CM of the lower lip is always midline and symmetrical; it may affect the entire lip and usually extends to the adjacent skin (Fig. 104.12). The LM may not be apparent in affected neonates, becoming evident later in life. Somatic mutations in *PIK3CA* are responsible for CLAPO syndrome[56].

Proteus syndrome

Proteus syndrome is characterized by progressive overgrowth over time and a mosaic distribution of anomalies (see Ch. 62)[57]. It is caused by somatic activating mutations in *AKT1*, which encodes a protein that positively regulates cellular growth and proliferation[58]. Manifestations are minimal at birth, typically becoming apparent at 6–18 months of age. Asymmetric, disproportionate bone overgrowth leads to consequences such as megaspondylodysplasia with scoliosis, knee deformities, asymmetric macrodactyly, and cranial hyperostosis. In addition to vascular malformations with variable capillary, venous, and lymphatic components, cutaneous features include highly characteristic cerebriform connective tissue nevi of the palms and soles (Fig. 104.13), epidermal nevi, lipomatous overgrowth, and regional absence of fat. Bullous pulmonary degeneration, specific neoplasms (e.g. ovarian cystadenoma, parotid monomorphic adenoma), and a facial phenotype with ptosis and anteverted nares represent other findings. Deep vein thrombosis results in premature death in up to 20% of patients[59]. The differential diagnosis of Proteus syndrome includes PROS as well as PTEN hamartoma tumor syndrome (see Table 104.5).

Cutis marmorata telangiectatica congenita

CMTC is characterized by a dark purple to red–purple, broad reticulated vascular pattern intermingled with telangiectasias and occasionally prominent veins (Fig. 104.14). It commonly affects one or more limbs and the corresponding quadrant(s) of the trunk. Unlike physiologic cutis marmorata, CMTC persists upon warming an affected infant. Atrophic depressions may be evident within the net-like pattern (see Fig. 104.14C), especially over joints, and can result in ulceration and scarring. CMTC often lightens after the first year of life, but some residual violaceous network is common[1,60]. Up to 50% of patients have hypoplasia (girth > length) of the affected limb(s) or additional vascular

malformations. Other skeletal (e.g. syndactyly), ocular (e.g. glaucoma), and neurologic defects have been reported, especially in patients with generalized CMTC; however, these associations may reflect misdiagnosis of CM-associated syndromes as CMTC. *Adams–Oliver syndrome* features CMTC or a reticulated CM together with distal transverse limb defects, variable cardiac malformations, and scalp/skull defects (aplasia cutis congenita; see Ch. 64).

A somatic *AKT3* mutation has been identified in patients with CMs reminiscent of CMTC but more sharply delineated, linear, and located on the lateral side of the trunk or an extremity[61]. Associated soft tissue atrophy and variable megalencephaly were also observed. Lastly, relatively short-lived skin findings resembling CMTC have been observed in patients with neonatal lupus.

Fig. 104.12 CLAPO syndrome. A Capillary malformation on the lower lip and chin, with swelling of the neck due to a lymphatic malformation. **B** Microcystic lymphatic malformation on the tongue. *A, Courtesy Julie V. Schaffer, MD.*

Telangiectasias

Telangiectasias are dilated capillary-type blood vessels (see Ch. 106). These punctate, stellate, or linear red lesions may have a localized, segmental, or widespread distribution. In some disorders, they tend to affect particular anatomic sites. For example, *angioma serpiginosum* features clusters of tiny punctate telangiectasias in serpiginous patterns with a predilection for the extremities, whereas *unilateral nevoid telangiectasia* usually refers to a segmental configuration favoring the face, neck, chest, and arms. The lesions of *hereditary benign telangiectasia* (HBT) may mimic those of hereditary hemorrhagic telangiectasia

Fig. 104.13 Plantar cerebriform connective tissue nevus in a man with Proteus syndrome.

Fig. 104.14 Cutis marmorata telangiectatica congenita (CMTC). Note the hypoplasia of the affected limb (**A**,**B**) and associated cutaneous atrophy leading to a depression (**C**). The color of the broad vascular network can be red–purple (**A**,**C**) or, as seen in this infant of Caribbean descent, brownish-purple (**B**). *C, Courtesy Richard Antaya, MD.*

(HHT; see below), but the former is not associated with epistaxis or visceral hemorrhage. In addition, some kindreds initially reported as having HBT actually had capillary malformation–arteriovenous malformation (CM-AVM; see below)[62].

Hereditary hemorrhagic telangiectasia

Hereditary hemorrhagic telangiectasia (HHT; Osler–Weber–Rendu disease) is an autosomal dominant disorder characterized by visceral AVMs and mucocutaneous telangiectasias, which actually represent small AVMs; these AVMs have a propensity to bleed. Phenotypes vary considerably, even within a given family[63–65]. The first manifestation of HHT is usually epistaxis during childhood or adolescence, beginning at a mean age of 12 years[65]. Multiple telangiectasias of the skin and oral mucosa usually appear after puberty and may not be evident until adulthood, with ~50% of affected children <10 years of age having at least one evident telangiectasia[66]. The telangiectasias most commonly affect the face, lips, tongue, palms and fingers, including periungual areas and the nail bed. These dark red lesions are either round, slightly elevated papules or ill-defined, stellate macules.

It is important to screen individuals suspected to have HHT for visceral AVMs (Table 104.6). In particular, AVMs in the lungs and brain are often asymptomatic prior to the sudden development of life-threatening complications[63–65]. Pulmonary AVMs can result in hypoxemia, hemorrhage, and cerebral abscesses or strokes due to paradoxical emboli. Transcatheter embolotherapy of pulmonary AVMs is recommended[65]. Lethal intracranial hemorrhage from cerebral AVMs can occur as early as infancy[64], and acute paraplegia due to spinal AVMs has also been described in children with HHT. Treatment strategies for AVMs of the CNS include embolization, microsurgery, and stereotactic radiation. Gastrointestinal or (less often) genitourinary tract bleeding typically occurs in mid adulthood and often presents as iron deficiency anemia. Lastly, hepatic AVMs may lead to high-output heart failure, portal hypertension, and biliary disease.

Classic HHT is due to heterozygous mutations in *ENG* (endoglin; HHT1) or *ACVRL1* (activin A receptor-like type 1, also known as *ALK1*; HHT2). Both genes encode glycoprotein components of endothelial transforming growth factor-β (TGF-β) receptors. A genotype–phenotype correlation has been established, with a higher risk of pulmonary (especially in women) and cerebral AVMs in HHT1 and a higher risk of liver AVMs in HHT2. A few reported patients with HHT-like manifestations but somewhat larger and more widespread cutaneous telangiectasias/AVMs had underlying mutations in *GDF2* (growth differentiation factor 2), which encodes a protein that binds to endoglin and ACVRL1. In addition, mutations in *SMAD4*, which encodes a protein that transmits signals from the TGF-β receptor, underlie a disorder that features juvenile gastrointestinal polyposis and HHT. Genetic testing can establish the diagnosis of HHT in children and young adults who do not yet meet clinical criteria (see Table 104.6). Information on medical centers and laboratories that specialize in HHT is available at curehht.org.

Ataxia–telangiectasia

Ataxia–telangiectasia is an autosomal recessive disorder that occurs in approximately 1 in 40000 births and is due to mutations in *ATM* (see Ch. 60). Ataxia is the initial symptom and usually presents in toddlers. Telangiectasias typically begin to appear at 4–6 years of age, primarily on the conjunctivae, face, and ears. Immunoglobulin deficiencies (e.g. IgA, IgG) and defective cell-mediated immunity explain the frequent sinopulmonary infections. Patients are at high risk for the development of lymphoma and leukemia. Elevated levels of circulating α-fetoprotein are found in affected individuals. Heterozygote carriers of a mutated *ATM* gene also have an increased risk of breast cancer and hematologic malignancies.

STUDIES RECOMMENDED TO SCREEN FOR SYSTEMIC INVOLVEMENT AND ASSIST IN THE DIAGNOSIS OF HEREDITARY HEMORRHAGIC TELANGIECTASIA (HHT)

Study	Indication(s)	Purpose of study	Intervention(s) if positive study
Transthoracic contrast echocardiography (bubble study)*	Definite or suspected HHT†	Detect **pulmonary** AVMs, which lead to right-to-left shunting (15%–50% of HHT patients)	• Transcatheter embolotherapy in all adults and in children with AVMs that are large or associated with hypoxemia • Antibiotic prophylaxis for procedures with risk of bacteremia, precautions to avoid air bubbles during intravenous access, and avoidance of SCUBA diving
Brain MRI with and without contrast‡	Definite or suspected HHT†	Detect **cerebral** AVMs and other vascular malformations (~25% of HHT patients)	• Referral to a center with neurovascular expertise for consideration of invasive testing and treatment
Annual hemoglobin and hematocrit testing	Adult HHT patients and children with recurrent bleeding and/or symptoms of anemia	Detect substantial bleeding related to **gastrointestinal** (GI) AVMs (~25% of HHT patients; less common before age 40 years)	• Esophagogastroduodenoscopy if anemia disproportionate to epistaxis • Iron supplementation • Treatment considerations for GI bleeding include endoscopic argon plasma coagulation, antifibrinolytics, and bevacizumab
Doppler ultrasonography, multiphase contrast CT, or contrast MRI of liver	(1) Adults with definite or suspected HHT† (2) HHT patients with signs/symptoms of heart failure or hepatobiliary disease	Detect **hepatic** AVMs (present in 30%–80% but symptomatic in <10% of HHT patients)	• Additional testing and treatment directed by findings and symptoms; liver biopsy should be avoided
Genetic analysis of *ENG* and *ACVRL1* ± *SMAD4* and/or *GDF2*	(1) "Index case" in HHT family (2) Patients at risk because of an affected first-degree relative¶ (e.g. who do not meet HHT criteria† or desire prenatal testing) (3) Patients clinically suspected to have HHT who do not meet criteria†	Detect underlying mutation in *ENG* or *ACVRL1* (~75% of HHT patients) > *SMAD4* (1%–3% of HHT patients) or *GDF2*	• Identification of a specific mutation facilitates genetic analysis in family members, including prenatal testing • Further screening for systemic involvement if diagnosis established

*If negative, repeat screening should be considered after puberty, within the 5 years preceding a planned pregnancy, after pregnancy, and otherwise every 5–10 years.
†Clinical diagnostic criteria are: spontaneous recurrent epistaxis, characteristic mucocutaneous telangiectasias, visceral telangiectasias/AVMs, and HHT in a first-degree relative; definite HHT if ≥3 criteria (met by ≥90% of HHT patients by age 40 years) and possible/suspected HHT if 1–2 criteria (especially for children and young adults).
‡Some authors have recommended omission of contrast in the initial MRI screening of children (especially those <2 years of age), and repeat screening with contrast at ~age 18 can be considered for children with negative studies; MRI screening for spinal AVFs can also be considered in children.
¶The causative mutation should first be identified in an "index case" from the family.

Table 104.6 Studies recommended to screen for systemic involvement and assist in the diagnosis of hereditary hemorrhagic telangiectasia (HHT). AVF, arteriovenous fistula; AVM, arteriovenous malformation; CT, computed tomography; GDF2, growth differentiation factor 2; MRI, magnetic resonance imaging. Based on the 2020 Second International HHT Guidelines[65].

Angiokeratomas

Angiokeratomas are currently categorized by ISSVA as a provisionally unclassified vascular anomaly. They consist of ectasias of dermal vessels plus an acanthotic and hyperkeratotic overlying epidermis (see Ch. 114). Immunohistochemical studies have shown that most angiokeratomas stain positively with lymphatic markers. These dark red-to-purple, papular vascular anomalies vary considerably in size, depth, and location[1]. The two most common types are *solitary papular angiokeratoma* and *angiokeratomas of the scrotum and vulva*. The former is often found on the lower extremity, and clinically it may be mistaken for a melanoma.

In *angiokeratoma circumscriptum*, clusters of ectasias form a plaque or linear array, usually on an extremity and often present at birth. A congenital hyperkeratotic vascular anomaly resembling angiokeratoma circumscriptum, but with a deeper dermal component consisting of thick-walled blood vessels larger than capillaries, may represent a *verrucous venulocapillary malformation* (*"verrucous hemangioma"*; see below and Ch. 114), which can be caused by somatic *MAP3K3* (mitogen-activated protein kinase kinase 3 gene) mutations. Grouped tiny lesions are also seen in *angiokeratoma of Mibelli*, which favors the toes, fingers, knees, and elbows.

Angiokeratoma corporis diffusum is characterized by more widespread lesions, often in a bathing trunk distribution; it can be associated with several hereditary lysosomal storage disorders such as *Fabry disease*, an X-linked recessive condition due to deficiency of α-galactosidase A, and *α-fucosidase deficiency* (see Table 63.7). Angiokeratoma-like lesions as well as microcystic lymphatic lesions may develop on the surface of geographic CMs in KTS (see above).

Venous Malformations

There are two major types of VMs: (1) common and familial VMs, together accounting for ~95% of VMs; and (2) glomuvenous malformations (GVMs). VMs may be confused with deep infantile hemangiomas or, when they involve a large portion of an extremity, KTS. Common and familial VMs are recognized clinically by their blue hue, softness, compressibility, and tendency to fill with dependency (Fig. 104.15). They are most often focal or segmental but may have a widespread distribution in forms with autosomal dominant inheritance. Somatic activating mutations in the *TEK* and *PIK3CA* genes account for ~50% and ~25% of sporadic common VMs, respectively; VMs due to mutations in the former gene are more likely to affect the surface of the skin[67]. VMs are best imaged using T2-weighted MRI (see Table 104.3)[1]. Fig. 104.16 provides an approach to the evaluation and management of patients with VMs.

Cephalic venous malformation

These lesions frequently lead to cosmetic and functional problems that worsen over time[1]. In addition to the skin, they may affect the lips, oral mucosa, and deeper structures such as muscles, the infratemporal fossa, and the orbit (see Fig. 104.16). Cephalic VMs expand when the head is in dependent position. With time, distortion of facial features often becomes conspicuous. Patients with parapharyngeal and laryngeal VMs should be monitored for sleep apnea, which can put them at risk of sudden death during sleep. Approximately 20% of patients with extensive cephalic VMs have defects of the underlying skull[1], which must be identified before performing sclerotherapy to avoid embolization through the defect.

Approximately 25% of patients with extensive cephalic VMs have developmental venous anomalies, previously referred to by the misnomer "venous angiomas", compared to <1% of the general population[1]. These are uncommon functional trajectories of venous drainage from the brain, usually with enlarged deep venous channels. Developmental venous anomalies may cause headaches, but they do not confer risk of cerebral hemorrhage and treatment is not needed. Of note, patients with cephalic VMs are not at increased risk of CCM-type cerebral vascular malformations (see below).

Trunk and limb venous malformation

VMs of the trunk and limbs often have cosmetic and functional consequences (see Fig. 104.17). VMs form spongy masses of saggy ectatic venous channels, which are easily emptied by elevating and massaging the affected region (see Fig. 104.16). However, permeation deep into muscles, joints, and bones is common[1]. Muscle involvement is associated with episodes of pain after motion and in the morning. The pain is linked to thromboses inside the low-flow channels, leading to phlebolith formation (round calcifications). Half of patients with large VMs have a chronic localized intravascular coagulopathy with elevated D-dimer levels[68,69]. Joint involvement usually becomes symptomatic before 10 years of age, with complications such as effusions and hemarthrosis. Limb VMs are commonly misdiagnosed as KTS, but undergrowth of a limb affected by a simple VM is more common than overgrowth.

Sinusoidal hemangioma

Sinusoidal "hemangioma" is thought to represent a distinctive type of venous malformation that typically presents in adults, especially

Fig. 104.15 Venous malformations (VMs). A Distortion of the tongue and lower lip has led to an open bite. **B** The skin and muscles of the entire arm are affected, with soft bluish nodules and obvious swelling in the dependent position. **C** This VM has a segmental distribution on the right trunk and involvement of the ipsilateral arm.

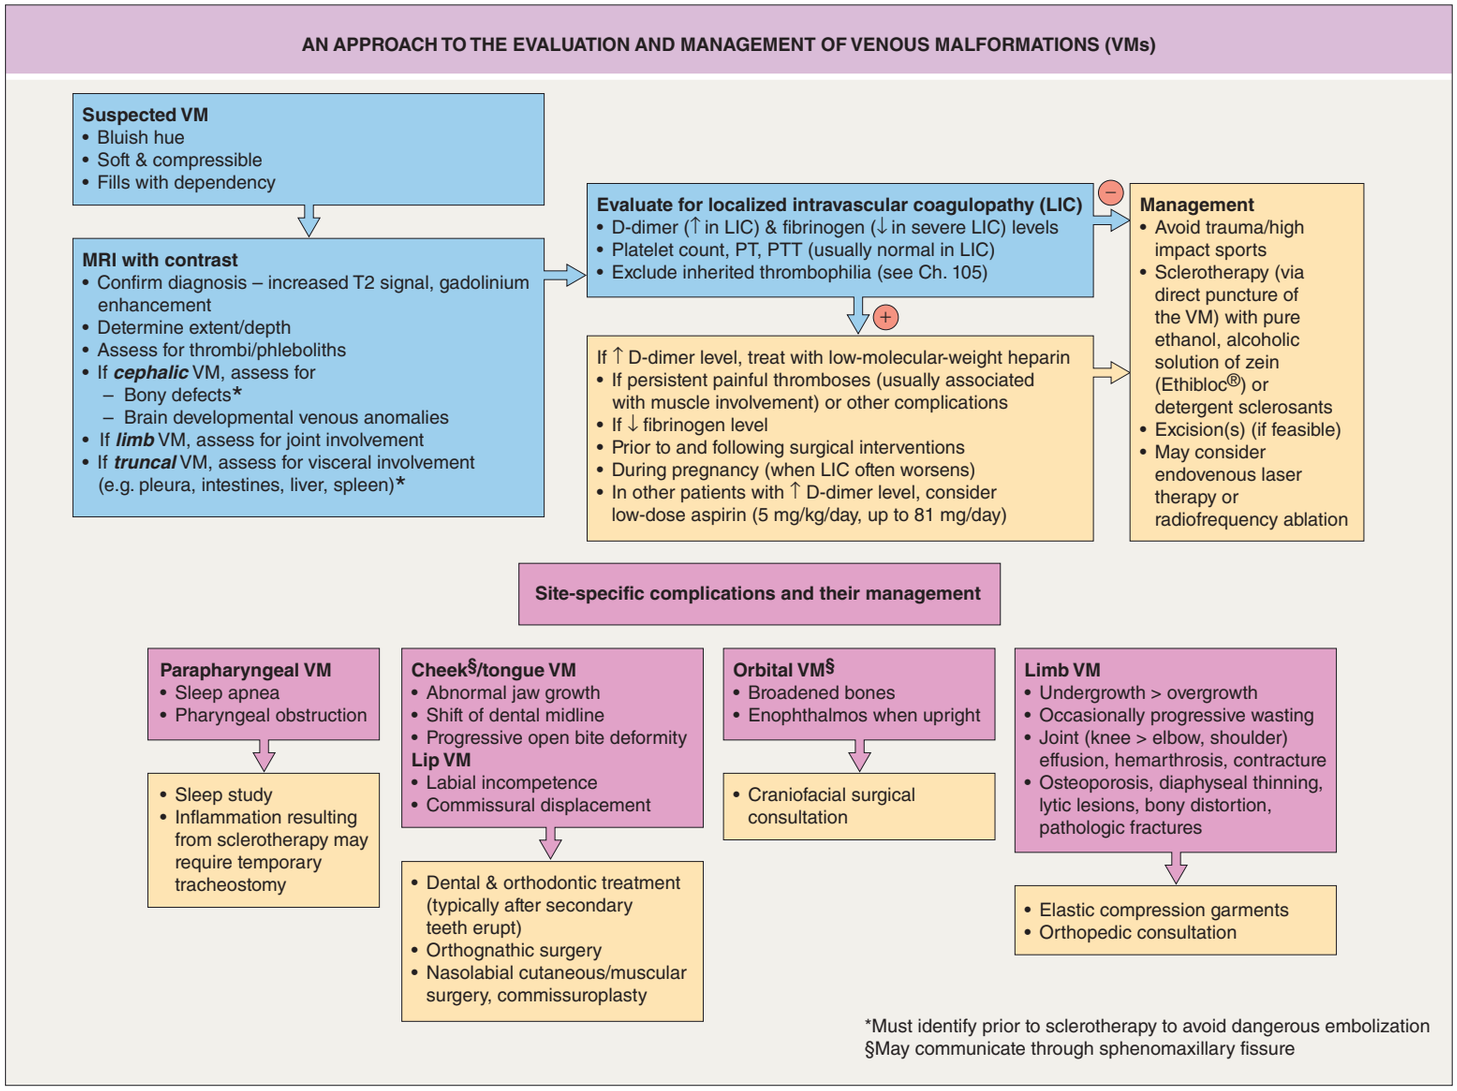

Fig. 104.16 An approach to the evaluation and management of venous malformations (VMs).

middle-aged women, with deep bluish nodules that favor the breast and extremities (see Ch. 114). Diagnosis is based on histologic features: well-circumscribed lobules composed of densely packed, large, thin-walled, blood-filled venous channels. Sinusoidal patterns have also been observed in congenital VMs.

Fibro-adipose vascular anomaly (FAVA)

FAVA presents between birth and early adulthood with a painful intramuscular mass, most often on the calf and in association with a contracture[70]. Histopathologically, there is a combination of fat, abnormal venous channels with perivascular fibrosis, and lymphoplasmacytic aggregates within atrophied skeletal muscle. Treatment options include excision or image-guided percutaneous cryoablation. Underlying somatic mutations in *PIK3CA* have been reported[38].

Verrucous venulocapillary malformation (verrucous VM, verrucous "hemangioma")

Verrucous VM (see Ch. 114) is included in the ISSVA classification as a subtype of VM, and an underlying somatic mutation in *MAP3K3* has been identified in a subset of these lesions (see Fig. 104.2)[71]. This malformation presents as a purple red birthmark, often with a segmental distribution on an extremity, and hyperkeratosis develops over time. The clinical appearance overlaps with that of angiokeratoma circumscriptum and the hyperkeratotic cutaneous capillary–venous malformation associated with familial cerebral cavernous malformation. Red vascular dots are seen with dermoscopy, which helps to distinguish verrucous VM from a CM or LM[72].

Syndromes associated with venous malformations

Familial cutaneous and mucosal venous malformation (VMCM)

Familial VMCM is an autosomal dominant condition in which multiple VMs affect the skin, oral mucosa, and muscles. Visceral VMs (e.g. of intestines, lungs, CNS) and cardiac malformations have been observed in a few families[73]. The disorder is caused by heterozygous germline mutations in *TEK* that result in hyperphosphorylation and constitutive activation of TIE-2, a vascular endothelium-specific tyrosine kinase receptor (see Fig. 104.2); the downstream signaling of this receptor is also altered[8,73]. Interestingly, approximately half of *sporadic* VMs have *somatic* activating *TEK* mutations within lesional tissue[8].

Blue rubber bleb nevus syndrome (BRBNS; Bean syndrome)

BRBNS is a sporadic disease characterized by the progressive appearance of dark blue papules and nodules and skin-colored compressible protuberances ("rubber blebs") in a widespread distribution, in addition to larger VMs affecting subcutaneous tissues and muscle (Fig. 104.17). Some patients have a large congenital VM with a characteristic darker purple–blue fern-shaped pattern on the surface[74]. Gastrointestinal lesions bleed and result in iron deficiency anemia. Other sites of visceral involvement (CNS, lungs, heart) are uncommon. BRBNS was recently found to be caused by double (cis) somatic activating *TEK* mutations, i.e. two mutations within the same allele of the gene[7].

Maffucci syndrome

Maffucci syndrome is a sporadic condition that features VMs, which present as blue to skin-colored nodules, and enchondromas similar to those of Ollier disease, which can lead to orthopedic consequences

Fig. 104.17 Blue rubber bleb nevus syndrome. Multiple scattered small blue venous nodules, several of which are superimposed on a larger subcutaneous venous malformation. *Courtesy Juan Carlos López, MD.*

Fig. 104.18 Maffucci syndrome. A Both nodular venous malformations and enchondromas distort the hand. **B** A radiograph demonstrates an enchondroma and multiple phleboliths.

(Fig. 104.18). It most commonly affects the extremities; however, cephalic lesions with severe neuro-ophthalmologic complications may also occur. Histologically, the cutaneous nodules demonstrate features of both a VM and a vascular tumor, the spindle cell hemangioma (see Ch. 114).

Fig. 104.19 Plaque-type glomuvenous malformation on the distal lower extremity.

Heterozygous somatic mutations in *IDH1* (NADP(+)-dependent isocitrate dehydrogenase 1) have been identified in affected tissues, with the same mutation in the spindle cell hemangiomas and enchondromas[75]; the latter lesions also rarely have underlying *IDH2* mutations.

Glomuvenous malformation (GVM)

GVMs (previously known as glomangiomas) represent a variant of VM with rows of glomus cells around distorted venous channels (see Ch. 114). They occur as small solitary lesions, widely scattered blue–purple nodules, or (less commonly) large segmental plaques (Fig. 104.19). GVMs may be evident at birth, especially larger plaques, or appear from childhood to adolescence; they often enlarge over time[76,77]. In contrast to classic VMs, GVMs tend to be painful when palpated, partially (rather than fully) compressible, and hyperkeratotic with a cobblestone-like appearance (especially on the extremities). GVMs do not typically affect viscera or joints, and they are not associated with a coagulopathy. Mucosal involvement with deep intraoral lesions and superficial invasion of muscles occasionally occurs. Approximately two-thirds of patients with GVMs, but only 1% of those with classic VMs, have a family history of similar lesions. GVMs result from a heterozygous germline mutation in the glomulin gene (*GLMN*), which is passed from generation to generation in an autosomal dominant manner, *plus* a somatic "second hit" (loss of heterozygosity) in this gene within lesional skin (see Table 104.2)[78].

Cerebral cavernous malformation and hyperkeratotic cutaneous capillary–venous malformation

A distinctive hyperkeratotic cutaneous capillary–venous malformation (HCCVM) occurs in a subgroup of patients with familial cerebral cavernous malformation (CCM)[79,80]. Neurologic manifestations, which develop at a mean age of 30 years (range, 2–72 years), may include headaches, seizures, and cerebral hemorrhage[79]. This autosomal dominant disorder can be caused by mutations in three different genes (see Table 104.2): *KRIT1* (*CCM1*), *CCM2* (malcavernin), and *PDCD10* (*CCM3*). Among the ~10% of familial CCM patients who have *cutaneous* capillary and/or venous malformations, ~90% have a *KRIT1* mutation[80].

HCCVMs occur almost exclusively in patients with *KRIT1* mutations, with one report to date in an individual with a *PDCD10* mutation. These irregularly shaped, dark crimson or reddish-purple plaques with surrounding bluish discoloration are typically congenital and located on the extremities; GLUT1-positivity has been described[81]. Smaller reddish-brown macules with peripheral telangiectatic puncta have also been observed[80]. Less frequently, children and adults with mutations in any of the three genes develop dark blue cutaneous papules and nodules reminiscent of the blue rubber bleb nevus syndrome, which represent VMs[80]. The differential diagnosis includes a verrucous VM.

Lymphatic Malformations

The spectrum of LMs includes primary lymphedema, common LMs, generalized lymphatic anomaly (GLA), and central conducting lymphatic anomalies (CCLAs; channel-type LMs)[82]. The targetoid

hemosiderotic lymphatic malformation (hobnail "hemangioma") is discussed in Chapter 114. Lymphedema results from inadequate drainage of lymph due to hypoplasia, aplasia, or disruption of lymphatic channels. Lymphedema is divided into *primary* forms due to abnormal lymphatic development and *secondary* forms due to acquired disruption of lymphatic drainage (see Ch. 105). In contrast, LMs are due to hyperplasia of the lymphatic network. This hyperplasia most commonly results in cysts, including smaller microcystic and/or larger macrocystic lesions; these cysts can develop within the skin, mucous membranes, muscles, bone, or occasionally viscera[1]. Somatic activating mutations in *PIK3CA* underlie most common LMs[38]. CCLAs affecting structures such as the cisterna chyli and thoracic duct result in lymphatic leakage that leads to pleural or pericardial effusions and ascites.

Primary lymphedema

Patients with primary lymphedema usually accumulate lymph fluid in the extremities (lower > upper); cephalic and genital involvement occasionally occurs. Affected individuals are at risk for bacterial infections and septicemia. Generalized lymphedema may be associated with intestinal or pulmonary lymphangiectasias, exudative enteropathy, and pleural effusions.

Primary lymphedema may be classified according to its age of onset into congenital, peripubertal (praecox), and late-onset (tarda; >35 years of age) forms[83], but since the time of onset can vary even within the same family, genetic bases are now more commonly used for classification (see Table 105.7). Table 104.2 outlines the multiple genes that have been implicated in isolated and syndromic forms of lymphedema. Many of the proteins encoded by these genes act in the vascular endothelial growth factor receptor-3 (VEGFR3) signaling pathway[82,83] (see Ch. 102).

The most common congenital form, classically referred to as *Milroy disease*, presents with lymphedema below the knees, prominent veins, and upslanting toenails. *Lymphedema–distichiasis syndrome* due to *FOXC2* mutations features lymphedema of peripubertal onset, congenital distichiasis (aberrant eyelashes arising from the meibomian glands lead to a double row of eyelashes), venous varicosities, and occasionally yellow nails. Lymphedema, chylothorax, and chylous ascites are also variably seen in Turner syndrome (see Ch. 55) and RASopathies including Noonan, cardio-facio-cutaneous, Costello, and rarely CM-AVM syndromes (see below and Table 61.3).

Macrocystic lymphatic malformation ("cystic hygroma")

Macrocystic LMs represent collections of large, interconnected lymphatic cysts lined by a thin endothelium. The most common locations are the neck, axilla, and lateral chest wall (Fig. 104.20A). Prenatal detection by ultrasound is possible as early as the first trimester of pregnancy. Some patients who are diagnosed prenatally have malformation syndromes caused by chromosomal abnormalities or other genetic disorders (e.g. Turner syndrome, Noonan syndrome). A macrocystic LM appears as a large, soft, translucent mass under normal skin. The diagnosis can be confirmed by ultrasound, CT, or MRI (see Table 104.3) as well as by direct puncture and cytologic analysis of the fluid. Hemorrhage inside a cyst can create sudden swelling, with the mass becoming tender, tense, firm, and purple to yellowish in color.

Microcystic lymphatic malformation ("lymphangioma circumscriptum")

These ill-defined aggregates of relatively small, abnormal lymphatic channels are the most common type of LM. They favor the proximal limbs and chest but can occur in any cutaneous site or in the mouth,

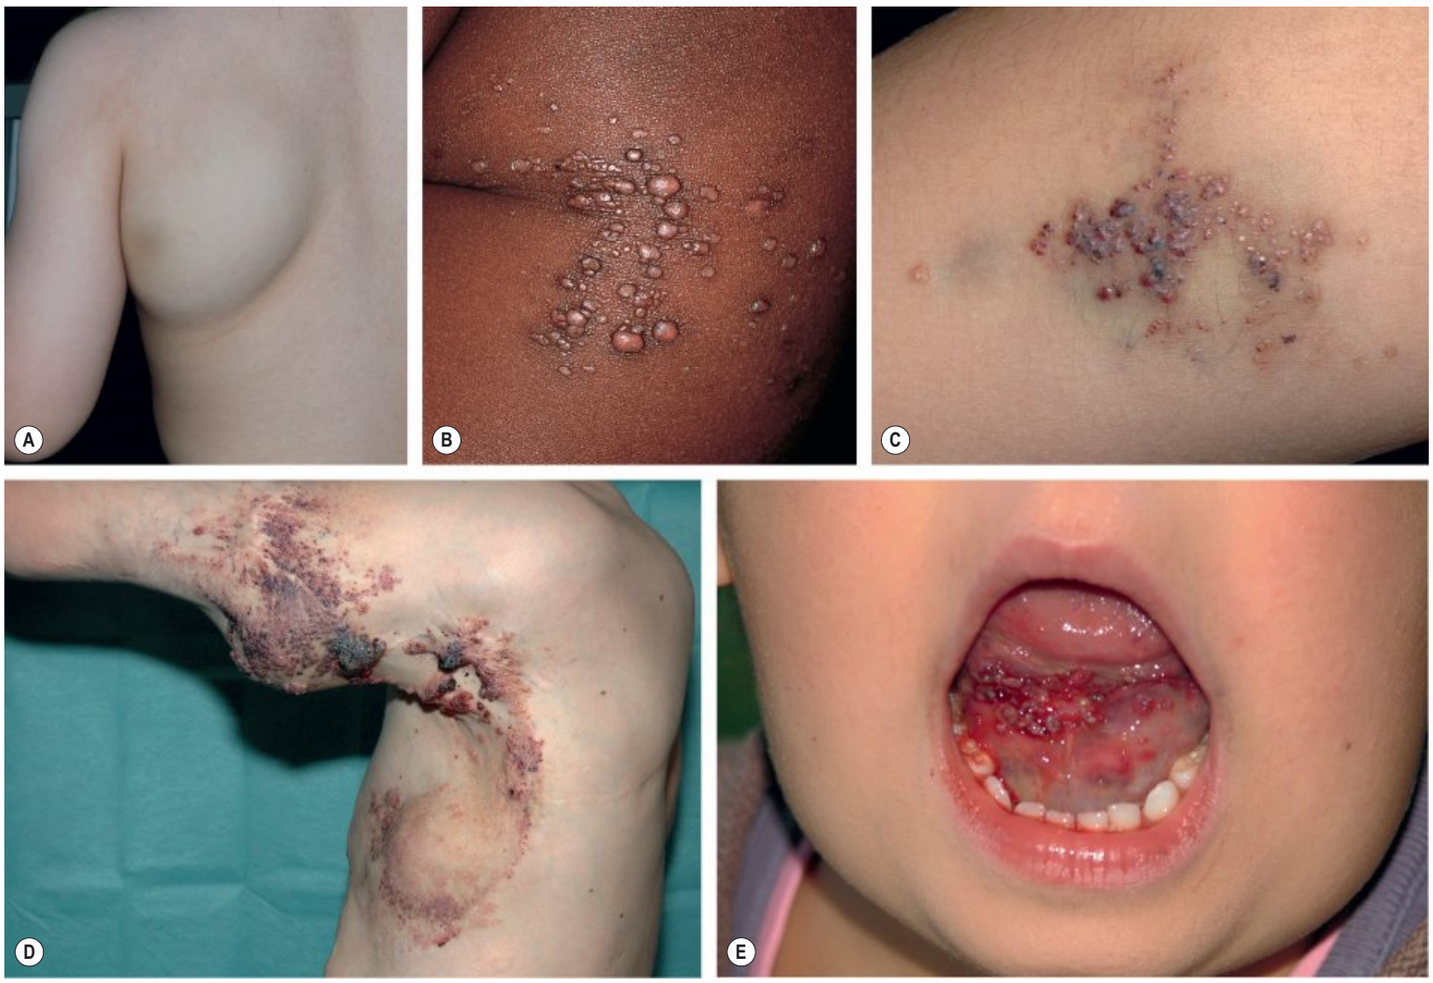

Fig. 104.20 Lymphatic malformations (LMs). A Macrocystic LM on the lateral trunk. The mass was soft except for a focal firm area of hemorrhage associated with bruise-like discoloration of the overlying skin. **B–E** Microcystic LMs presenting as clusters of clear or hemorrhagic vesicles, with active bleeding from lesions in the mouth (**E**). The crops of vesicles in (**D**) recurred years after surgical resection (utilizing grafting and linear closure) of a large microcystic LM affecting the skin and deeper structures of the arm and thorax. *A, C, Courtesy Julie V. Schaffer, MD.*

including the tongue, buccal mucosa, lips, and oral floor. Plaques with crops of clear or hemorrhagic vesicles scattered on their surface vary over time, both in size and in the number and color of superimposed vesicles (Fig. 104.20B–E). Additional clinical findings are intermittent swelling, hemorrhage, and leakage of lymph from superficial vesicles. Lesions are often much more extensive than clinically expected from the number of vesicles. Complications include erysipelas-like reactions following minor injuries, other inflammatory flares, and infections.

Combined microcystic and macrocystic lymphatic malformation

Extensive cervicofacial combined LMs commonly have bony involvement. This can lead to mandibular overgrowth and prognathism, resulting in a long or asymmetric face, bite deformities, and abnormal occlusal planes[84]. Intraoral combined LMs are frequently complicated by inflammatory flares or spontaneous bleeding in the setting of upper respiratory or dental infections. This can result in sudden expansion of the lesions, particularly those in the tongue. Local infections can lead to cellulitis or even septicemia. In some patients with massive oropharyngeal combined LMs, airway compromise (extrinsic or intrinsic) requires tracheostomy. Hypersalivation and dental caries are common, with the potential for loss of teeth. Speech, mastication, and swallowing may be impaired. In addition to swelling, pain, and infections, specific complications of combined LMs in the orbital region include chemosis, strabismus, amblyopia, proptosis, and visual loss[85].

On the trunk and limbs, combined LMs tend to worsen as the child grows. When a minor wound on the affected extremity becomes infected, the inflammatory reaction results in expansion of the LM, as also occurs in patients with limb lymphedema. Perineal and gluteal cleft LMs, which are particularly prone to fluid leakage and infection, severely impair quality of life. Extensive combined LMs, in particular those with a venous component, may be associated with a chronic localized intravascular coagulopathy with elevated D-dimer levels (see above).

Generalized lymphatic anomaly (GLA)

GLA, previously referred to as "lymphangiomatosis", represents an extensive, multifocal abdominal and thoracic LM that extends into viscera such as the spleen, liver, intestines, and pleura/lung; the bones are often involved, but the cortex is typically spared. GLA may have a lethal outcome due to expansion, chylous effusions, visceral complications, and vertebral compression.

Kaposiform lymphangiomatosis (KLA)

KLA is currently considered to represent an aggressive subtype of GLA that is characterized by progressive involvement of the mediastinum, lungs, pleura, retroperitoneum, spleen, bones, soft tissue, and skin[86]. Histologically, it features clusters or sheets of hemosiderotic, spindled lymphatic endothelial cells oriented in a parallel fashion amid abnormal dilated lymphatic channels. Circulating angiopoietin-2 levels are elevated in KLA and may serve as a biomarker.

Patients present at a median age of 6 years (range, birth to fifth decade) with respiratory symptoms, thrombocytopenia, hypofibrinogenemia, and life-threatening hemorrhagic pericardial and pleural effusions[87]. An enlarging subcutaneous mass may be evident, sometimes with an overlying red–purple birthmark and lymphatic vesicles. An underlying somatic *NRAS* mutation is present in most affected individuals[87,88]. The reported 5-year survival is ~20%–50%[86,87], and successful treatment with sirolimus (rapamycin) and MEK inhibitors has been described (see Fig. 113.1).

Gorham–Stout disease

In *Gorham–Stout (disappearing bone)* disease, a LM creates progressive radiolucent bone lesions with cortical involvement and eventually massive osteolysis. This results in pathological fractures and deformities. Involvement of the thoracic skeleton may be associated with pulmonary lymphangiectasia. A somatic activating *KRAS* mutation has been identified in affected tissue from a patient with Gorham-Stout disease.

Central conducting lymphatic anomalies (CCLAs; channel-type LMs)

CCLAs are characterized by dilation, dysfunction, or obstruction of major thoracic or abdominal lymphatic channels. The manifestations depend on the site of the anomaly and can include chylothorax, chylous ascites, protein-losing enteropathy, peripheral lymphedema, lymphorrhea, and cutaneous vesicles. Underlying mutations have been identified in genes encoding various components of the RAS–*m*itogen-*a*ctivated *p*rotein *k*inase (MAPK) pathway (germline or mosaic; see Fig. 55.4) as well as other proteins with roles in lymphatic development (e.g. MyoD family inhibitor domain containing protein, piezo-type mechanosensitive ion channel component 1)[89,90].

Arteriovenous Malformations

AVMs are fast-flow vascular malformations with direct communications (AV shunting) between arteries and veins, creating an AV nidus. They are rare and constitute the most dangerous group of vascular anomalies. Schobinger staging was adopted by the ISSVA in order to classify AVMs according to their clinical severity[1,2,91]. The stages are: (1) *quiescent/dormant* – macular or slightly infiltrated, red, warm lesions mimicking a CM (Fig. 104.21A,B); (2) *expansion* – warm masses with throbbing and thrills over dilated draining veins (Fig. 104.21C); (3) *destruction* – necrosis, hemorrhage, ulceration and (occasionally) lytic bone lesions (plus findings of stage 2) (Fig. 104.21D); (4) *cardiac decompensation* (plus findings of stage 2 ± 3). Initial evaluation with ultrasonography and MRI studies can confirm the diagnosis and delineate the extent of the lesion (see Table 104.3). Somatic activating mutations in *MAP2K1* and less commonly *KRAS*, *NRAS*, or *BRAF* have been found to underlie AVMs[92,93] (see Fig. 104.2).

In 40% of patients, AVMs are visible at birth; the remainder appear later in life. Features that can help to distinguish an early-stage AVM from a CM include heterogeneous color saturation, peripheral pallor, sharply demarcated "archipelago-like" borders (see Fig. 104.21A), and warmth to touch as well as associated soft tissue swelling/overgrowth (see Fig. 104.21B) and prominent veins[94]. The most frequent location is cephalic (~70% of patients; Fig. 104.22)[91]. Puberty (75% of patients), pregnancy (25% of women), and trauma may result in worsening of AVMs[91]. In an analysis of 65 patients with cephalic AVMs (Odile Enjolras, personal data), 39 were centrofacial and 7 were hemifacial; 10 affected the forehead, 10 the ear, and 4 the scalp.

Stage 3 cephalic AVMs are disfiguring and function- or even life-threatening lesions, and those on an ear or extremity may lead to amputation[95]. Multifocal AVMs affecting an extremity can lead to cardiac overload and distal ischemia. Attempted treatment with arterial or venous ligatures, partial excision, or proximal (rather than selective distal) embolization often precipitates complications. *Stewart–Bluefarb syndrome* represents *acroangiodermatitis* (pseudo-Kaposi sarcoma; see Ch. 105) occurring in association with an AVM of the lower extremity.

Syndromes associated with arteriovenous malformations

Cobb syndrome

This rare sporadic condition features cutaneous, intraspinal (intramedullary ± meningeal), and vertebral AVMs in the same segment. These findings can occur as a manifestation of CM-AVM syndrome due to *RASA1* mutations (see below). Congenital red or red–brown vascular birthmarks mimicking a CM, but actually representing stage 1 AVMs (Fig. 104.23), or throbbing masses with dilated veins (stage 2 AVMs) are present in 20% of patients with spinal AVMs. Neurologic deficits typically develop during young adulthood due to a mass effect of the expanding AVM on the spinal cord or subarachnoid hemorrhage. Neurologic signs range from back pain and radiculalgia to rectal and bladder dysfunction to paraparesis and paraplegia. MRI and angiography establish the presence of the spinal AVM. Endovascular embolization of the spinal AVM may improve the prognosis.

Bonnet–Dechaume–Blanc syndrome (BDBS; Wyburn–Mason syndrome)

This rare segmental AVM extends from the craniofacial region to the orbit and brain. Incomplete forms of the disease also exist. The brain AVM may remain asymptomatic or manifest as seizures or hemiparesis/hemiplegia. In 12 BDBS patients between 5 and 51 years of age, the facial AVMs (stage 1, 2, or 3) were midfacial in 3, hemifacial in 3, and both midfacial and hemifacial in 6 (Odile Enjolras, personal observations). The presence of an orbital AVM was an inconsistent finding (4 patients), but brain AVMs of the chiasm, choroid plexus, or thalamus

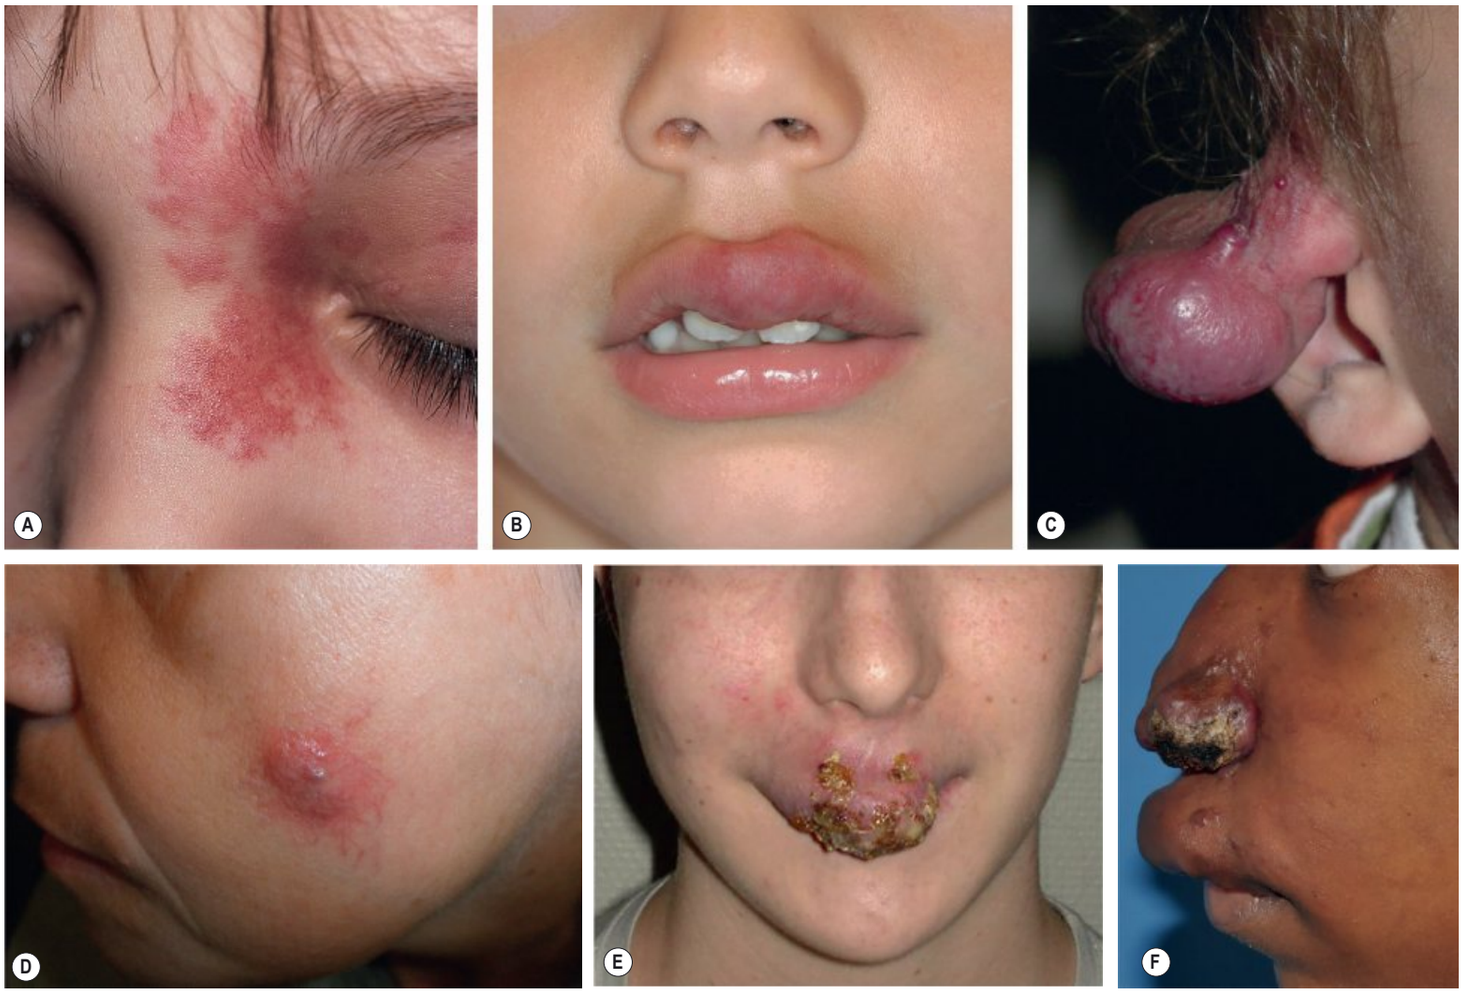

Fig. 104.21 Arteriovenous malformations (AVMs). A,**B** Dormant (stage 1) AVMs mimicking a port-wine birthmark (**A**) and infantile hemangioma (**B**). **C**, **D** Expanding (stage 2) AVMs on the external ear and cheek. **E, F** Destructive (stage 3) AVMs that have led to cutaneous necrosis. *D, Courtesy, Fernando Alfageme, MD; E, Courtesy Juan Carlos López, MD.*

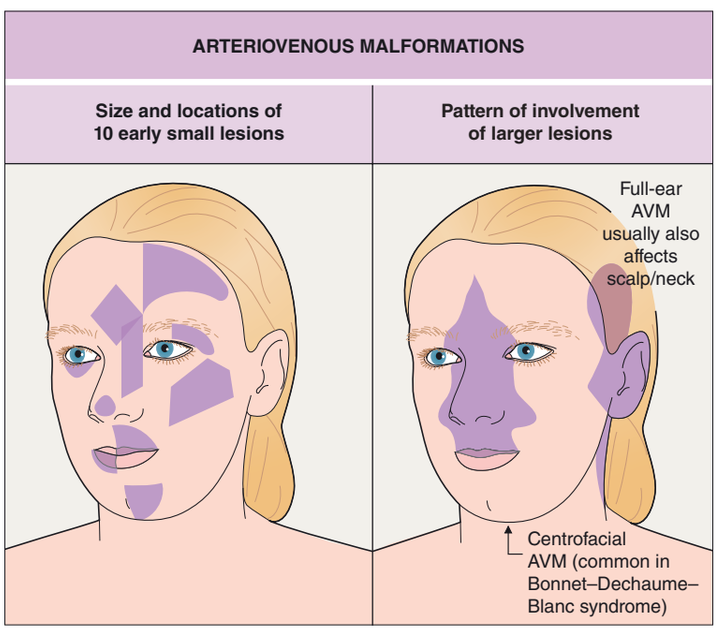

Fig. 104.22 Arteriovenous malformations – size, locations, and patterns.

Fig. 104.23 Cobb syndrome. This birthmark on the nape has an appearance reminiscent of a salmon patch, but it was warm and superimposed darker red macules progressively appeared. Doppler ultrasonography, MRI, and arteriography confirmed the presence of a arteriovenous malformation of the skin and spine.

were present in all 12 individuals and led to cerebral hemorrhage in 4 patients. In a second series of 15 patients with BDBS[96], orbital AVMs were present in 14 and frequently affected the optic nerve (13 patients) and retina (11 patients); symptoms in this group included reduced visual acuity or fields, blindness, recurrent epistaxis, nasal obstruction, and gingival hemorrhage.

Parkes Weber syndrome

In this rare *fast-flow* vascular malformation syndrome, limb overgrowth (in length and girth) occurs secondary to arteriovenous fistulae (AVF); this must be differentiated from the purely *slow-flow* malformations of KTS. A red CM, excess fat, and lymphatic anomalies may also be observed in Parkes Weber syndrome. Lytic bone lesions and cardiac failure often develop, and prognosis is poor after puberty. Over 50% of patients with Parkes Weber syndrome have a germline *RASA1* or *EPHB4* mutation plus an early somatic "second hit" mutation in the same gene underlying their larger AVM/AVF (see Ch. 62); these individuals also display the characteristic features of the CM-AVM syndrome (see below)[9,52].

Capillary malformation–arteriovenous malformation (CM-AVM) syndrome

This autosomal dominant disorder is caused by mutations in *RASA1* (~50% of patients; CM-AVM1) and less often in *EPHB4* (CM-AVM2) (see Table 104.2 and Fig. 104.2)[97,98]. Multiple, scattered small cutaneous CMs are evident at birth and continue to appear during childhood and adolescence. These CMs present as pink to red–brown macules, often with a narrow blanched border or in CM-AVM2 a blanched central region, as well as hypotrichosis of the affected skin (Fig. 104.24). Some macules are warmer than adjacent uninvolved skin, and pulsed Doppler may show decreased peripheral vascular resistance, suggesting a pre-AVM lesion. Histologically, the macules have numerous thick-walled arterioles in the superficial dermis, suggestive of an incipient AVM rather than a CM[99].

Patients sometimes have numerous punctate red macules, each surrounded by a white halo, located primarily on the extremities[97]. Patients with CM-AVM2 may also have telangiectasias favoring the lips, perioral area, and upper trunk. Approximately 35% and 15%–20% of individuals with CM-AVM1 and 2, respectively, also have high-flow lesion(s)[9,52]. Among 138 patients from 68 families with CM-AVM1, >90% had multifocal small CMs, 6% had a solitary "atypical" CM, 18% had an AVM/AVF of the skin/subcutaneous tissue (extremities > face/neck), 5% had Parkes Weber syndrome, and 15% had an intracranial or intraspinal AVM[62,97]. The CNS AVMs may lead to neurologic symptoms, which typically develop in the first decade of life and can include headaches, seizures, and sensorimotor deficits. MRI of the brain/spine is recommended for asymptomatic infants and young children with CM-AVM as well as patients of any age with neurologic manifestations[100].

PTEN hamartoma tumor syndrome (PHTS)

PHTS due to *PTEN* mutations encompasses the autosomal dominant Bannayan–Riley–Ruvalcaba and Cowden syndromes as well as the type 2 mosaic *s*egmental *o*vergrowth, *l*ipomatosis, *AVM*s, and *e*pidermal *n*evus (SOLAMEN) syndrome (see Ch 63)[101,102]. Affected individuals are often macrocephalic, and they are predisposed to the development of malignancies, especially of the breast, thyroid, and endometrium. Cutaneous manifestations with onset at birth or in childhood include genital pigmented macules, segmental excess of hypervascularized fat, and vascular malformations. The latter are typically multifocal, intramuscular, fast-flow lesions associated with ectopic fat and focal segmental dilatation of draining veins[103]. By both imaging and histopathologic features, these vascular malformations differ from sporadic AVMs and they have been renamed *PTEN hamartomas of soft tissue*. Oral sirolimus has been used to treat these lesions[104]. Cerebral developmental venous anomalies are also common in PHTS patients, and additional mucocutaneous lesions in affected adolescents and adults include tricholemmomas, acral keratoses, sclerotic fibromas, neuromas, and oral papillomas.

PATHOLOGY

The histologic characteristics of the four major types of vascular malformations are illustrated in Fig. 104.25[1].

Capillary Malformations

A CM is composed of ectatic capillaries within the papillary and reticular dermis, lined by a flat continuous endothelium. Thickening of affected skin can occur over time due to a progressive increase in the diameter of the capillaries, involvement of the dermis and subcutis, fibrosis of the dermis, and, occasionally, venous channels in the subcutis.

Venous Malformations

Large convoluted and interconnected anomalous venous channels dissect the normal connective tissues and muscles. Organized thrombi, phleboliths (round calcifications), and intravascular papillary endothelial hyperplasia are frequently observed. Anomalous vessels of a VM have a continuous flat endothelium and a thin basement membrane. Their walls have discontinuous media due to foci with a relative lack or absence of smooth muscle cells.

Lymphatic Malformations

LMs of the *microcystic* type exhibit enlarged, distorted, irregular lymphatic channels with varying numbers of smooth muscle cells in their walls and a very thin endothelium, sometimes barely visible. Larger polyhedral lymphatic vessels may exhibit valves, and they are usually separated by fibrous septa. Lymphatic clefts dissect the host connective tissues. Hyperkeratotic epidermis may overlie some clusters of dermal lymphatic vesicles. LMs of the *macrocystic* type are composed of large lymphatic cisterns, often interconnected with thinner channels. Vesicles and large cysts in LMs usually contain watery fluid, lymphocytes, and macrophages; hemorrhage can also be seen. Lymphatic endothelium can be identified by immunohistochemical staining for podoplanin, LYVE-1, and Prox1 (see Ch. 102).

Fig. 104.24 Capillary malformation–arteriovenous malformation (CM-AVM) due to a *RASA1* mutation. Multiple pink–red (**A,B**) to brownish (**C**) macules. A subtle blanched halo is often evident at the periphery of the lesions. *B, Courtesy Margarita Larralde, MD.*

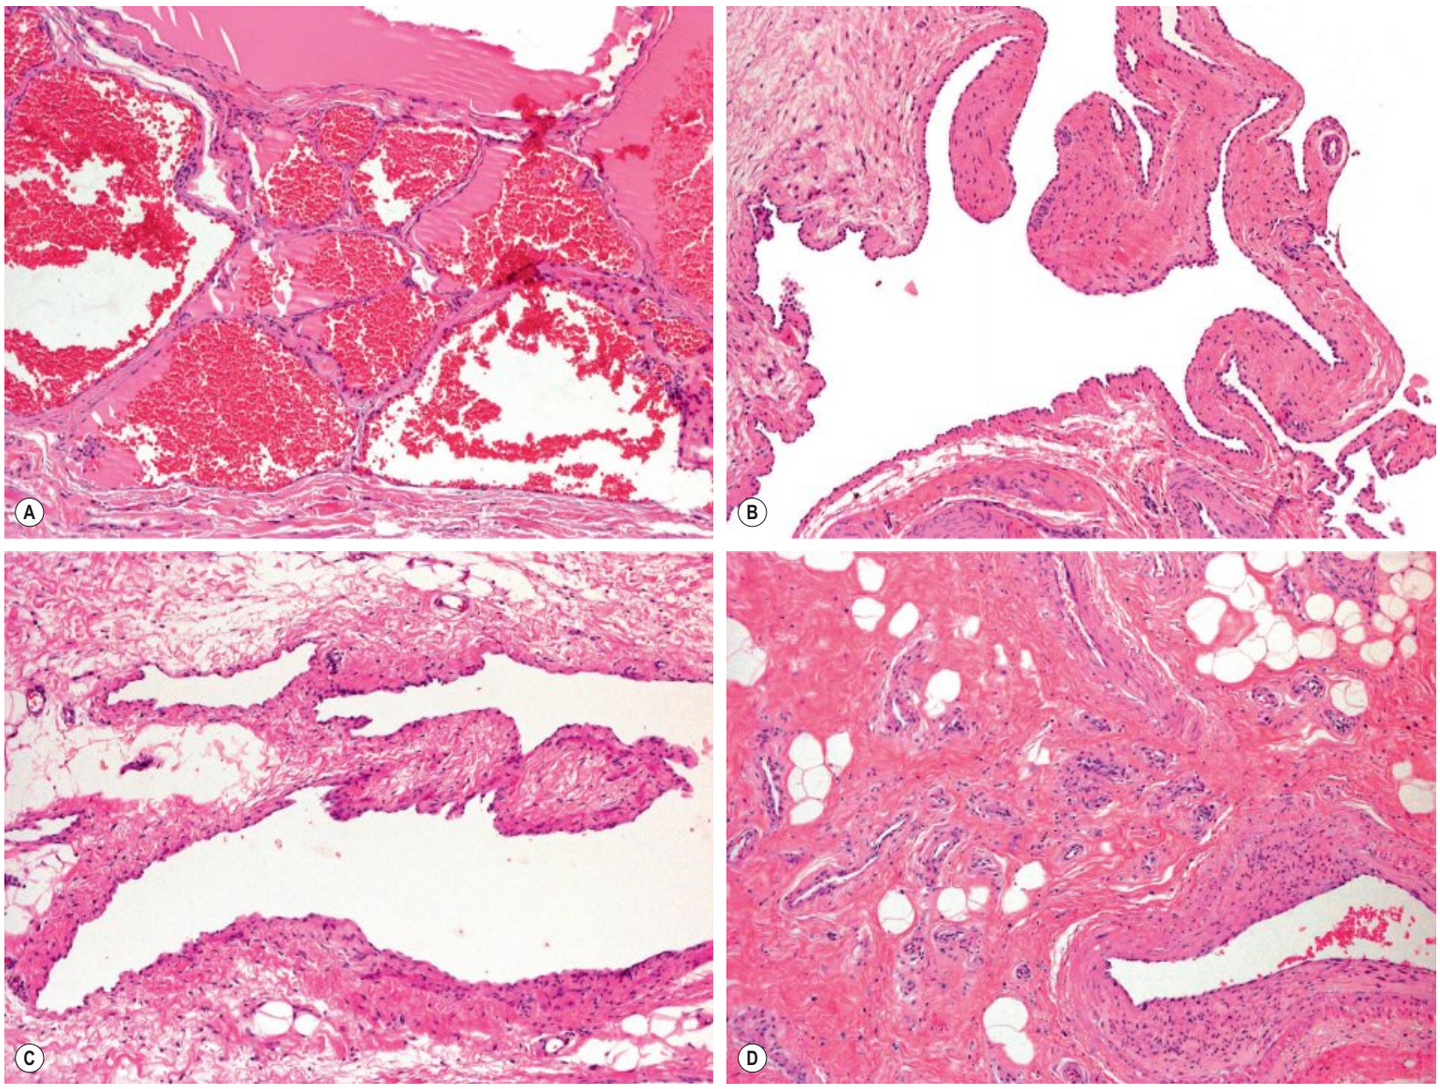

Fig. 104.25 Histologic features of vascular malformations. A Capillary malformation in an adult that was thickened and nodular. An increased number of dilated capillaries are present in the dermis. **B** Venous malformation composed of large, irregularly shaped, thin-walled channels. **C** Lymphatic malformation with large, irregularly shaped channels. **D** Arteriovenous malformation demonstrating an area of intense capillarogenesis near the AV nidus. This finding is sometimes misinterpreted as a "capillarovenous" malformation. *A–D, Courtesy Lorenzo Cerroni, MD.*

Arteriovenous Malformations

AVMs have irregularly thickened walls and are usually randomly distributed in the dermis and other involved tissues. Direct communications between vessels with different elastic components, typically arteries and veins, may be evident. A capillary component is often obvious in the overlying papillary dermis, and it may have a lobular architecture.

DIFFERENTIAL DIAGNOSIS

Vascular malformations must be distinguished from vascular neoplasms. Superficial infantile hemangiomas at the beginning of their proliferative phase or with minimal/arrested growth may resemble CMs, whereas deep infantile hemangiomas and other vascular tumors such as kaposiform hemangioendothelioma, infantile hemangiopericytoma, and benign lymphangioendothelioma (acquired progressive lymphangioma) can mimic VMs, LMs, and LVMs (see Chs. 103 & 114). Multifocal lymphangioendotheliomatosis with thrombocytopenia should be considered in patients with multiple vascular malformations, especially when associated with gastrointestinal bleeding (see Ch. 114).

Occasionally, other neoplasms and inflammatory disorders are misdiagnosed as vascular anomalies. A red or blue color and/or a mass underneath normal skin can represent potentially misleading clinical signs. For example, erythematous lesions of lupus erythematosus, plaque-type angiofibromas, telangiectasia macularis eruptiva perstans, and other telangiectatic conditions can mimic CMs (see Ch. 106). Dermal melanocytosis has a deep blue color that may lead to misdiagnosis as a VM. Masses beneath normal skin that may be erroneously diagnosed as a macrocystic LM in infants and children include a lipoblastoma, teratoma, bronchogenic cyst, branchial cleft cyst, thyroglossal duct cyst, myofibroma, rhabdomyosarcoma, and fibrosarcoma.

Acquired cutaneous lymphangiectasia imitating a LM can develop in several settings (Table 104.7).

TREATMENT

No single treatment exists for this heterogeneous group of lesions.

Capillary Malformations

PWBs and telangiectasias are best treated with a pulsed dye laser (PDL; see Ch. 137)[105–107]. This treatment of PWBs, which is typically initiated early in life for facial lesions to decrease potential psychosocial impact and avoid lesional thickening, is often very effective. However, not all lesions respond well; PWBs on the central face and distal limbs tend to be more resistant to therapy than those in other sites. PDL treatment is safe, producing temporary purpura but a low risk of hypo- or hyperpigmentation and scarring[106]. Although the latter side effects

CAUSES OF ACQUIRED CUTANEOUS LYMPHANGIECTASIA
Inflammatory causes
Crohn disease (favors perineal area) Orofacial granulomatosis Morphea profunda Systemic sclerosis
Infectious causes
Tuberculosis (e.g. scrofuloderma) Recurrent erysipelas/cellulitis
Neoplastic causes
Intralymphatic metastases (e.g. breast carcinoma, melanoma)
Iatrogenic causes
Surgical resection, lymphadenectomy, and/or radiotherapy for cancer (e.g. of the breast, prostate, bladder, cervix) Amputations Corticosteroid-induced atrophy ± photoaging Penicillamine-induced dermopathy
Other causes
Pregnancy (vulvar) Cirrhotic ascites (abdominal) Porphyrias (e.g. porphyria cutanea tarda, variegate porphyria; centrofacial) Spontaneous development in elderly patients (genital)

Table 104.7 Causes of acquired cutaneous lymphangiectasia. In the literature, this is sometimes referred to as acquired lymphangioma circumscriptum.

are more common in individuals with darkly pigmented skin (e.g. skin phototype V), these patients may have a good response and should not be excluded from PDL treatment.

Intervention during infancy with modified PDL therapy using a longer wavelength, increased pulse duration, higher fluence (11–12 J/cm^2), and dynamic cooling spray can maximize lightening or clearing of PWBs[107]. Use of a topical anesthetic (see Ch. 143), together with the anesthetic effect of the cryogen spray, helps to reduce the need for general anesthesia in children. In a longitudinal study of 51 patients whose facial CM was treated with classic PDL, redarkening was evident in one-third of the lesions after a median follow-up period of 10 years[108]. Relapses may be less common in patients treated at a younger age. If treatment is delayed, facial and gingival PWBs may develop hyperplastic changes that require additional dermatologic (e.g. dermabrasion prior to PDL treatment) as well as orthodontic and surgical interventions (e.g. to correct open-bite deformities and macrocheilia). For PWBs resistant to PDL, other lasers such as the alexandrite or Nd:YAG may be of utility. Topical application of sirolimus in conjunction with PDL may also provide additional benefit[109] (see Ch. 129).

Multidisciplinary care is necessary for patients with SWS[30]. Anticonvulsants are the mainstay of treatment for seizures, although selected patients with severe, uncontrolled seizures may benefit from surgical management. Low-dose aspirin (3–5 mg/kg) can also be considered in symptomatic and presymptomatic patients with brain involvement[110]. Oral sirolimus also has potential benefit for uncontrolled seizures, cognitive impairment, and perhaps as a preventive treatment in SWS patients with extensive leptomeningeal involvement[111,112]. Glaucoma usually responds to medical or surgical treatment. As discussed above, PDL therapy for PWBs can begin during infancy[113]. Psychological counseling may be helpful for patients and families affected by SWS, and support is also available through the Sturge–Weber Foundation (www.sturge-weber.org).

Venous Malformations

Satisfactory treatment of a cephalic VM typically requires multiple sclerotherapy procedures over a period of years, often spanning from childhood to adulthood, combined with surgical excisions (see Fig. 104.16)[1]. The aims are to maintain facial symmetry, preserve muscular functions, and restore the dynamics of the smile. Limb VMs may also benefit from sclerotherapy and resection; however, many are too extensive and invasive for such interventions to be advisable. Use of elastic compression garments helps to reduce swelling and pain in the affected extremity. Treatment with low-molecular-weight heparin can control chronic coagulopathy associated with VMs, especially before surgery and during painful thrombotic events[68,69]. Low-dose aspirin (3–5 mg/kg/day, up to 81 mg/day) may be of some benefit in patients with a mild coagulopathy[114].Treatment of VMs with oral sirolimus or the PI3K inhibitor alpelisib has also been reported to improve the associated coagulopathy as well as reduce lesion size and pain[115], although sirolimus appears to have greater benefit for combined lesions with a lymphatic component[116].

Lymphatic Malformations

The choice and outcome of treatment depend on the type and extent of the LM[84,85]. Macrocystic LMs are best treated with percutaneous sclerotherapy utilizing agents such as killed bacteria (picibanil/OK-432), alcoholic solution of zein (Ethibloc®), sodium tetradecyl sulfate, pure ethanol, doxycycline, or bleomycin. This creates an inflammatory reaction with subsequent fibrosis and shrinkage of the treated cyst; repeated procedures are usually necessary. Surgical excision can be employed if sclerotherapy fails or gives incomplete results.

Surgical excision is the treatment of choice for microcystic LMs, either with direct closure or (for large lesions) use of skin grafts or tissue expanders. However, incomplete excisions occur in virtually all cases, whether because of concern regarding functional consequences of extensive surgeries or underestimation of the extent of the LM (see Fig. 104.21D). Other techniques that are often used in combination include laser therapy (e.g. CO_2, surface application or intralesional bare fiber Nd:YAG, diode), radiofrequency ablation, cryoablation, and sclerotherapy[117–119]. Topical application of sirolimus may have benefit for the superficial component of microcystic LMs, with case series noting reductions in vesicle volume, lymphatic leakage, and bleeding[120]. Microcystic LMs of the tongue and floor of the mouth are particularly difficult to treat, and careful dental hygiene is important. Transient inflammatory swelling of LMs usually responds to therapy with NSAIDs, corticosteroids, and/or antibiotics.

Patients with complex lymphatic anomalies may need replacement of albumin and immunoglobulins. A low-fat diet and substitution of long-chain fatty acids with medium-chain fatty acids may benefit those with intestinal lymphangiectasia. Oral sirolimus has been used with success in patients with LMs, GLA, and Gorham–Stout disease[116,121,122], and PI3K inhibition with alpelisib represents another promising therapeutic strategy[123]. Sildenafil treatment has led to variable decreases in volume and softening of large LMs in some patients[124], but no responses were seen in other series[125]. Zoledronate may be of benefit for osteolysis secondary to LMs in Gorham–Stout disease.

Arteriovenous Malformations

In general, stage 2 and 3 AVMs of the head and neck should be excised completely after careful preoperative embolization using arterial ± direct puncture approaches to prevent excessive intraoperative bleeding. Reconstruction often requires techniques such as skin grafting, preoperative tissue expansion, and free tissue transfer[1,91]. Subtotal excision frequently results in subsequent progression of the AVM, with recruitment of adjacent vessels and apparent angiogenesis. Stage 1 and early stage 2 AVMs are often managed conservatively if postsurgical cosmetic results might be worse than the lesion itself. However, resection of early-stage AVMs can prevent further progression.

Embolization alone usually cannot cure a superficial AVM. The most effective embolic agent, pure ethanol, poses substantial risks (especially at higher doses) that include renal or pulmonary toxicity and cardiac arrest. For AVMs that begin to hemorrhage, embolization may be life-saving. Distal hand or foot AVMs are rarely controlled long-term by embolotherapy, and ischemic complications resulting in extreme pain, necrosis, and bleeding may require amputation. In one report, treatment of a diffuse AVM in the arm of a young girl using a metalloproteinase inhibitor (Marimastat®) with antiangiogenic effects produced sustained improvement over a 12-year period, including reconstruction of affected bones and without adverse effects[126]. Treatment with trametinib, a

MEK inhibitor, was beneficial in a child with a large, progressive truncal *MAP2K1*-related AVM and a young woman with cardiac compromise due to CM-AVM syndrome[127].

Combined Malformations and the PIK3CA-Related Overgrowth Spectrum (PROS)

A combined vascular malformation of a limb requires an individualized management plan. Longitudinal orthopedic evaluation is essential for lower extremity lesions in growing children. Carefully timed epiphysiodesis before the end of the growth period can potentially correct a leg-length discrepancy in KTS, but it may worsen vascular disease in Parkes Weber syndrome. Treatment of a component of the vascular malformation (e.g. surgery for varicose veins in KTS or embolization of the AV nidus in Parkes Weber syndrome) often has suboptimal results. Elastic support garments and a compensatory shoe-lift are indispensable conservative interventions.

The PI3K inhibitor alpelisib is FDA-approved for patients ≥2 years of age with severe manifestations of PROS[128]. In a retrospective study in 32 patients with PROS, alpelisib therapy for 24 weeks led to improvement in vascular malformations and overgrowth in 79% and 74% of patients, respectively, with 38% achieving a ≥20% reduction in the volume of PROS lesions. Treatment of Proteus syndrome patients with miransertib, an oral AKT inhibitor, has led to stabilization of overgrowth and pain improvement[129]. Additional clinical trials and long-term follow-up studies are needed to provide further data on the benefits of targeted therapies in these overgrowth syndromes.

Acknowledgment

The author wishes to acknowledge the late Odile Enjolras, MD for her valuable contribution to this chapter in the previous editions.

APPENDIX

EXAMPLE OF A GENETIC PANEL: ADDITIONAL CODES	
VANSeq Panel*	**Genes**
Capillary malformations – 7 genes	*AKT1, EPHB4, GNA11, GNAQ, PIK3CA, PIK3R1, RASA1*
Lymphatic malformations, venous malformations, arteriovenous malformations (LM/VM/AVM) – 17 genes	*ACVRL1, ARAF, BRAF, ELMO2, ENG, EPHB4, GDF2, GLMN, HRAS, KRAS, MAP2K1, MAP3K3, NRAS, PIK3CA, PTEN, RASA1, TEK (TIE2)*
Lymphedema – 23 genes	*ARAF, BRAF, CCBE1, CELSR1, DCHS1, EPHB4, FAT4, FLT4, FOXC2, GATA2, GJC2, HGF, HRAS, KIF11, KRAS, MAP2K1, MET, NRAS, PIEZO1, PTPN14, RASA1, SOX18, VEGFC*
Vascular tumor – 10 genes	*BRAF, CTNNB1, GNA11, GNA14, GNAQ, HRAS, IDH1, IDH2, KRAS, NRAS*
VANseq expanded – 47 genes	*ACVRL1, AKT1, ARAF, BRAF, CCBE1, CCM2, CELSR1, CTNNB1, DCHS1, ELMO2, ENG, EPHB4, FAT4, FGFR1, FLT4, FOXC2, GATA2, GDF2, GJA4, GJC2, GLMN, GNA11, GNA14, GNAQ, HGF, HRAS, IDH1, IDH2, KIF11, KRAS, KRIT1, MAP2K1, MAP3K3, MET, NRAS, PDCD10, PDGFRB, PIEZO1, PIK3CA, PTEN, PTPN11, PTPN14, RASA1, SMAD4, SOX18, TEK, VEGFC*
*Modifed from the Seattle Children's Hospital vascular anomalies sequencing panel.	

Example of a genetic panel: additional codes. Panels vary depending on the laboratory.

105 Ulcers

Ariela Hafner and Eli Sprecher

Chapter Contents

Venous Ulcers 1844
Lymphedema 1852
Arterial Ulcers 1854
Diabetic (and Neuropathic) Ulcers 1855
Ulcers Due to Physical Factors 1857
Other Causes of Skin Ulceration 1859

Synonyms: ■ Ulcer – wound, sore ■ Venous ulcer – ulcer due to venous insufficiency/venous hypertension ■ Arterial ulcer – ulcer due to atherosclerosis ■ Neuropathic ulcer – mal perforans ■ Livedoid vasculopathy – atrophie blanche, livedoid vasculitis ■ Pressure ulcer – decubitus ulcer, pressure sore, bed sore

Key features

- The history should include onset, course, symptoms, exacerbating and alleviating factors, past medical history, family history, social history, travel, and medications
- Important aspects of the physical examination include location, size, shape and depth of the ulcer, characteristics of the ulcer edge and base, and associated physical findings
- Helpful laboratory evaluation includes vascular studies, blood tests (e.g. for thrombophilia), microbial cultures, and biopsy
- A biopsy of non-healing chronic ulcers is indicated to exclude carcinoma or other underlying diseases
- In addition to local care, therapy of ulcers should aim to correct or treat the underlying cause:
  - Venous insufficiency: compression
  - Arterial insufficiency: revascularization
  - Neuropathic or pressure ulcer: relief of pressure or other local factor that might be causing or exacerbating the ulceration
  - Infection: antibiotics
  - Neoplasm: surgery, chemotherapy, radiotherapy
  - Vasculopathy: treat the underlying cause of the occlusive disorder
  - Vasculitis or other inflammatory process (e.g. pyoderma gangrenosum): corticosteroids, immunosuppressive agents
- A key factor in therapy is the promotion of wound healing:
  - Debridement: mechanical, enzymatic, autolytic
  - Dressings: maintain a moist wound environment
  - Infection control: antibiotics
  - Skin grafting or skin substitutes
  - Growth factors

INTRODUCTION

A chronic wound is defined as one that fails to progress through a normal orderly and timely sequence of repair or a wound that passes through the repair process without restoring a functional result[1]. A cutaneous ulcer is a wound that is associated with loss of both epidermal and dermal tissues. Chronic ulcers, which are due to a variety of systemic and/or local factors, can represent both a diagnostic and therapeutic challenge to the dermatologist. The majority of ulcers occur on the lower extremities, and most are related to venous insufficiency/venous hypertension, peripheral artery disease, or peripheral neuropathy (Table 105.1). Less common causes are outlined in Figure 105.1 and sites other than the legs may be involved (e.g. pressure-induced ulcers).

Wound therapy has advanced considerably over the past few decades with the advent of innovative dressings and technologies, but the key factor in the management of chronic ulcers remains proper patient evaluation and correction of the underlying cause, when identified.

VENOUS ULCERS

Chronic venous disease is a common problem in adults, with its prevalence increasing with age. Due in large part to a lack of standardized diagnostic criteria, the prevalence varies considerably, from <1% to 17% in men and from <1% to 40% in women[2].

Risk factors for chronic venous disease include family history, age, female sex, obesity, pregnancy, prolonged standing, and height[3]. Venous hypertension and venous insufficiency represent the most common cause of chronic leg ulcerations. Venous ulcers tend to recur, are sometimes painful, and clearly have an impact on quality of life[4]. Because of their prevalence and chronicity, there are significant healthcare costs, estimated to be ~$3 billion per year in the US[3].

Pathogenesis

The venous system of the lower extremities consists of an interconnected network of superficial veins, deep veins, and perforator or communicating veins which connect the superficial and deep systems[5] (see Ch. 155). Throughout the superficial, communicating and deep veins, one-way bicuspid valves ensure unidirectional flow toward the deep system, thus allowing blood to flow in a cephalad direction and preventing reflux (Fig. 105.2A). It is primarily the contraction of calf muscles that drives blood from the leg toward the heart[4].

During standing, as leg muscles relax, venous pressure in the legs may reach up to 80 to 90 mmHg[3]. Calf muscle contractions, e.g. when walking, transiently increase pressure within the deep leg veins, propelling blood towards the heart. When pressure rises within the deep system, the valves close, preventing retrograde flow and transmission of high pressure to the superficial system[4]. When the deep system empties, the deep vein pressure abruptly falls to <30 mmHg and the valves open, enabling flow from the superficial into the deep system[3,4].

In the absence of competent valves, however, the decrease in venous pressure with leg movements is attenuated, and high pressures generated in the deep veins by calf muscle contraction are transmitted to the superficial venous system and to the microcirculation within the skin[3]. A sustained elevation in venous pressure is responsible for the typical clinical picture seen in chronic venous disease and is termed *venous hypertension* or *venous insufficiency*.

In most patients, venous hypertension is caused by reflux through incompetent valves (Fig. 105.2B), whether primary (congenital) or secondary to deep vein thromboses or recurrent trauma. Additional causes of venous hypertension include venous outflow obstruction and failure of the calf muscle pump due to obesity or leg immobility[3].

Although venous hypertension appears to be central to the skin changes seen in chronic venous disease, the exact pathogenic cascade from valvular incompetence to frank ulceration remains obscure. A few pathomechanisms have been suggested, but it is still unclear whether they represent causative factors or epiphenomena[6]. One proposal was that cuffs of fibrin around dermal capillaries (due to leakage of fibrinogen) could impede the diffusion of oxygen and nutrients to

COMPARISON OF CLINICAL FINDINGS IN THE THREE MAJOR TYPES OF LEG ULCERS			
	Venous	**Arterial**	**Neuropathic/mal perforans***
Location	Medial malleolar region	Pressure sites Distal points (toes)	Pressure sites
Morphology	Usually shallow Irregular borders Yellow fibrinous base	Dry, necrotic base Well-demarcated ("punched out")	"Punched out"
Surrounding skin	Yellow–brown to brown discoloration due to hemosiderin deposits Pinpoint petechiae ("stasis purpura") Lipodermatosclerosis	Shiny atrophic skin with hair loss	Thick callus
Other physical examination findings	Varicosities Leg/ankle edema Acroangiodermatitis ± Stasis dermatitis ± Lymphedema	Weak/absent peripheral pulses Cool feet Prolonged capillary refill time (>3–4 seconds) Pallor on leg elevation (45° for 1 min) Dependent rubor	Peripheral neuropathy with decreased sensation ± Foot deformities

*Most commonly due to diabetes mellitus.

Table 105.1 Comparison of clinical findings in the three major types of leg ulcers. *Adapted from Phillips TJ, Dover JS. Leg ulcers. J Am Acad Dermatol 1991;25:965–87.*

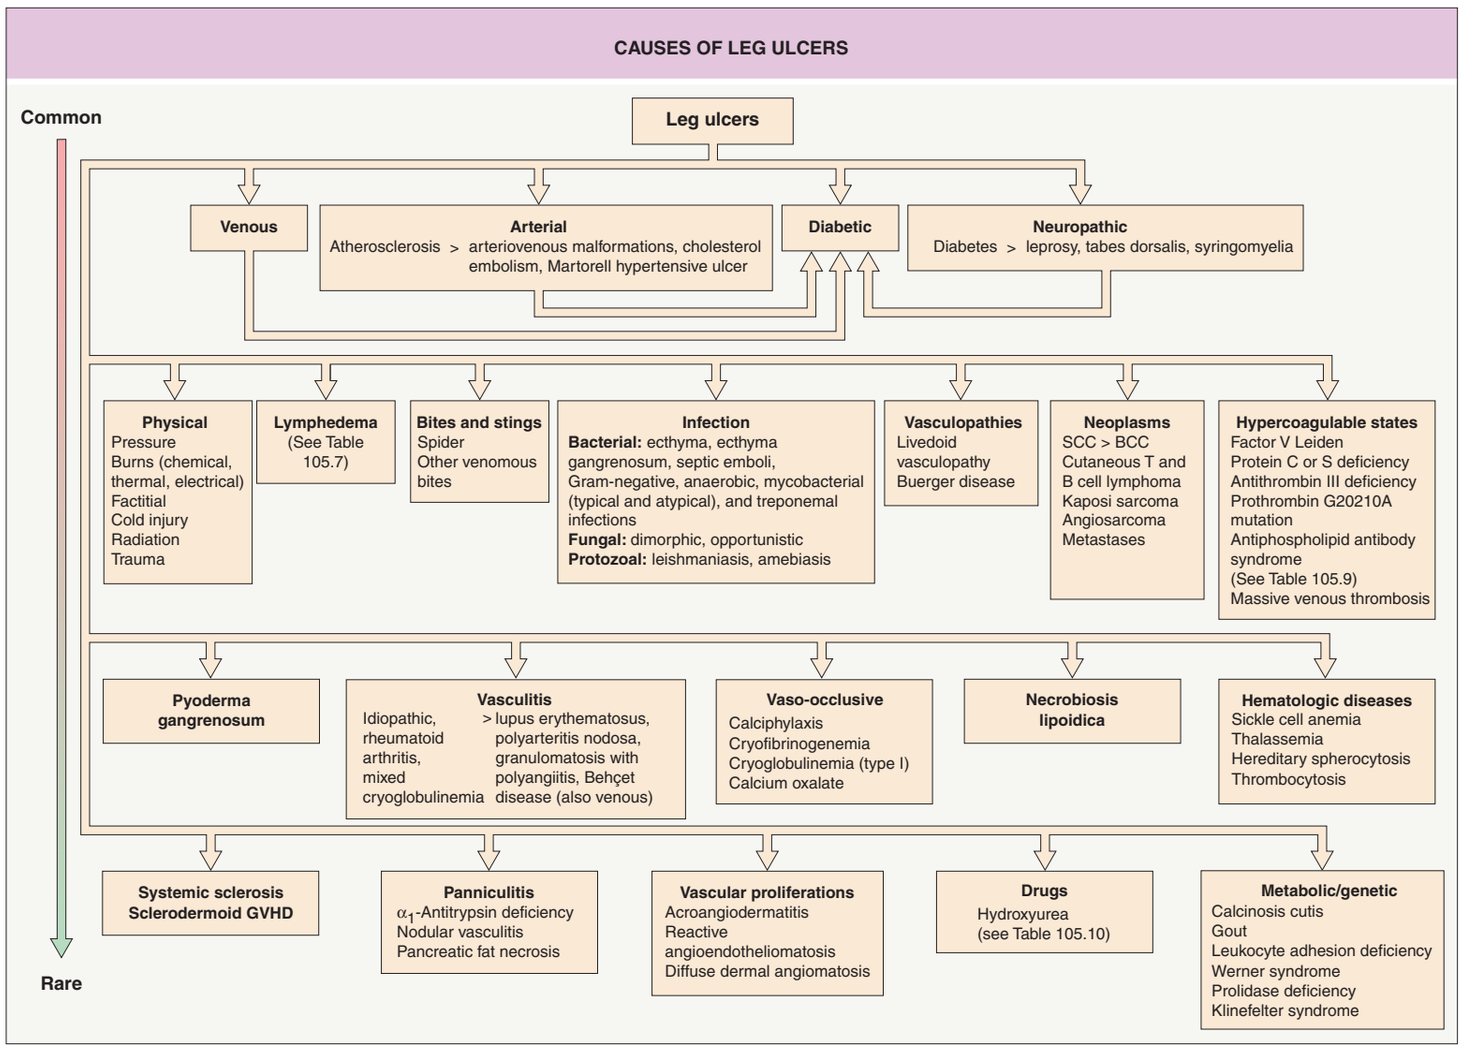

Fig. 105.1 Causes of leg ulcers. Patients with Behçet disease develop lower extremity ulcers due to vasculitis and/or venous insufficiency related to deep vein thromboses, and, occasionally, erosive pustular dermatosis is a cause of leg ulcers. Hydroxyurea-induced leg ulcers are often on the malleolus or tibial crest, exceedingly painful, and surrounded by atrophic skin. Additional genetic syndromes associated with ulceration are listed in Table 105.10. GVHD, graft-versus-host disease.

surrounding tissues and lead to degenerative skin changes[7]. Other investigators suggested that venous pooling induced inter-endothelial space widening and deposition of fibrin and other macromolecules that then "trapped" growth factors, rendering them unavailable for wound repair[8].

Nowadays, however, the predominant theory is that chronic inflammation plays a key role in chronic venous ulcers (Fig. 105.3)[3]. With elevated venous pressure, shear stress on the endothelial wall is altered, leading to glycocalyx disruption and endothelial cell activation. As a result, there is release of vasoactive mediators, proinflammatory

molecules (e.g. chemokines), and prothrombotic precursor proteins. Increased expression of adhesion molecules such as ICAM-1, VCAM-1, and platelet-endothelial leukocyte adhesion molecule-1 (PECAM-1) on endothelial cells leads to leukocyte recruitment followed by diapedesis into the dermis (see Fig. 102.11). This inflammatory response then leads to further venous wall damage[9].

Increased expression and activity of matrix metalloproteinases (MMPs) also contribute to the breakdown of the extracellular matrix, which promotes the formation of ulcers and impairs healing. Elevated levels of cytokines such as transforming growth factor-beta (TGF-β) and vascular endothelial growth factor (VEGF) translate into increased dermal fibrosis and proliferation of dermal capillaries, respectively (see Fig. 141.3). Capillary hyperpermeability and extravasation of red blood cells lead to deposition of ferric iron within affected skin, resulting in brown discoloration.

While the persistent inflammatory response gives rise to ulcer formation (see above), continued production of MMPs and cytokines (e.g. interleukin-1, tumor necrosis factor [TNF]) leads to impaired fibroblast function and increased degradation of growth factors necessary for wound healing. In addition, oxidative stress-induced premature aging and dysfunction of wound fibroblasts contribute to the chronicity of venous ulcers[10,11].

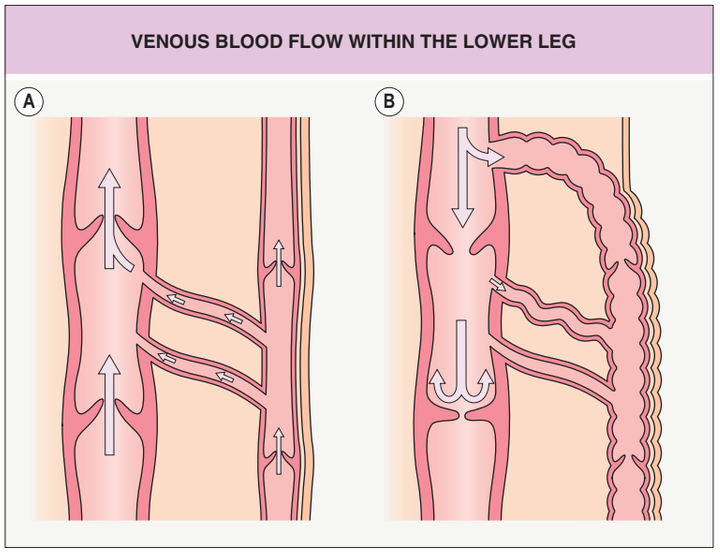

Fig. 105.2 Venous blood flow within the lower leg. A Under normal circumstances, blood is pumped against gravity towards the heart by the calf muscles. Blood flows from the superficial veins to the deep venous system via the perforating veins. Bicuspid valves ensure the unidirectionality of the blood flow. **B** When the valves are incompetent and/or hydrostatic pressure is elevated, blood flows back into the superficial venous system, leading to the formation of varicose veins.

Clinical Features

Chronic venous disease is associated with a wide spectrum of clinical findings, ranging from uncomplicated telangiectasias and varicose veins to lipodermatosclerosis and large chronic ulcerations[5]. Patients with venous ulcers often complain of swelling and aching of the legs, typically worsened by dependency and prolonged standing but improved by leg elevation, use of gradient support stockings or walking, all of which decrease venous pressure. Additional symptoms sometimes ascribed to chronic venous disease include muscle cramps, pruritus, and restless legs[4,5].

Most commonly, venous ulcers are located above the medial malleolus (Fig. 105.4). The ulcer is usually shallow with a border that is typically irregular; the wound bed is often covered by a yellow, fibrinous exudate. If the latter is appropriately debrided, a base of healthy, non-ischemic granulation tissue is usually seen. When untreated, venous ulcers tend

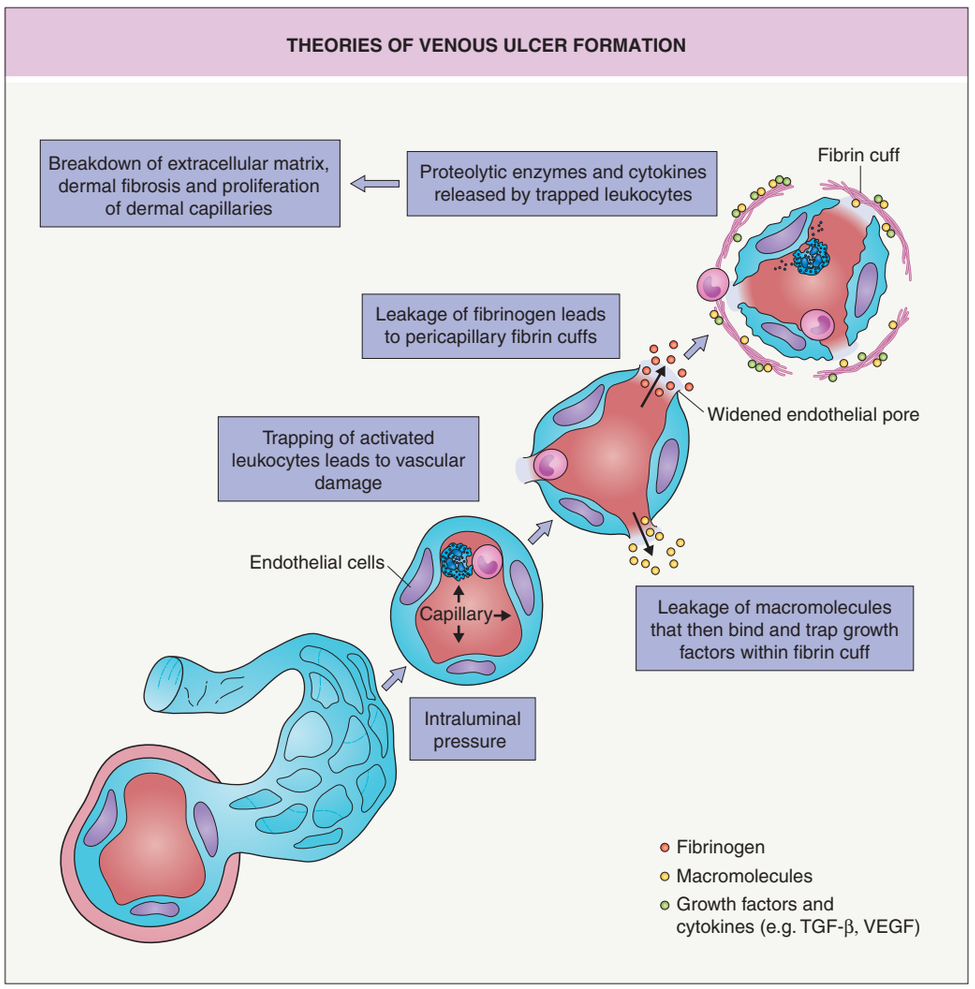

Fig. 105.3 Theories of venous ulcer formation. The theories include the presence of pericapillary cuffs due to leakage of fibrinogen, binding of growth factors by leaked molecules, and the trapping of leukocytes, with subsequent chronic inflammation, dermal changes, and ulcer formation. TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

Fig. 105.4 Venous ulcer and stasis dermatitis. Note the erythema, crusting, and scaling of the skin surrounding the ulcer of the medial malleolus. There is a yellowish fibrinous exudate and granulation tissue is seen in 15%–20% of the ulcer bed. In a chronic ulcer, the thickened rolled border is referred to as epibole.

to become larger than most other chronic wounds and can even become circumferential on the lower extremity[4]. Pedal pulses are usually palpable. If they are not palpable because of induration or edema, an ankle–brachial index (see below) should be obtained to exclude concomitant peripheral artery disease[5].

Characteristic associated features include (Fig. 105.5): (1) varicose veins of varying severity (see Ch. 155); (2) pinpoint petechiae superimposed on a yellow–brown discoloration due to extravasation of red blood cells and deposition of hemosiderin within macrophages (see Fig. 22.7), which is sometimes accompanied by hyperpigmentation; (3) edema; and (4) stasis dermatitis with pruritus, erythema, scaling, and weeping (see Ch. 13). Of note, stasis dermatitis is sometimes aggravated by allergic contact dermatitis to topically applied medications, e.g. neomycin. The smooth, ivory-white, sclerotic plaques of atrophie blanche that are often surrounded by punctate telangiectasias and/or brown discoloration are observed in up to 40% of patients with chronic venous insufficiency[12].

Patients with longstanding venous hypertension and insufficiency may develop chronic lipodermatosclerosis (also known as sclerosing panniculitis) with induration and fibrosis that begins on the lower medial aspect of the leg above the malleolus (see Fig. 105.5C, D). Eventually, the entire lower third of the leg may become involved, leading to an appearance that has been likened to an "inverted champagne bottle". Some authors believe the degree of lipodermatosclerosis correlates with delayed wound healing. Chronic lipodermatosclerosis may be preceded or accompanied by an acute inflammatory stage characterized by warm, erythematous, firm plaques that are tender and painful and are often misdiagnosed as cellulitis or another type of panniculitis, especially erythema nodosum[4].

Lipodermatosclerosis, along with ulcerations, is not limited to the lower extremities, as these changes can be seen in other sites such as the most dependent portion of the pannus (Fig. 105.6).

Laboratory Evaluation

Standardized evaluation of patients with chronic venous disease is based on the CEAP classification system which generates scores derived from objective clinical signs (C), etiology (E), anatomic (A) location of the affected veins, and pathophysiology (P) (reflux, obstruction, or both)[13]. Table 155.1 outlines the details of the CEAP classification system.

Color duplex ultrasonography, preferably performed with the patient in a standing position, is useful for assessing both reflux and obstruction within the deep, superficial, and perforating veins, from the inferior vena cava to the calf veins[14]. It provides information that is necessary when determining the CEAP score. For most indications, color duplex ultrasonography has replaced venography. The latter is an invasive test that can provide a detailed view of the venous system in preparation for reconstructive surgery and stenting procedures.

Pathology

In the skin surrounding the ulceration, nonspecific features are seen including reactive epithelial hyperplasia, dermal fibrosis, and an inflammatory infiltrate, along with a proliferation of capillaries, extravasation of red blood cells, and deposits of hemosiderin within macrophages. Biopsies are occasionally performed to exclude a neoplastic, vasculitic, vasculopathic, or infectious process.

Differential Diagnosis

A significant number of patients may have a combination of venous and arterial insufficiency, so before treatments such as compression stockings are prescribed, the latter should be excluded (see below). In patients with livedoid vasculopathy (Fig. 105.7) or recurrent deep vein thromboses, the possibility of thrombophilia (hypercoagulability) as a contributing factor needs to be considered (see Table 105.9 & Ch. 23). Additional clues from the history, e.g. rate of expansion, and physical examination aid in narrowing the differential diagnosis (Table 105.2). Histologic examination of a longstanding or recalcitrant ulcer is recommended to exclude other diagnoses, such as squamous cell carcinoma[12] or atypical mycobacterial infection (see Fig. 105.1), and the biopsy specimen should include surrounding non-ulcerated skin.

Treatment

Most of the therapeutic principles described in the following sections can be applied to the care of other types of cutaneous ulcers, unless otherwise specified. In general, normal wound healing requires adequate perfusion, good nutritional and immune status, and avoidance of deleterious mechanical forces[15]. The initial step in the approach to an ulcer should be to address all systemic and local factors that may impair healing.

Moisture and occlusion

In the past, the mainstay of wound management was to dry the wound bed with absorptive gauzes. A major breakthrough in the management of chronic wounds was the realization that a moist environment is critical for wound healing and occlusive dressings do not increase the risk of infection[16]. Moist retentive wound dressings stimulate collagen synthesis, promote angiogenesis by creating a hypoxic environment, encourage re-epithelialization, and decrease pain. By serving as a barrier against external contamination and by lowering wound pH, occlusive dressings actually decrease wound infection rates[15].

Dressings should be changed based on their potential for absorbency and the amount of exudate, with attention to the delicate balance between overhydration and excessive dryness. For example, occlusive dressings applied to highly exudative wounds may cause maceration and erosion of the surrounding skin, possibly leading to further deterioration of the wound. In addition, chronic wound fluid can perpetuate cytokine and MMP production (see above), thereby affecting the function of fibroblasts and growth factors and contributing to chronicity. It is therefore important to protect the skin surrounding the wound bed with an ointment in order to preserve barrier integrity[15].

Debridement

Debridement consists of the removal of necrotic, non-viable, or infected tissue from the wound bed in order to promote healing. In a sense, debridement is an attempt to shift the wound from a chronic state (with a milieu characterized by an abnormal extracellular matrix, an excess of proteolytic enzymes, and senescent cells) into an acute state. Debridement can be surgical (sharp debridement), mechanical (wet-to-dry), autolytic, chemical (enzymatic), and biologic (maggot therapy)[17].

Sharp debridement with surgical instruments represents the most rapid method for debriding a wound and is most appropriate for large necrotic and/or infected wounds. It also enables the clinician to estimate the extent and severity of a wound. Although damage to viable tissue is possible, sharp debridement performed by a skilled physician is usually highly selective[17]. Caution is advised in the case of arterial

Fig. 105.5 Associated findings in patients with venous hypertension and venous insufficiency. **A** Venulectasias of the instep referred to as corona phlebectasia. **B** Brown discoloration of the foot and ankle due to hemosiderin deposits within dermal macrophages in addition to hyperpigmentation. Note the cut-off at Wallace's line. **C** Lipodermatosclerosis with violet–brown discoloration, tenderness, and induration that typically begins above the medial malleolus. **D** Stasis dermatitis and chronic lipodermatosclerosis with serous crusts and the "inverted champagne bottle" or "bowling pin" configuration. **E** Acroangiodermatitis (pseudo-Kaposi sarcoma). Violaceous plaque in a patient with venous hypertension. Histologically, these lesions can resemble Kaposi sarcoma. *A, B, Courtesy Jean L. Bolognia, MD; C, Courtesy Kalman Watsky, MD.*

ulcers because of the potential risk for tissue desiccation and ulcer enlargement[15]. Sharp debridement may be associated with bleeding and pain and may necessitate analgesia.

Wet-to-dry (mechanical) debridement consists of placing gauze moistened with saline over the wound, allowing the gauze to dry, and then removing the dry gauze along with adherent non-viable tissue. It is relatively fast and easy to perform but is painful and does not discriminate between viable and non-viable tissue. It is indicated for wounds with large amounts of necrotic tissue.

Autolytic debridement is the process by which the body uses its own proteolytic enzymes and phagocytic cells to clear necrotic debris. The process is enhanced by moist retentive wound dressings and may require weeks to accomplish. Autolytic debridement is selective, painless, and suited primarily for wounds with minimal debris. It is contraindicated if the wound is infected[17].

Enzymatic (chemical) debridement utilizes topically applied proteolytic enzyme preparations such as papain–urea or collagenase to digest necrotic tissue, collagen, fibrin, and wound exudate. Chemical debridement is a gradual process. The papain–urea preparation contains papain, which is derived from the plant *Carica papaya* and is a non-selective cysteine protease. It is active over a broad pH range and is associated with an intense inflammatory response and digestion of viable tissue; local pain or a burning sensation is often described. Therefore, the product should be applied only to the wound bed and not to the surrounding intact skin. Collagenase preparations are derived from *Clostridium histolyticum*; they specifically target native collagen and are active within a narrow pH range of 6 to 8. These preparations are highly selective and do not harm viable cells[16]. Prior to application, it is advisable to cross-hatch the eschar, if present, in order to increase penetration[15].

POINTS TO INCLUDE IN THE HISTORY AND PHYSICAL EXAMINATION OF PATIENTS WITH A LEG ULCER	
History	**Physical examination**

• Onset and clinical course of ulcer
• Symptoms, including those of vascular disease or neuropathy
• Alleviating factors
• Exacerbating factors
• Past medical history, e.g. diabetes mellitus, ASCVD, autoimmune CTD
• Family history
• Medications, topical and systemic
• Personal habits (e.g. smoking, alcohol intake)
• Nutritional status
	General, emphasizing the following:
	• Ulcer characteristics
	  • Location and size
	  • Morphology, including depth, shape, border, and base
	  • Type and amount of exudate
	  • Surrounding skin, e.g. edema, dermatitis, fibrosis, cellulitis, necrosis
	• Peripheral pulses
	• Capillary refill time
	• Evidence of peripheral neuropathy
	• Deep tendon reflexes

Table 105.2 Points to include in the history and physical examination of patients with a leg ulcer. ASCVD, atherosclerotic cardiovascular disease; CTD, connective tissue disease. *Courtesy Tania Phillips, MD.*

Fig. 105.7 Livedoid vasculopathy. A Multiple hemorrhagic crusts and small, very painful ulcers associated with brown discoloration due to hemosiderin deposits. **B** Stellate, porcelain-white atrophic scars with peripheral telangiectatic papules, referred to as atrophie blanche. *B, Courtesy Julie V. Schaffer, MD.*

For therapy-resistant, chronic ulcers with marked necrosis and slough, *maggot debridement* therapy can be considered. Essentially, it exploits the ability of maggots to decompose necrotic tissue (benign myasis), but the debridement is done in a controlled manner so as to avoid undesirable effects on healthy tissues[18]. Degradation via proteinases that are in larval excretory/secretory products is thought to contribute to wound debridement[19]. It is important to select larval strains that feed preferentially on necrotic tissue and to avoid applying too many larvae to a wound. The flies most often employed are facultative calliphorids, in particular the green bottle blowfly, *Lucilia sericata*[18].

Maggots are used to treat various types of chronic ulcers, including pressure ulcers, venous ulcers, and neurovascular diabetic ulcers, as well as traumatic and postsurgical wounds. In a multicenter, randomized, open study that compared the clinical effectiveness of larval therapy to a standard debridement technique (hydrogel) for "sloughy" or necrotic leg ulcers, larval therapy did not improve the rate of healing or reduce bacterial load, but it did significantly reduce the time to debridement and increase ulcer pain[20].

Novel approaches to wound debridement are currently under investigation, including both hydrosurgery and ultrasound- and radiofrequency-based techniques[21].

Wound dressings

The ideal wound dressing should: (1) provide a moist retentive environment; (2) absorb excess exudate without causing maceration of surrounding skin; (3) protect against bacteria; (4) leave no residual debris but cause no trauma when removed; (5) decrease odor; and (6) relieve pain. In addition, the ideal wound dressing should be cost-effective, easy to handle, and be neither irritating nor allergenic. While there is no single dressing that can fulfill all these criteria throughout the entire healing process, a vast array of dressings exists, and the choice of a dressing depends upon the wound type and its characteristics at a given time (Table 105.3)[15,16].

Management of wound infection

The presence of a microbial infection is always detrimental to wound healing. However, all chronic open wounds are colonized with bacteria and it is important, although often difficult, to distinguish true infection from bacterial colonization. Of note, colonization is defined by the presence of replicating bacteria and adherent microorganisms, but without evidence of tissue damage.

Critical colonization is a relatively new concept in which the bacterial burden within a chronic wound does not elicit the typical symptoms or signs of an infection but does delay healing. The presence of $>10^6$ colony-forming units of bacteria/gram of tissue predicts delayed wound healing and a high risk for developing an infection[16]. More recent studies have demonstrated that in many chronic wounds, bacteria persist in the form of biofilms. The latter represent communities of bacteria, protected by an adhesive polymeric matrix cover, that communicate with each other

TYPES OF WOUND DRESSINGS			
Dressing type	**Properties**	**Disadvantages**	**Indications**

Gauzes	• Good absorption
	• Can be impregnated with:
	  • NaCl to become highly absorbent, discourage bacterial overgrowth, and prevent formation of excess granulation tissue
	  • petrolatum so less drying and adherent, but then less absorbent
	  • iodine or silver as an antiseptic
		• Adhere to wound bed and promote desiccation
		• Can cause pain and trauma, including removal of epithelium, upon removal
			• Wet wounds with heavy exudate
			• May serve as a secondary dressing

Films	• Semi-occlusive, thin polyurethane membranes • Maintain moisture • Permeable only to vapors, not to liquids • Transparency enables wound visualization	• Non-absorbent • Can cause maceration if applied to wounds with heavy exudate	• Wounds with minimal exudate • As a secondary dressing
Hydrogels	• Maintain a moist environment • Promote autolytic debridement • Non-adhesive • Relieve pain	• Can lead to maceration of skin surrounding wound if used in exudative wounds	• Dry wound • Wound with minimal exudate
Hydrocolloids	• Adhesive, occlusive dressings that absorb exudates with the formation of hydrophilic gel • Provide a moist environment	• Not suitable for wounds with heavy exudate or infected wounds • May produce a brown, malodorous exudate • May be traumatic on removal • Excess granulation tissue with prolonged use	• Wounds with a mild to moderate exudate
Alginates	• Fibrous dressings derived from brown seaweed • Highly absorbent and require moisture to function • Ion exchange between calcium in the alginate and sodium in the wound fluid leads to the formation of a moist retentive gel • Hemostatic	• May adhere to dry wounds • May leave fibrous debris in the wound • Can lead to maceration around the wound unless cut to the size of the wound bed	• Wounds with a moderate to heavy exudate • Undermined or tunneling wounds
Foams (polyurethane)	• Good absorbance capacity • Non-traumatic upon removal • Provide thermal and shear protection	• May produce malodorous drainage • Maceration around wound possible	• Wounds with a moderate to heavy exudate
Collagens	• Collagen matrix that physically entraps MMPs and facilitates growth factor activity	• Nonspecific inhibition of MMPs	• Clean, non-infected, recalcitrant chronic wounds

Table 105.3 Types of wound dressings. For additional details, see Chapter 145. MMPs, matrix metalloproteinases.

via water channels. Through these communication channels, bacteria are able to regulate the transcription of genes and protein products in a manner that is beneficial to them, but which can delay healing (quorum sensing)[16]. Biofilms are particularly resistant to antimicrobial therapy.

Wounds become clinically infected when host defenses are overwhelmed. Signs and symptoms of infection include an increased exudate, purulent discharge, pain, and surrounding erythema and swelling. However, sometimes an increase in ulcer size and malodorous or friable granulation tissue are the only clues to the presence of an active infection within a chronic wound. Systemic signs of infection such as fever, chills, tachycardia, and leukocytosis may suggest that the infection has progressed to a bacteremia or septicemia, although the former may be subtle in elderly patients, necessitating a high index of suspicion.

Most chronic wounds have a polymicrobial flora. Bacterial cultures usually grow aerobic Gram-positive cocci, which are often mixed with Gram-negative bacilli and sometimes anaerobes[22]. Clinically infected wounds should be cultured and treated initially with broad-spectrum systemic antibiotics. The antibiotic regimen is then adjusted based on the results of sensitivity testing.

In properly treated, non-healing wounds that demonstrate critical colonization, topical antimicrobials should be considered. Topical antimicrobial agents are divided into two major categories: antiseptics and antibiotics. Antiseptics have a broad antimicrobial spectrum as well as multiple microbial targets, but they are often toxic to host tissues. Topical antibiotics have specific cellular targets and a narrower spectrum of activity; they are not toxic to human cells but are more likely to induce bacterial resistance. Commonly used *topical antibiotics* include bacitracin, neomycin, mupirocin, retapamulin, ozenoxacin, gentamicin, and fusidic acid. However, topical antibiotics can cause allergic contact dermatitis, in particular neomycin and bacitracin. It is also preferable to avoid topical antimicrobials that have a systemic counterpart[22].

Commonly used *antiseptics* include hydrogen peroxide, chlorhexidine, iodine-based preparations (e.g. povidone-iodine, cadexomer iodine), and silver-releasing agents. Hydrogen peroxide and povidone-iodine have a broad antimicrobial spectrum with minimal resistance but may be cytotoxic. Cadexomer iodine is a complex of 0.9% elemental iodine plus cadexomer microbeads which are composed of a modified starch-based polymer. Upon absorption of exudate, the cadexomer beads swell and slowly release iodine into the wound bed, thus maintaining non-toxic iodine concentrations[23].

Silver is an effective antiseptic agent with broad-spectrum activity, including against methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and extended-spectrum β-lactamase producers. Resistance has rarely been reported, primarily with Gram-negative species[22]. Only the ionized form of silver (Ag^+) has antimicrobial properties, so exposure to wound fluid or exudate is required if the source is metallic silver[24]. Silver ions kill bacteria by damaging bacterial cell walls and intracellular and nuclear membranes as well as denaturing bacterial DNA, RNA, and key enzymes (e.g. respiratory enzymes)[15,24]. Silver may also promote cellular proliferation and re-epithelialization by inducing the production of metallothionein by epidermal cells. Metallothionein increases zinc- and copper-dependent enzymes required for cellular proliferation and matrix remodeling[24]. Silver has been incorporated into various dressing products (e.g. gauzes, hydrocolloids, alginates, foams) in addition to creams, gels, and barrier protectants which differ in their solubility and the rate at which silver ions are released into the wound bed[15]. Disadvantages of silver products include potential irritation, permanent blue–gray discoloration (localized argyria), and cost. Topical silver sulfadiazine has induced neutropenia in children which was reversible once the cream was discontinued[16].

Lastly, as chronic wounds may serve as a portal of entry for *Clostridium tetani*, it is recommended that the tetanus immune status of patients with chronic leg ulcers be assessed[25].

Adjuncts to wound care

Compression

Compression therapy is a mainstay in the treatment of venous insufficiency. Compression stockings improve venous return, reduce edema, stimulate healthier granulation tissue within venous ulcers[15], and improve quality of life[15]. A Cochrane meta-analysis of 39 randomized controlled trials concluded that compression therapy increased ulcer healing rates when compared to no compression[26].

Elastic stockings, preferably with graduated compression, are available in a wide range of compressive pressures (15 to 60 mmHg), lengths, and materials (Table 105.4). Lower levels of compression (20 to 30 mmHg) are sufficient for preventing mild edema, whereas higher levels of compression (30 to 40 mmHg) are required to control stasis dermatitis or lead to the healing of ulcers. Compression stockings also prevent the recurrence of venous ulcers once healed. Therefore, lifelong use of compression is recommended for patients with a history of venous ulcers[5]. In addition to stockings, there are other forms of compression such as bandages and wraps, as outlined in Tables 105.5 and 105.6. Of note, early endovascular ablation of superficial venous reflux as an adjunct to compression therapy led to faster healing of venous ulcers than compression therapy alone[27].

It is important to remember that compression therapy in patients with undiagnosed arterial insufficiency can lead to ulcer worsening, gangrene, or even limb amputation. As many patients with venous disease have concomitant arterial insufficiency, clinically significant arterial disease must be excluded before prescribing compression therapy. The latter is also relatively contraindicated in patients with uncompensated congestive heart failure[15].

Manual lymph drainage

Edema is a significant cause of delayed healing of venous ulcers. Identifying the cause of the edema is instrumental in choosing the appropriate therapy, which in turn is critical for ulcer resolution. However, even with identification and treatment of contributing factors (e.g. afterload reduction, diuretics), edema may be persistent.

Manual lymph drainage is a massage technique in which lymph conduits are contracted more frequently and lymphatic fluid is moved away from affected lymphedematous regions toward more centrally located, functioning lymph basins, thereby reducing edema volume. This manual drainage is employed during the early, intensive phase of lymphedema therapy and is combined with short-stretch compression bandaging applied immediately after treatment. The regimen also includes a series of exercises to increase lymphatic flow through functioning collateral pathways, skin care, and sometimes the use of intermittent pneumatic compression. This intensive, short-term

CLASSES OF COMPRESSION STOCKINGS		
Class	**Pressure at the ankle**	**Indication**
I	20–30 mmHg	Simple varicose veins
		Mild edema
		Leg fatigue
II	30–40 mmHg	Moderate edema
		Severe varicosities
		Moderate venous insufficiency
III	40–50 mmHg	Severe edema
		Severe venous insufficiency
		Post-thrombotic lymphedema
IV	50–60 mmHg	Elephantiasis

Table 105.4 Classes of compression stockings. *Adapted from Phillips TJ. Current approaches to venous ulcers and compression. Dermatol Surg 2001;27:611–21.*

TYPES OF COMPRESSION THERAPY		
Bandage	**Advantages**	**Disadvantages**
Elastic wraps (e.g. ACE™ bandage)	Inexpensive Can be reused	Often applied incorrectly by the patient Tend to unravel Do not maintain sustained compression Lose elasticity after washing
Self-adherent wraps (e.g. Coban™)	Self-adherent Maintain compression	Expensive Cannot be reused
Unna boot	Comfortable Protects against trauma Full maintenance of ambulatory outpatient status Minimal interference with regular activities Substitutes for a failing pump	Pressure changes over time Needs to be applied by well-trained physicians and nurses Does not accommodate highly exudative wounds
Four-layer bandage	Comfortable Can be left in place for 7 days Protects against trauma Maintains a constant pressure for 7 days because of the overlap and elasticity of the bandages Useful for highly exudative wounds	Needs to be applied by well-trained physicians and nurses Expensive
Graduated compression stockings	Reduce the ambulatory venous pressure Increase venous refilling time Improve calf pump function Different types of stockings accommodate different types of leg disorders Dressings underneath can be changed frequently	Often cannot monitor patient compliance Difficult to put on, unless have zipper or Velcro® straps
Orthotic device	Adjustable compression Sustained pressure Easily put on and removed Comfortable	Expensive Bulky appearance
Compression pump	Augments venous return Improves hemodynamics and microvascular functions Enhances fibrinolytic activity Prevents postoperative thromboembolic complications in high-risk patients	Expensive Requires immobility for a few hours per day

Table 105.5 Types of compression therapy. *Adapted from Choucair M, Phillips TJ. Compression therapy. Dermatol Surg 1998;24:141–8.*

CLASSES OF COMPRESSION BANDAGES	
Class	**Properties**
Class I	Lightweight and conforming
	Stretch and simple dressing retention properties
Class II	Also known as short stretch bandages
	Act like rigid, non-elastic bandages
	Used for light support
Class III	
• Class IIIA	Light compression bandages
• Class IIIB	Moderate compression bandages
• Class IIIC	Extra-high performance
	Achieve 40 mmHg at the ankle
	Useful for severe varicosities, severe edema, post-phlebitic syndrome

Table 105.6 Classes of compression bandages.

therapy is referred to as "complete decongestive physiotherapy" and is followed by a maintenance phase that consists of skin care, elastic compression, and exercise[28,29].

Topical negative pressure wound therapy

In topical negative pressure therapy, ideally performed using a vacuum-assisted closure (VAC) system, negative pressure is applied to hasten wound healing. It is used primarily for ulcers that are due to venous disease or diabetes. The system includes an open pore foam conduit (cut to the wound size) sealed with a semi-occlusive drape which is then attached to a vacuum source via a tube (see Fig. 145.13). When subatmospheric pressure (100–125 mmHg) is applied to the foam–wound interface (continuously or intermittently), accumulated fluid is transferred to a canister. Topical negative pressure therapy promotes wound healing by creating mechanical forces that stimulate a biological response while maintaining a moist environment. It also removes exudate, reduces edema, increases local perfusion, decreases the bacterial count, and enhances granulation tissue formation[15,30].

Before application, the wound must be debrided of necrotic tissue in order to prevent infection. Topical negative pressure therapy is contraindicated for ischemic wounds and ulcerated malignancies because it may cause necrosis of the wound edges and tumor growth, respectively. The foam should be changed every 48 to 72 hours. Sometimes, new granulation tissue grows into the foam, which can result in pain during foam changing. If this occurs, then the foam should be changed more frequently or a denser foam employed. In up to 25% of patients, there are complications such as pain, odor, periwound irritation or maceration, infection, bleeding, and necrosis; most of these problems can be avoided with careful patient selection and skilled management[30,31].

Skin substitutes

Patients with recalcitrant chronic ulcers can sometimes benefit from autologous skin grafting, especially when the ulcers are due to venous disease (see Ch. 148). However, there has been an increase in the use of biologic dressings and synthetic skin substitutes in such patients. Living skin substitutes are tissue-engineered products that contain a cellular component of autologous or allogeneic origin plus a biodegradable scaffold, and they serve as a replacement for the epidermis, dermis or both. These skin mimetics provide temporary wound coverage, serving primarily as a source for growth factors and extracellular matrix. Although effective in wound repair, their clinical use is still limited due to their high cost and complex technology (see Ch. 145)[32]. In general, these living skin substitutes are indicated for venous and diabetic ulcers.

There are also biologic dressings that consist of just an extracellular matrix (i.e. they have no cellular component). Structural extracellular matrix components, such as collagen, fibronectin, and proteoglycans, provide a temporary scaffold that supports cellular proliferation and migration. In addition, they contain cytokines, e.g. TGF-β, bFGF, which promote wound healing. These dressings are also used for diabetic and venous ulcers.

Another approach is a bio-inspired artificial hydrogel matrix that utilizes natural enzymatic reactions to become bioactive. It is able to incorporate and then deliver biomolecules (e.g. MMPs, growth factors) and at the same time be degraded and remodeled by them, ultimately being replaced by newly formed tissue. Emerging therapies include application of bone marrow-derived mesenchymal cells, mesenchymal stem cell-derived extracellular vesicles, and spraying of autologous fibroblasts and keratinocytes onto the wound[33,34].

Topical and oral medications

Daily, short-contact application of topical tretinoin solution (0.05%; currently requires compounding) was reported to stimulate granulation tissue formation and healing of chronic leg ulcers[35]. Application of small amounts of 0.025% tretinoin cream was also observed to induce neovascularization in ischemic wound beds[15]. Daily application of 0.5% timolol maleate solution (one drop per 2 cm of wound perimeter) can also improve healing of chronic diabetic and venous leg ulcers via promotion of keratinocyte migration[36]. Topical growth factors, in particular PDGF, have been utilized to enhance wound healing (see below).

Pentoxifylline, a drug that targets inflammatory cytokine release, leukocyte activation and platelet aggregation at the microcirculatory level, is occasionally a component of the treatment regimen for chronic venous insufficiency. Although evidence of a beneficial effect when the drug is used as monotherapy is largely lacking, pentoxifylline has been shown (at a dose of 1200 mg/day), in conjunction with compression therapy, to modestly improve ulcer healing as compared to compression plus placebo[37]. This effect has been attributed to the drug's fibrinolytic properties, antithrombotic effects, and/or ability to inhibit the production of proinflammatory cytokines.

The use of veno-active drugs, especially flavonoids such as micronized purified flavonoid fraction (MPFF), either alone or in combination with compression, may lead to improved healing of venous ulcers and a reduction in edema[38]. The proposed mechanism is inhibition of leukocyte trapping and as a consequence, a decrease in the release of proinflammatory molecules that damage the endothelium and increase capillary permeability.

Ulcers secondary to livedoid vasculopathy may benefit from antiplatelet and anticoagulant agents including aspirin, direct oral anticoagulants (DOACs), and low-molecular-weight heparin, as well as fibrinolytics, vasodilators, and immunosuppressants or immunomodulators (e.g. IVIg) (see Ch. 23).

Figure 105.8 outlines an approach to the patient with a presumed venous ulcer.

LYMPHEDEMA

Lymphedema is the accumulation of lymph fluid within the interstitium that is due to a reduction in lymph drainage in the presence of *normal* capillary filtration. Lymphedema should be differentiated from edema which results from an imbalance between capillary filtration and lymph drainage.

Lymphedema can be primary or secondary (Table 105.7). **Primary** lymphedema can be further subdivided based on age at time of clinical presentation, but because the time of onset may vary, even within the same family, genetic bases when known are currently used for classification[39]. *Congenital lymphedema* usually appears before 1 year of age and is sporadic or familial (e.g. lymphatic malformation 1 [Milroy disease]; Fig. 105.9). Meige disease (lymphatic malformation 5), classically a type of *lymphedema praecox*, is the most common form of primary lymphedema and it usually presents around puberty and more often affects girls. *Lymphedema tarda* usually presents after 35 years of age and is probably the result of an environmental trigger such as trauma or infection superimposed on inherently weakened lymphatics.

Common causes for **secondary** or acquired lymphedema are malignancy, radiation, and surgical lymph node dissection, as well as recurrent cellulitis, trauma, filariasis, morbid obesity, and chronic venous insufficiency (Fig. 105.10). Filariasis, due to infection of the lymphatics by the nematode *Wuchereria bancrofti*, is the most common cause of lymphedema in low-income tropical and subtropical countries. Podoconiosis, due to pedal exposure to volcanic soils, occurs most commonly in eastern Africa (Fig. 105.11A).

Clinically, lymphedema begins as painless pitting edema of the dorsal aspect of the foot which then progresses proximally. Over time, the skin becomes indurated due to fibrosis, and the affected areas are prone to ulceration and secondary infection. Recurrent infections lead to worsening of the lymphedema and a vicious cycle is established[28].

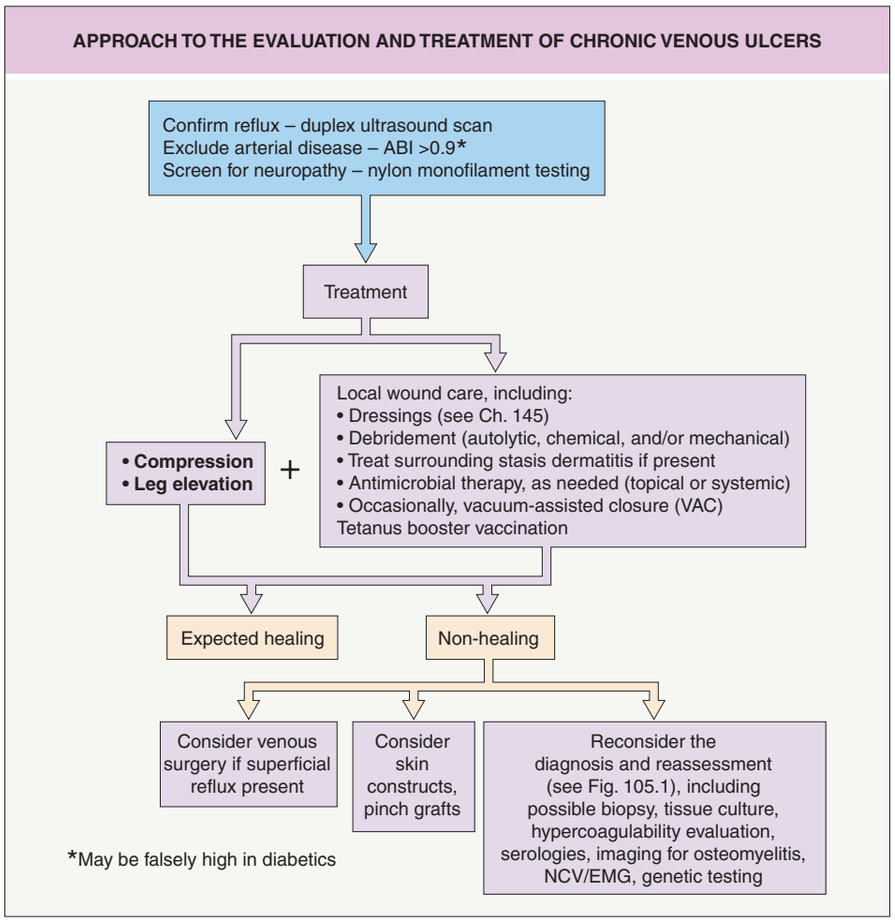

Fig. 105.8 Approach to the evaluation and treatment of chronic venous ulcers. See Table 105.8 for determination and interpretation of the ankle–brachial index (ABI). EMG, electromyography; NCV, nerve conduction velocity test.

CAUSES OF LYMPHEDEMA	
Primary lymphedema	**Secondary lymphedema**
Congenital lymphedema (presents at birth or within first 1–2 years of life)*	• Recurrent lymphangitis and cellulitis • Parasitic infections, e.g. filariasis • Lymph node dissection, e.g. for melanoma or breast cancer • Malignant obstruction, e.g. lymphoma, Kaposi sarcoma, retroperitoneal sarcoma • Radiation injury • Obesity • Surgical excisions, e.g. mastectomy, prostatectomy • Podoconiosis (exposure to mineral microparticles in volcanic soils) • Acne vulgaris and acne rosacea (midface) • Granulomatous disease (e.g. Crohn disease, granuloma inguinale, sarcoidosis)
• Congenital aplasia of the thoracic duct • Hypoplasia of peripheral lymphatics • Congenital abnormalities of the abdominal or thoracic lymphatics *Genetic disorders:* • Lymphatic malformation 1† (AD; *FLT4*), 2 (AD), 3 (AD; *GJC2*), 4 (AD; *VEGFC*), 5‡, 6 (AR; *PIEZO1*), 7 (AD; *EPHB4*), 8 (AR; *CALCRL*), 9 (AD; *CELSR1*), 10 (AD; *ANGPT2*), 11 (AD; *TIE*), 12 (AR; *MDFIC*) • Turner syndrome (see Ch. 55) • Noonan syndrome and other RASopathies (see Ch. 55) • Ectodermal dysplasia and immunodeficiency 1 (XLR; *IKBKG*)	
Lymphedema praecox (presents around puberty)*	
• Yellow nail syndrome • Lymphedema–distichiasis syndrome/lymphedema–distichiasis syndrome with renal disease and DM: AD (*FOXC2*) • Hypotrichosis–lymphedema–telangiectasia syndrome: AR or AD (with renal defect) (*SOX18*)	
Lymphedema tarda (presents after age 35 years)	

*Original classification was based upon age of onset, with an early onset termed Milroy disease and an onset around puberty termed Meige disease, but time of onset varied even within the same family so genetic bases now used for classification.
†Also referred to as Milroy disease.
‡Also referred to as Meige disease.

Table 105.7 Causes of lymphedema. In distichiasis, there is abnormal growth of eyelashes from the orifices of meibomian glands, leading to a double row of eyelashes. Table 104.2 lists additional forms of hereditary lymphedema, e.g. Hennekam lymphangiectasia–lymphedema syndrome 1, 2, 3 (*CCBE1*, *FAT4*, *ADAMTS3*), microcephaly with or without chorioretinopathy, lymphedema, or mental retardation (*KIF11*), and lymphedema, primary, with myelodysplasia (*GATA2*). WILD syndrome is discussed in Chapter 79, with the L representing lymphedema. AD, autosomal dominant; AR, autosomal recessive; DM, diabetes mellitus; XLR, X-linked recessive.

Elephantiasis nostras verrucosa is a complication of chronic lymphedema and most commonly affects the feet and distal lower extremities. In addition to profound non-pitting edema and progressive fibrosis of the dermis and subcutaneous tissue, there are verrucous changes with papillomatosis and hyperkeratosis (Fig. 105.11B). The skin acquires a mossy or cobblestone appearance and discrete firm fibrous papules or nodules may develop. Colonization with bacteria and fungi often results in ulcers becoming crusted and malodorous[40].

Elephantiasis nostras verrucosa is difficult to treat. Compression stockings, pneumatic pumps, and manual lymph drainage (see above)

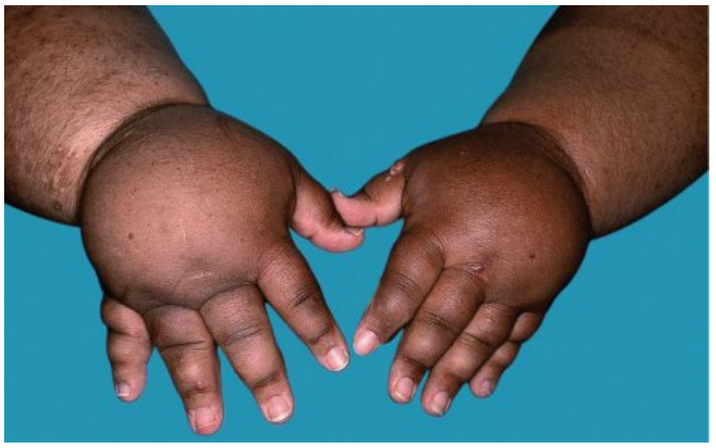

Fig. 105.9 Bilateral primary lymphedema due to lymphatic malformation 1 (also referred to as Milroy disease).

Fig. 105.10 Lymphedema secondary to morbid obesity associated with myxedema.

Fig. 105.11 Elephantiasis nostras verrucosa. A Podoconiosis (endemic, nonfilarial elephantiasis) due to pedal exposure to volcanic soils. **B** The patient had both lymphedema and venous insufficiency. Note the involvement of the foot. *A, Courtesy Claire Fuller, MD.*

are used to decrease lymph accumulation. Topical keratolytics or humectants, such as salicylic acid and urea, may improve the hyperkeratosis[40]. Oral retinoids have been reported to be of benefit for both the verrucous changes and the lymphedema[41]. Surgical management of lymphedema includes physiologic procedures such as lymphaticovenous anastomosis for relatively early (stage I) lymphedema. Debulking and reduction surgery with preservation of perforators are reserved for patients with advanced (stage III) disease[42].

Fig. 105.12 Lipedema. This middle-aged woman has bilateral "stovepipe" enlargement of the legs and minimal involvement of the feet. Note the sharp demarcation between normal and abnormal tissue at the ankle, referred to as the "cuff sign". *Courtesy Jean L. Bolognia, MD.*

The differential diagnosis includes lipedema[43], in which there is an abnormal deposition of subcutaneous fat and lymphatic vessel dysfunction with sparing of the feet (Fig. 105.12), thyroid dermopathy (pretibial myexedema), and obesity-associated lymphedematous mucinosis, where there can be dermal mucin deposition in the absence of thyroid disease.

ARTERIAL ULCERS

Peripheral arterial disease (PAD) is a common manifestation of atherosclerosis. Cigarette smoking and diabetes mellitus are the strongest risk factors, with hypertension, dyslipidemia, and hyperhomocysteinemia representing additional risk factors[44]. Up to 25% of patients with leg ulcers have PAD, and a significant number of patients have a combination of arterial and venous insufficiencies[15].

Pathogenesis

A lack of blood perfusion decreases tissue resilience and leads to tissue necrosis; it also impedes wound healing by reducing the supply of oxygen, nutrients, and soluble mediators involved in the repair process. Although PAD alone infrequently precipitates ulceration, arterial insufficiency plays a major role in delayed wound healing and complications including gangrene. Ischemic foot ulcers are often precipitated by trauma in a patient with relatively mild symptoms of arterial insufficiency. In such an individual, the degree of skin perfusion is sufficient to maintain cutaneous integrity but is not adequate enough to support proper wound healing. In such a setting, the ulcer will inevitably progress into a chronic wound or gangrene unless perfusion is restored[45].

Clinical Manifestations

Most patients with significant PAD are symptom-free. Intermittent claudication, defined as leg pain induced by ambulation and relieved by resting, represents the earliest and the most common presenting symptom of PAD of the lower extremities. With disease progression, patients begin to complain of pain at rest, especially when the legs are elevated in bed at night, which is ameliorated by dependency. While symptoms of claudication are usually localized to the calf or the thigh, pain at rest is often felt in the feet. In advanced stages of PAD, the reduction in cutaneous blood supply may lead to ischemic ulceration and gangrene, and this may necessitate amputation[46].

Arterial ulcers are usually round with a sharply demarcated border and are characterized by an absence of bleeding (Fig. 105.13). These wounds typically occur on the distal lower extremities, often over bony prominences. The surrounding skin may be hairless, shiny, and atrophic. Wound pain is often significant and is exacerbated by limb elevation.

Fig. 105.13 Arterial ulcer. The punched-out appearance and surrounding smooth shiny skin are common features.

Fig. 105.14 Cholesterol emboli. Ischemia of the toes and necrosis with early ulcer formation.

DETERMINATION AND INTERPRETATION OF THE ANKLE–BRACHIAL INDEX

- With the patient in a supine position, the systolic blood pressure is measured in the:
  - brachial arteries (right and left)
  - dorsalis pedis and posterior tibial arteries (right and left)
- The ABI is determined by:

$$\frac{\text{the highest of the systolic pressures from the dorsalis pedis or posterior tibial arteries}}{\text{the higher of the brachial artery systolic pressures}}$$

- Interpretation of the ABI:
  - 0.91–1.40 = normal range
  - >1.40 = suggests incompressible tibial arteries due to medial calcification (diabetes mellitus, chronic renal insufficiency, older age; in these patients the toe–brachial index is measured)
  - <0.9 = indicative of peripheral artery disease (PAD)
  - 0.71–0.90 = mild PAD
  - 0.41–0.70 = moderate PAD
  - 0.00–0.40 = severe PAD

Table 105.8 Determination and interpretation of the ankle–brachial index (ABI).

Additional manifestations of impaired arterial perfusion to the foot include diminished or absent pedal pulses, cool feet, pallor of the foot with elevation of the leg and then subsequent redness with lowering (dependent rubor), sluggish refilling of toe capillaries, thickened nails, and absence of toe hair (see Table 105.1)[15,45].

Laboratory Evaluation

The ankle–brachial pressure index, more commonly referred to as the ankle–brachial index (ABI), is a simple, non-invasive test that is widely used for diagnosis of PAD and to assess its severity. The ABI is calculated by dividing the systolic blood pressure in the ankle by the systolic blood pressure in the arm while the patient is in a resting supine position (Table 105.8). A decrease in arterial blood pressure at the ankle (relative to the central blood pressure) implicates arterial stenosis at any point between the aorta and the ankle[47]. The normal range for the ABI is 0.91 to 1.40, with a reading <0.9 being indicative of PAD[48].

Depending on the patient's presentation and symptoms, further non-invasive imaging techniques may be employed, including duplex ultrasound, computed tomography angiography (CTA), and magnetic resonance angiography (MRA). Both CTA and MRA produce images of vascular structures in cross-sectional slices that can be reconfigured into three-dimensional angiographic images. CTA is less expensive than MRA, with higher spatial resolution. However, CTA involves ionizing radiation and the use of iodinated contrast material. The gold standard for diagnosis and evaluation of PAD is invasive digital subtraction angiography[44], but amongst radiologists, it is being replaced by CTA and MRA.

Measurement of transcutaneous oxygen pressure (TcPO2) quantifies skin oxygenation and indirectly assesses blood flow. The reduction in TcPO2 correlates with the severity of lower extremity ischemia[49], and when the TcPO2 is <40 mmHg, wound healing is impaired.

Differential Diagnosis

Patients with PAD can also develop cutaneous ulcers due to *cholesterol emboli* (Fig. 105.14) and risk factors include arterial or coronary catheterization and anticoagulation (see Ch. 23). In *Buerger disease*, ulcers occur distally on both the upper and lower extremities, with smoking as a risk factor. *Martorell hypertensive ischemic ulcers* result from arteriolosclerosis and in contrast to arterial ulcers, they are typically located on the posterolateral leg. These ulcers are characterized by excruciating pain and patients have treatment-resistant hypertension. Histologically, subcutaneous stenotic arteriolosclerosis and medial calcinosis are prominent. Treatment includes surgical debridement, skin grafting, and pain and blood pressure control.

Additional disorders to consider are shown in Figure 105.1, including diffuse dermal angiomatosis (see below).

Treatment

Arterial ulcers can benefit from restoration of peripheral arterial blood flow, either by endovascular interventions (e.g. percutaneous angioplasty, stent placement, cryoplasty) or by more invasive surgical reconstruction (e.g. femoral popliteal bypass)[15]. In principle, local treatment of arterial ulcers is similar to that of other types of skin ulcers, with two major exceptions: (1) sharp debridement should be performed very cautiously or avoided in order to prevent further necrosis and ulcer enlargement; and (2) VAC therapy should be avoided as it can lead to worsening of the ulcer. Additional interventions include smoking cessation, exercise training, antiplatelet drugs (e.g. aspirin, clopidogrel), cilostazol, and treatment of diabetes, hyperlipidemia, and hypertension.

DIABETIC (AND NEUROPATHIC) ULCERS

Patients with diabetes mellitus have a 10%–25% lifetime risk of developing a foot ulcer. These foot ulcers constitute a major medical and economical burden, with a substantial morbidity and impaired quality of life. Approximately 15% of diabetic patients with foot ulcers will eventually undergo a lower extremity amputation. The rising incidence of both type 1 and type 2 diabetes has made diabetic foot ulcers the most important risk factor for lower extremity amputation in high-income countries[50,51].

Pathogenesis

The etiology of diabetic ulcer formation is multifactorial. Although ischemia, trauma, and infection have traditionally been incriminated as underlying pathogenic factors, nowadays diabetic neuropathy is considered to be the major cause of foot ulcers in diabetic patients[52].

Diabetic neuropathy typically involves the sensory, motor and autonomic nerves, with *sensory* neuropathy substantially impairing the patient's perception of touch, deep pressure, temperature, and joint position. With the loss of protective sensation, foot trauma is unrecognized and this can lead to ulceration. Peripheral *motor* neuropathy results in weakness and atrophy of the intrinsic muscles of the feet, producing altered biomechanics and structural deformities that, in the presence of sensory neuropathy, increase the risk for skin injury and ulceration from repetitive mechanical stress. Continuous pressure to the skin overlying bony prominences typically results in the formation of a thick, keratotic plaque (callus), which eventually breaks down and ulcerates[15,52]. *Autonomic* neuropathy also plays a role because it can lead to a loss of sweating, with the resultant dry skin being susceptible to cracks and fissures that serve as a portal of entry for bacteria[52]. In addition, a potential consequence of autonomic neuropathy is arteriovenous shunting within the skin microcirculation which results in decreased cutaneous perfusion and oxygen saturation, thus contributing to ulceration and an impaired response to infection[50]. Moreover, this abnormal vascular autoregulation, coupled with sensory neuropathy, contributes to the development of Charcot joints (degenerative arthropathy), further adding to the risk of ulceration from an abnormal distribution of pressure forces and foot deformities[53].

Diabetes is also associated with an increased risk of developing PAD, which characteristically affects vessels between the knee and the ankle[51]. Although microcirculatory dysfunction occurs early on in the course of diabetes, it is primarily atherosclerotic macrovascular disease that accounts for ischemic complications in these patients[50]. In general, diabetic foot ulcers are not purely related to vascular occlusion; rather, mechanical damage that typically occurs to the insensate foot, in the presence of a decreased blood supply, rapidly results in neuroischemic ulcers. PAD also contributes to an altered response to foot infections and poor wound healing. The combination of a depressed immune response plus a decrease in cutaneous blood supply plays a key role in the development of cellulitis, abscesses, and osteomyelitis, all of which increase the risk of limb amputation[53].

Occasionally, patients with diabetes develop ulcerations within lesions of necrobiosis lipoidica as well as ulcers due to streptococcal infections.

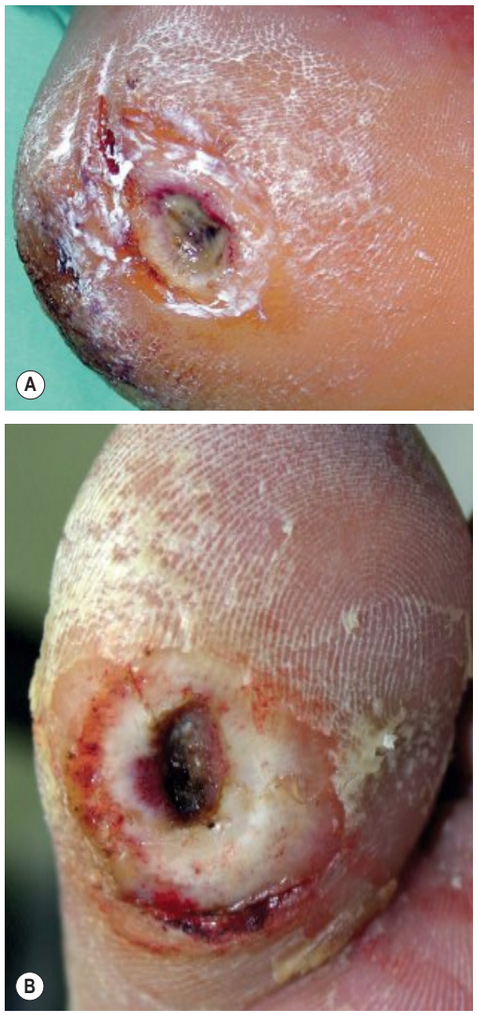

Fig. 105.15 Neuropathic ulcers (mal perforans) in patients with diabetes mellitus and peripheral neuropathy. Common locations are the plantar surface of the heel (**A**) and the great toe (**B**). Note the thick rim of callus.

Clinical Features

Diabetic ulcers are usually located on pressure points and bony prominences such as the metatarsal heads, great toes, and heels (Fig. 105.15). They often arise within exuberant, moist, malodorous calluses (mal perforans). In the absence of peripheral atherosclerotic disease, the diabetic foot is warm, with good color and palpable pulses, but with decreased sensation. Foot deformities are frequently present, e.g. hammer toes, claw toes, collapse of the longitudinal arch (Charcot foot).

Laboratory Evaluation

Because diabetic ulcers are heterogeneous in nature, a thorough evaluation of the patient is crucial in determining the underlying causes. More specifically, peripheral neuropathy can be detected via a neurologic examination of the lower extremities that includes the use of a 10 g monofilament to test for sensation[54]. More invasive testing, i.e. nerve conduction studies/electromyography, is sometimes required. The degree to which vascular perfusion is compromised can be assessed via determination of the ABI (see above).

A complete blood count, ESR, C-reactive protein level, and blood glucose level are obtained when assessing for a possible associated infection. Of note, sometimes an elevated blood glucose level is the only sign of infection[55]. Microbial cultures (bacterial, mycobacterial, and fungal) should be obtained from the wound bed. Although swabs are often used, deep tissue specimens, obtained aseptically, are preferable[54].

Diagnostic imaging, including plain radiographs of both feet, bone scintigraphy, MRI, CT and sometimes ultrasound, is used to better define the presence or absence of a bone or deep soft tissue infection. Of these, MRI is the most accurate test for diagnosing osteomyelitis. If osteomyelitis is suspected, a bone biopsy processed for culture and histology is the gold standard[51,52].

Treatment

Conservative treatment of diabetic foot ulcers consists of providing a proper wound healing environment, eradication of infection, and avoidance of repetitive trauma by alleviating the mechanical load on ulcers (off-loading). Methods of off-loading include bed rest and the use of a wheelchair, crutches, total contact casting, cast walkers, felted foam, half-shoes, or therapeutic shoes. Total contact casting is considered to be the best approach as it enables pressure redistribution and continuous off-loading of the ulcer area. The inability of the patient to remove the cast ensures compliance and reduces the level of activity[54,56]. However, total contact casting is somewhat impractical because it is expensive and requires skill and experience. In addition, as the edema subsides, cast changing and size adjustments are often required (usually twice a week or more often). Total contact casting is contraindicated if the wound is infected or has a significant exudate and it can lead to new ulcerations over bony prominences[52].

Another approach to off-loading is the use of specialized shoes that reduce pressure about the forefoot and heel and multilayered insoles that enhance shock absorption[52]. Half-shoes assist in off-loading forefoot plantar ulcers as they support only the rear and mid foot, while the forefoot is left suspended in the air[54].

Initial wound management consists of cleansing the wound and proper debridement of any necrotic material, including the callus; the latter can contribute to increased pressure on the insensate foot. In addition, debridement promotes wound healing at the cellular level by removing excess extracellular matrix, thus liberating trapped growth factors and facilitating cell migration[53]. Moist wound healing is recommended as with other types of chronic ulcers but avoidance of maceration of surrounding skin is of particular importance.

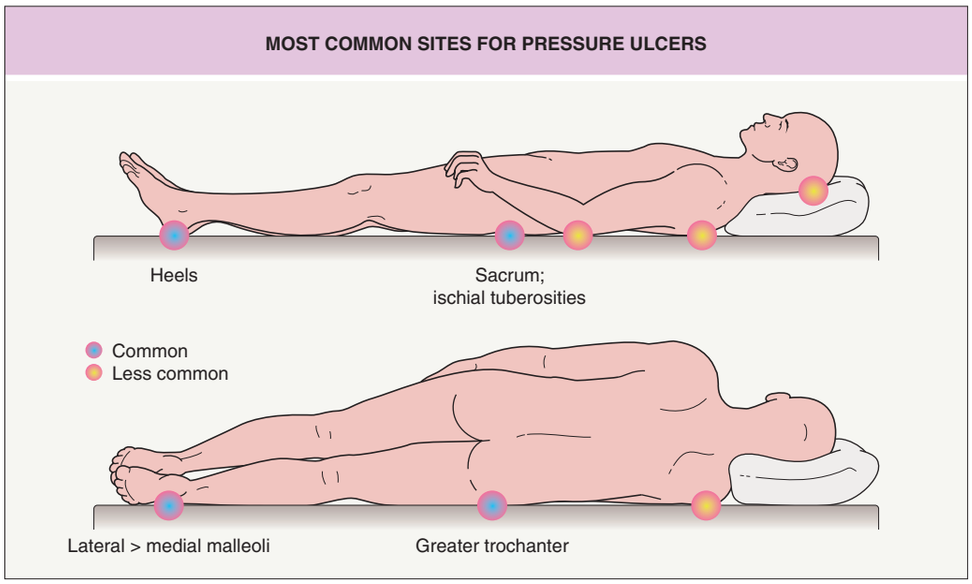

Fig. 105.16 Most common sites for pressure ulcers.

Apart from standard therapies (see above), hyperbaric oxygen has been shown to be of specific benefit to patients with diabetic foot ulcers. While it is unclear to what extent it benefits other types of ulcers[57], hyperbaric oxygen therapy has been shown to be effective in the treatment of diabetic foot ulcers, with a decrease in healing time and amputation rate. Oxygen (100%) at supra-atmospheric pressures is intermittently inhaled, either in a full-body (monoplace) chamber or in a multiplace chamber via a gas mask. In theory, tissue hypoxia impairs wound healing and hyperbaric oxygen therapy leads to an increase in the blood oxygen level within the wound. In addition, there is reallocation of blood flow to hypoxic areas due to hyperoxic vasoconstriction of surrounding normal tissue[58]. Side effects include oxygen toxicity to the brain (e.g. seizures) and lungs, and barotrauma to the lungs, ears, sinuses, and eyes (transient myopia)[15].

As endogenous growth factors are often degraded or trapped within chronic wounds, genetically engineered exogenous growth factors have been used to try to enhance wound healing[59]. Becaplermin gel (Regranex®) is recombinant platelet-derived growth factor whose biologic activity is similar to its endogenous counterpart, with stimulation of granulation tissue production and release of other growth factors important to wound repair. It is the only growth factor currently approved for use in chronic neuropathic diabetic ulcers[15]. In the setting of best wound care, becaplermin gel has been shown to increase healing rates and shorten healing time of diabetic ulcers[60]. However, in routine clinical practice, becaplermin has not been as successful and it has an FDA black box warning of an increased risk of cancer mortality (when exposed to three or more tubes). More recently, strategies have focused on improving growth factor activity and protecting these factors from degradation[32].

Living skin equivalents (e.g. Apligraf®, Dermagraft®) are bioengineered products that act as delivery systems for growth factors and extracellular matrix (see Ch. 145)[61–63]. Both are indicated for recalcitrant diabetic foot ulcers that have no exposed muscle, bone or tendon, are not infected, and have had aggressive debridement.

Prevention

Preventing wound recurrence is of critical importance. The risk of ulceration and/or amputation is increased in patients who have had diabetes for >10 years, are male, have poor glucose control, or have target organ complications. Foot-related conditions that are associated with an increased risk of amputation are peripheral neuropathy, altered biomechanics, evidence of increased pressure, foot deformity, PAD, history of an ulcer or previous amputation, and severe nail pathology[64]. Tight control of glucose levels is required in order to prevent diabetic complications that are due to microvascular changes, as the latter predispose the patient to neuropathy, ischemia, and infection. Lower HbA1c values are associated with a decrease in healing times for leg and foot ulcers[65]. Smoking cessation and control of low-density lipoprotein (LDL) and total cholesterol levels are also important in the prevention of atherosclerotic vascular disease.

All diabetic patients should receive an annual foot examination to assess neurologic and vascular status, biomechanics, skin integrity, and the presence and types of foot deformities. Patients with significant risk factors for ulcer formation should be evaluated more frequently. Education regarding daily foot care that includes inspection for any scratch, blister or erythema, daily washing in warm water, appropriate footwear selection (e.g. avoiding pointed shoes), skin moisturizing, and treatment of nail and foot fungal infection should be provided.

ULCERS DUE TO PHYSICAL FACTORS

Any form of mechanical trauma to the skin can result in the formation of an ulcer if factors that compromise the skin's ability to recover from physical insults are present. The most common form of physical injury which leads to ulceration is prolonged pressure due to immobilization. The resultant ulcer is commonly referred to as a *pressure ulcer* or *decubitus ulcer* (decubitus means lying down in Latin). These ulcers are caused by unrelieved pressure to soft tissues compressed between a bony prominence and an external surface. The most common bony prominences involved are the sacrum, ischial tuberosities, greater trochanters, heels, and lateral malleoli[66] (Fig. 105.16). A special type of pressure ulcer, often presenting as a pear- or butterfly-shaped ulcer in the sacral area, is termed a Kennedy terminal ulcer because it often precedes death.

Approximately 1.5–3 million people in the US have pressure ulcers, with an annual cost of treatment of up to $5 billion[66]. It has also been estimated that 10% of hospitalized patients and 25% of nursing home residents have pressure ulcers, with most developing during the first few weeks of hospitalization. An estimated 70% of pressure ulcers occur in patients over 70 years of age; 95% are located on the lower portion of the body: 65% in the pelvic girdle area (Fig. 105.17) and 30% on the lower limbs (Fig. 105.18). Risk factors that predispose to the development of pressure ulcers include prolonged immobility, sensory deficit, circulatory disturbance, and poor nutrition[66].

Pathogenesis

Four major etiologic factors have been identified as playing an important role in the development of pressure ulcers: external pressure, shearing forces, friction, and moisture.

Interstitial pressures >32 mmHg (normal capillary pressure range = 12–32 mmHg) usually compromise oxygenation and microcirculation. There is an inverse time–pressure curve, with slow ulcer

Fig. 105.17 Pressure ulcer (stage III) over the sacral area.

Fig. 105.18 Black eschar of the heel at site of pressure necrosis.

formation at low pressures and rapid ulcer formation at high pressures (>70 mmHg). The length of continuous exposure of the skin to pressure is also of critical importance, thus explaining why intermittent relief of the pressure can prevent ulcer formation. Because subcutaneous tissues are most susceptible to the damaging effects of prolonged exposure to pressure, deep tissue trauma can occur with relatively little superficial damage that would alert caregivers to the extent of tissue injury[66].

Shearing forces result from the sliding and relative displacement of two apposing surfaces. Although externally applied pressure is more effective than shearing forces alone in reducing skin arteriolar blood flow, these two factors can combine to enhance vascular occlusion. When the head of a supine patient is raised more than 30°, shearing forces occur in the sacral and coccygeal areas. Sliding of the torso transmits pressure to the sacrum and deep fascia, as the outer sacral skin is fixed because of friction with the bed. Vessels within the deeper portion of the superficial fascia angulate and thrombose, which manifests clinically as undermining of the ulcer[66].

Friction is often associated with shearing and it reflects the degree of resistance generated when two surfaces move across each other. When a bedridden patient is dragged across the bed sheets, friction is produced. Damage to the protective stratum corneum enhances ulcer formation by compromising the skin barrier.

Moisture results from perspiration due to fevers and from urine and feces. It has been shown to increase the risk of pressure ulcer formation fivefold[66].

Clinical Features

Pressure ulcers are usually classified according to a four-stage system designed by the National Pressure Ulcer Advisory Panel (NPUAP) (Fig. 105.19). Of note, the ulcers do not necessarily progress sequentially from stage I to stage IV, nor do they necessarily heal from stage IV to stage I[67].

- *Stage I*: non-blanchable erythema of intact skin which heralds skin ulceration. For individuals with more darkly pigmented skin, warmth, edema, discoloration of the skin, and induration may serve as indicators of impending ulceration[66,67].
- *Stage II*: partial-thickness skin loss involving the epidermis, dermis, or both. This superficial lesion presents as an erosion, blister, or shallow ulcer[66,67].
- *Stage III*: full-thickness skin loss with damage to the subcutaneous tissue, extending down to (but not including) the underlying fascia. This deep lesion presents as a crater-like ulcer and sometimes involves adjacent tissue[66,67].
- *Stage IV*: full-thickness skin loss and extensive tissue necrosis with destruction extending to muscle, bone, or supporting structures such as tendons or joint capsules. Undermining or sinus tracts can be present[66,67].

As mentioned previously, a major limitation in the clinical classification of pressure ulcers stems from the fact that extensive deep tissue damage may be accompanied initially by minimal superficial manifestations. Adequate evaluation may also be hampered by the presence of an eschar, which should be debrided for full assessment[66].

Pathology

When the diagnosis is in doubt or when a secondary malignancy is suspected in the setting of a longstanding lesion, histologic examination is indicated. In all four stages, the histopathologic findings are rather nonspecific. When there is *blanchable* erythema clinically, the superficial dermal capillaries and venules are dilated. Mild to moderate edema within the papillary dermis is seen in association with a mild perivascular lymphocytic infiltrate. The epidermis, pilosebaceous structures, and reticular dermis remain normal. At the stage of *non-blanchable* erythema, engorgement of capillaries and venules with red blood cells, platelet thrombi, and hemorrhage are observed in the papillary dermis. Although the epidermis still appears normal, sweat gland and subcutaneous fat degeneration is often present[66]. Subepidermal separation can occur with formation of a subepidermal bulla. In early ulcers, the epidermis is lost and acute inflammation of the papillary and reticular dermis is seen. Chronic ulcers have a diffusely fibrotic dermis with a loss of adnexa. The surface may have a hemorrhagic crust containing acute inflammatory cells or a thin zone of coagulation necrosis. In the black eschar stage, full-thickness destruction of the skin occurs. General dermal architecture is preserved, but there is obliteration of cellular details.

Treatment

Pressure ulcers are preventable, primarily by relief of pressure on the skin. This can be accomplished by frequent position changes in addition to use of a variety of support surfaces to relieve pressure; the latter include air- or liquid-filled flotation devices, foam products, and pillows or foam wedges as positioning devices. Adequate nutrition, education, pain management, and psychosocial support are also important interventions. Causes of immobility and systemic conditions that interfere with wound healing or decrease tissue perfusion must be addressed, including congestive heart failure, diabetes, and/or spastic paresis.

The general principles of ulcer and chronic wound care discussed previously also apply to pressure ulcer management. Briefly, debridement may be accomplished via mechanical, enzymatic, and/or autolytic means (see above). Wounds should be cleansed as non-traumatically as possible, and normal saline for irrigation is preferred rather than cytotoxic agents such as hydrogen peroxide or povidone-iodine.

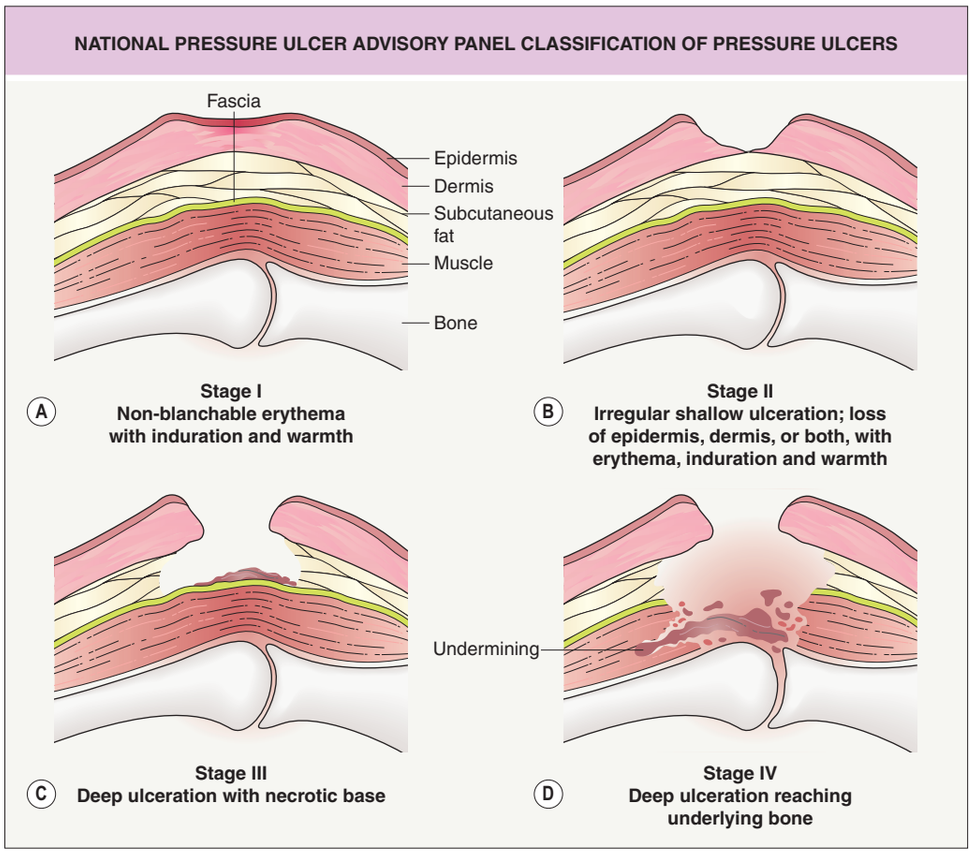

Fig. 105.19 National Pressure Ulcer Advisory Panel classification of pressure ulcers. A Stage I: non-blanchable erythema of intact skin. This lesion is the heralding sign of impending skin ulceration. For darker-skinned individuals, other signs may be indicators and include warmth, edema, discoloration of the skin, and induration. **B** Stage II: partial-thickness skin loss involving the epidermis, dermis or both. This superficial lesion presents as an abrasion, blister, or shallow crater. **C** Stage III: full-thickness skin loss, in which subcutaneous tissue is damaged or necrotic and may extend down into, but not including, the underlying fascia. This deep lesion presents as a crater and sometimes involves adjacent tissue. **D** Stage IV: full-thickness skin loss and extensive tissue necrosis, destruction to muscle, bone, or supporting structures such as a tendon or joint capsule. Undermining or sinus tracts can be present.

As always, bacterial colonization and infection must be controlled. Dressings should provide a moist, but not macerated, environment and occlusive dressings are often utilized.

In general, stage I, II, and III pressure ulcers are more likely to heal with local therapy, whereas stage IV ulcers, particularly those over the ischial tuberosities, often require surgical intervention. Adjuvant therapies such as laser, ultrasound, hyperbaric oxygen, and UV irradiation are investigational and to date cannot be considered as standard of care. The application of growth factors, cultured keratinocyte grafts, and skin substitutes is promising, but these are also still in the investigational stage.

OTHER CAUSES OF SKIN ULCERATION

Ulcers that are apparently recalcitrant to prescribed treatments should be reevaluated regarding compliance with the program of care, and when non-compliance is excluded, then rare or unusual causes should be considered (Fig. 105.20; see Fig. 105.1).

Diffuse Dermal Angiomatosis

Diffuse dermal angiomatosis is an unusual manifestation of vascular atherosclerosis. There is rather rapid development of one or several violaceous plaques in a reticulated pattern, often with central ulceration. The lesions are typically painful and are usually located on the lower extremities, but they may appear elsewhere (e.g. breast, forearm) (see Fig. 105.20A). Histologically, a diffuse interstitial proliferation of CD31-positive endothelial cells is present within the papillary and reticular dermis, with focal formation of small vascular channels. Cytologic atypia and atypical mitoses are absent.

Interventions to correct the underlying PAD, such as femoral artery angioplasty or femoral popliteal bypass surgery, lead to rapid resolution. Less often, lesions resolve without therapy[68].

Hematologic Disorders

Anemia is a major and often underrecognized cause for delayed wound healing. It prevents proper tissue oxygenation. In addition, some forms of anemia are associated with a marked tendency for ulcer formation, such as the hemoglobinopathies (see Fig. 105.20C)[69]. Hematologic malignancies are also associated with ulcerative processes including pyoderma gangrenosum, vasculitis, and cryoglobulinemia (particularly type I). Clotting abnormalities can play a direct role in the formation of ulcers (e.g. antiphospholipid antibody syndrome)[70,71], as well as serving as a predisposing factor for more common types of cutaneous ulcerations such as venous ulcers[72,73]. Acute massive venous thrombosis, also known as phlegmasia cerulea dolens, can lead to massive edema in the legs, with subsequent ischemia and ulceration due to venous limb gangrene[74]. Table 105.9 summarizes the recommended evaluation when thrombophilia is suspected.

Tropical Ulcers

These ulcers are found in children and adults residing in the tropics who typically live in rural areas and are malnourished or otherwise debilitated. They may also occur in travelers returning from those areas. Although many tropical diseases manifest with chronic ulceration, the term "tropical ulcer" is often used to describe a phagedenic ulcer, usually located on the leg, which often occurs secondarily to minor trauma[75]. The ulcer is invariably associated with a polymicrobial infection including *Fusobacterium* spp., other anaerobic bacteria, and spirochetes.

Tropical ulcers are always painful and progress rapidly to often involve deep tissues. The edges are undermined and violaceous, and malignant degeneration can occur. Assessment includes a smear and cultures plus soft tissue and bone imaging when deep involvement is suspected. These ulcers are best managed with systemic antibiotics

EVALUATION FOR THROMBOPHILIA/HYPERCOAGULABILITY			
Disorder	**%***	**Screening tests**	**Potential confounding conditions**
Inherited			
Factor V Leiden	5	Activated protein C (APC) resistance†	Warfarin, heparin, DOACs, OCP, pregnancy, ↑ factor VIII level, lupus anticoagulant†
	5	Factor V Leiden mutation (AD) [reflex text if APC detected]	–
Prothrombin G20210A	2	Prothrombin G20210A mutation (AD)	–
Hyperhomocysteinemia	>5	↑ Homocysteine level (may have homozygous *MTHFR* C677T mutation or be compound heterozygote > heterozygous *CBS* mutation)	Deficient folate, B_{12} or B_6; older age, smoking
Protein C deficiency	0.3	↓ Protein C activity (AD)	Warfarin, DOACs, OCP, pregnancy, liver disease, ↑ factor VIII level, lupus anticoagulant
Protein S deficiency	0.05	↓ Free protein S antigen level and/or activity (AD)	Warfarin, DOACs, OCP, pregnancy, liver disease, ↑ factor VIII level, lupus anticoagulant, acute thrombosis
Antithrombin III deficiency	0.1	↓ Antithrombin III activity (AD)	Heparin, DOACs, liver disease, acute thrombosis
Excess factor VIII	10	↑ Factor VIII level	Acute phase response, OCP, pregnancy, old age
Excess fibrinogen	ND	↑ Fibrinogen level	Acute phase response, pregnancy, smoking, older age
Dysfibrinogenemia	ND	↓ Functional fibrinogen; ↑ thrombin time	Recent birth, liver disease
Excess factor IX or XI	ND	↑ Factor IX or XI level	Warfarin (factor IX)
Plasminogen deficiency	ND	↓ Plasminogen	–
Excess plasminogen activator inhibitor-1 (PAI-1)	ND 10	↑ PAI-1 *PAI* 4 G/4 G, 4 G/5 G, or 5 G/5 G promoter region polymorphism	Wide range of normal values and diurnal variation
Excess lipoprotein (a)	10	↑ Lipoprotein (a) level	–
Tissue factor pathway inhibitor (TFPI)	10	↓ TFPI	–
Thrombin-activatable fibrinolysis inhibitor	ND	↑ Thrombin-activatable fibrinolysis inhibitor	–
Thrombomodulin deficiency	ND	↓ Thrombomodulin	–
Acquired			
Lupus anticoagulant‡	ND	↑ RVVT (dilute), sensitive PTT, or kaolin clotting time¶	Warfarin, heparin, DOACs
Anticardiolipin antibodies‡	ND	IgG or IgM anticardiolipin antibodies at moderate–high levels, on ≥2 occasions ≥12 weeks apart	Various infectious diseases
Anti-β_2-glycoprotein I antibodies‡	ND	Anti-β_2-glycoprotein I antibodies present, on ≥2 occasions ≥12 weeks apart	–
Cryoglobulinemia, type I	ND	Type I cryoglobulins present	–
Heparin-induced thrombocytopenia§	ND§	• *Screening*: anti-heparin/platelet factor 4 (PF4) antibodies • *Confirmatory*: serotonin release assay	–
Cryofibrinogenemia	ND	Cryofibrinogens present	Acute phase response

*Approximate percentage of general population with the defect.
†Factor V Leiden accounts for ~95% of patients with APC resistance when the latter is assessed by "second generation" assays, which are not limited by most potential confounding conditions.
‡Antiphospholipid antibodies.
¶Confirmed by: (1) failure to correct the prolonged coagulation time in mixing studies; and (2) correction with the addition of excess phospholipids.
§Exposure to heparin or low-molecular-weight heparin.

Table 105.9 Evaluation for thrombophilia/hypercoagulability. Shaded areas represent first-tier screening tests. The initial laboratory evaluation should also include a complete blood count with differential and platelet count, examination of a peripheral blood smear, ESR, activated partial thromboplastin time (PTT), and hepatic and renal function panels. Testing for anti-neutrophil cytoplasmic antibodies (ANCA) can be considered for patients with retiform purpura, as ANCA-positive vasculitides occasionally present with minimally inflammatory lesions; patients with levamisole-induced vasculopathy may have anti-phospholipid antibodies (as well as ANCA). Infections can also lead to coagulopathy (e.g. COVID-19-associated) in which abnormalities such as elevated fibrinogen or antiphospholipid antibodies are detected. Additional inherited causes of hypercoagulability include polymorphisms in the genes encoding the endothelial protein C receptor, the protein Z-dependent protease inhibitor, and E-selectin. AD, autosomal dominant; CBS, cystathionine β-synthase; DOACs, direct-acting oral anticoagulants; MTHFR, methylenetetrahydrofolate reductase; ND, not determined; OCP, oral contraceptive pills; RVVT, Russell viper-venom time.

Fig. 105.20 Additional causes of ulcers. A Diffuse dermal angiomatosis develops most often in pendulous breasts (note the scars from previous breast reduction surgery) and the lower extremities in association with atherosclerosis. **B** Systemic sclerosis with an ulcer of the fingertip. **C** Multiple ulcers in a patient with sickle cell anemia. **D** Necrobiosis lipoidica. Controversy exists about the exact risk of diabetes mellitus in such patients, but it is more strongly associated with diabetes than is granuloma annulare. **E** Prolidase deficiency with spontaneous ulcers and scarring from previous ulcerations. **F** Ulceration of the lateral malleolus in a patient receiving hydroxyurea. **G** Henoch–Schönlein purpura in an adolescent. *A, Courtesy Margo Peters, MD; D, Courtesy Jeffrey P. Callen, MD; E, Courtesy Duygu Gülseren, MD; F, Courtesy Karynne O. Duncan, MD; G, Courtesy Julie V. Schaffer, MD.*

(e.g. tetracycline, metronidazole) and non-adherent dressings; they occasionally require surgical debridement.

The differential diagnosis of tropical ulcers[76] includes other common causes of ulceration in tropical areas such as bacterial (including anthrax), mycobacterial, deep fungal, and parasitic (leishmaniasis) infections as well as non-infectious causes such as sickle cell anemia, venous insufficiency, neuropathy, and trauma.

Additional Causes

A variety of physical, inflammatory, infectious, metabolic, and inherited disorders are also associated with cutaneous ulceration (see Fig. 105.20B, D–G) and they are outlined in Fig. 105.1 and Table 105.10.

Additional figures available in our eBook (see inside front cover for access code).

ADDITIONAL CAUSES OF CUTANEOUS ULCERATION		
Cause	**Favored anatomic site**	**Location of review**
Physical		
Burns – thermal, electrical, chemical	Site of exposure	Chapters 15, 16, 88
Cold injury (e.g. frostbite)	Acral	Chapter 88
Radiation (e.g. orthovoltage)	Site of exposure	Chapter 139
Inflammatory		
Vasculitis (small and medium-sized vessels, primary and secondary)	Lower extremities	Chapter 24; Fig. 105.20G
Pyoderma gangrenosum	Lower extremities, sites of trauma	Chapter 25
Necrobiosis lipoidica	Lower extremities	Chapter 93; Fig. 105.20D
Behçet disease	Lower extremities	Chapter 25
Panniculitis, (e.g. nodular vasculitis, equestrian cold panniculitis/perniosis)	For the two examples, calves and outer thighs	Chapter 100
Vascular		
Raynaud phenomenon and systemic sclerosis	Digital, extensor surface of joints	Chapter 43; Fig. 105.20B
Hemoglobinopathies (e.g. sickle cell anemia)	Lower extremities	Fig. 105.20C
Diffuse dermal angiomatosis	Lower extremities, pendulous breasts	Fig. 105.20A
Infectious		
Bacterial (e.g. *Streptococcus* spp., *Treponema* spp.), mycobacterial, viral (e.g. chronic HSV), fungal, parasitic	Exposed sites Pressure sites in the case of leprosy and tertiary syphilis*	Chapters 74–83; Fig. 105.1
Bites and stings		Chapter 85
Neoplastic		
BCC, SCC > metastases, other primary cutaneous malignancies (epithelial and non-epithelial), cutaneous T and B cell lymphomas	For BCC and SCC, sites of chronic sun exposure For SCC, chronic ulcers, scars, sites of chronic inflammation or oncogenic HPV infection	Chapters 108, 119–122
Metabolic		
Examples: calcinosis cutis, calciphylaxis, gout	Varies from juxta-articular (calcinosis cutis, gout) to "fatty" areas (calciphylaxis)	Chapters 48, 50
Genodermatoses		
Examples: Adams–Oliver syndrome, prolidase deficiency, laryngo-onycho-cutaneous syndrome, familial tumoral calcinosis, Werner syndrome, familial chilblain lupus (*TREX1* mutations), Klinefelter syndrome, leukocyte adhesion deficiency, SAVI	Varies from scalp due to aplasia cutis congenita to lower extremity	Chapters 41, 45, 50, 60, 63, 64; Fig. 105.20E
Drugs		
Hydroxyurea	Lower extremities	Chapters 21, 23; Fig. 105.20F
Methotrexate	Psoriatic plaques	
Warfarin	"Fatty" areas, e.g. breasts	
Heparin	Sites of injection and distant sites	
All-*trans* retinoic acid (systemic), anti-angiogenic multi-kinase inhibitors (e.g. cabozantinib, sunitinib)	Scrotum > vulva	
Interferon, glatiramer acetate, bortezomib, anti-sense oligonucleotides	Sites of sc injection†	
NSAIDs (e.g. diclofenac), penicillin, hydroxyzine, vitamin K, bismuth salts	Sites of IM injection†	
Photodamage		
Erosive pustular dermatosis	Usually hairless scalp, but occasionally lower extremity	Chapter 25

*Due to neuropathy.
†Associated with ischemia in a livedo pattern in Nicolau syndrome.

Table 105.10 Additional causes of cutaneous ulceration. In addition to lower extremity ulcers, patients with prolidase deficiency develop diffuse telangiectasias, dermatitis, lymphedema and manifestations of systemic lupus erythematosus. BCC, basal cell carcinoma; HPV, human papillomavirus; HSV, herpes simplex virus; IM, intramuscular; SAVI, STING (*st*imulator of *in*terferon *g*enes)-associated vasculopathy with onset in infancy; sc, subcutaneous; SCC, squamous cell carcinoma.

INTRODUCTION

This chapter will cover several disorders of the skin vasculature, including livedo reticularis, flushing, and erythromelalgia, as well as vascular ectasias such as telangiectasias and venous lakes. Some of the diseases described here are important skin signs of systemic disease, while others are incidental findings. Additional disorders of blood vessels are covered elsewhere, e.g. infantile hemangiomas (Ch. 103), vascular malformations (Ch. 104), and vascular neoplasms and proliferations (Ch. 114).

LIVEDO RETICULARIS AND LIVEDO RACEMOSA

Key features

- Livedo reticularis – may be physiologic or pathologic, presenting as an even and complete reticulated vascular network; due to slow flow and subsequent accumulation of blood within the cutaneous vasculature, with histologic findings that are generally unremarkable
- Livedo racemosa – due to pathologic changes within cutaneous vessels that are identifiable histologically, leading to disruption of cutaneous blood flow; presents as an uneven and fragmented reticular vascular pattern
- Appropriate investigations depend on the clinical context and associated findings

Introduction

The term "livedo" refers solely to a color change, but it is commonly combined with a modifier to describe two different net-like patterns of blanchable, red–purple discoloration. These two types are livedo reticularis (LRe) and livedo racemosa (LRa). LRe is an extremely common finding and usually results from a physiologic vasospastic response to cold exposure. It presents as an even and complete red–purple net-like pattern. Among normal healthy individuals, the predisposition to LRe will vary. However, it can also be a reflection of a number of underlying systemic diseases.

LRa is less common and is associated with underlying pathology. A broken reticular vascular pattern with a disrupted branching appearance is observed. The distribution is often patchy, and depending on the underlying cause and severity, LRa may be accompanied by retiform purpura.

Both LRe and LRa can vary with changes in external temperature, i.e. disappearing with warming and reappearing with cooling. The reticular vascular pattern can become more prominent with rest or it may become less pronounced with exercise or leg elevation due to reduced stasis of blood within cutaneous vessels.

History

The term "livedo reticularis" was first used by Hebra over a century ago to describe a violaceous skin discoloration caused by an abnormality of the cutaneous circulation. Renault (1883) and later Unna (1896) and Spalteholz (1927) suggested that a cone arrangement of the cutaneous microvasculature served as an explanation for the occurrence and pattern of LR[1].

Pathogenesis

Both LRe and LRa result from alterations in blood flow through the cutaneous microvasculature (Fig. 106.1). The latter consists of arterioles that are oriented perpendicularly to the skin surface. The vessels ultimately divide into capillary beds that in turn drain into a subpapillary plexus. It has been proposed that this arrangement of vessels gives rise to a series of 1- to 3-cm cones with the ascending arteriole at the apex of each cone. At the edge of the cone, the venous plexus is more prominent, and the arterial bed is diminished. Any process that either reduces blood flow to and through the skin or reduces drainage of blood out of the skin will result in the accumulation of deoxygenated blood in the venous plexus, leading to the clinical appearance of LRe or LRa[1–3].

There are a number of causes of LRe and LRa (Table 106.1), and the clinical pattern can vary with the nature of the underlying cause.

A complete fine network, as seen in LRe, is indicative of alterations in blood flow caused by vasospasm or by factors within the blood that alter the viscosity and flow through the vessels. On the other hand, vessel wall pathology and intraluminal obstruction can give rise to the irregular, disrupted, patchy pattern of LRa (Figs. 106.2 & 106.3). When LRa is widespread, disorders such as lymphocytic thrombophilic arteritis[4,5], Sneddon syndrome, and antiphospholipid antibody syndrome (APS)[6,7] should be strongly considered.

Clinical Features

Livedo reticularis

Congenital livedo reticularis

Cutis marmorata telangiectatica congenita

Cutis marmorata telangiectatica congenita (CMTC) is characterized by a persistent reticulated vascular pattern that is often limited to one extremity (see Ch. 104), but can be more widespread. Lesions are usually noted at birth, and, when the trunk is involved, there may be a sharp cut-off at the midline. Associated anomalies include other vascular malformations, limb asymmetry, and occasionally neurologic or ocular abnormalities[8,9]. Cutaneous vascular changes can improve during the first few years of life, with 20% of patients showing complete resolution.

Acquired livedo reticularis

Cutis marmorata/physiologic livedo reticularis

These terms are synonymous and refer to a normal pattern of LRe that is due to vasospasm in response to cold (Fig. 106.4A). It is often more marked in neonates, infants, and young children[2,3], with the term *cutis marmorata* often used to describe LRe in children. The LRe is often widespread, particularly on the lower extremities. There is significant fluctuation with changes in temperature, and the vascular pattern generally disappears with warming. Although frequently physiologic in nature, secondary causes such as vasospasm in the setting of lupus erythematosus and Raynaud phenomenon need to be considered (see Table 106.1)[2,3]. In adults, it may be associated with a tendency towards acrocyanosis and chilblains.

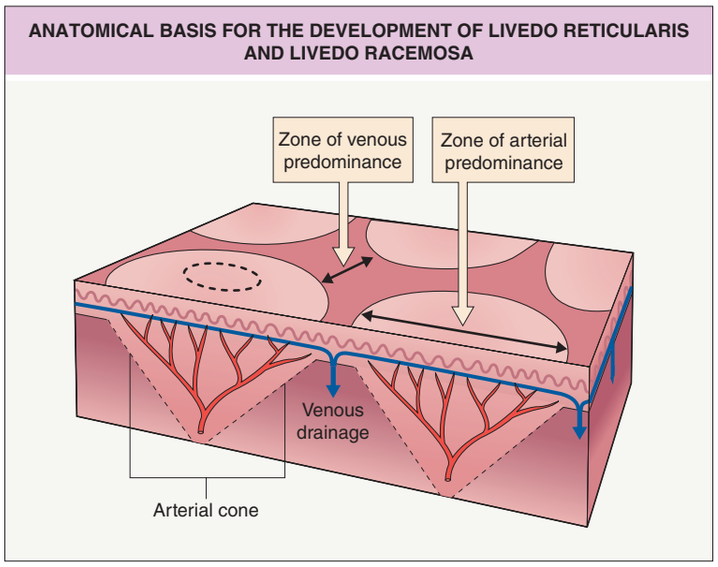

Fig. 106.1 Anatomical basis for the development of livedo reticularis and livedo racemosa. An elliptical biopsy from the paler central "hole" in the net pattern is necessary in order to sample the affected arterioles (dashed oval); serial sectioning may be required.

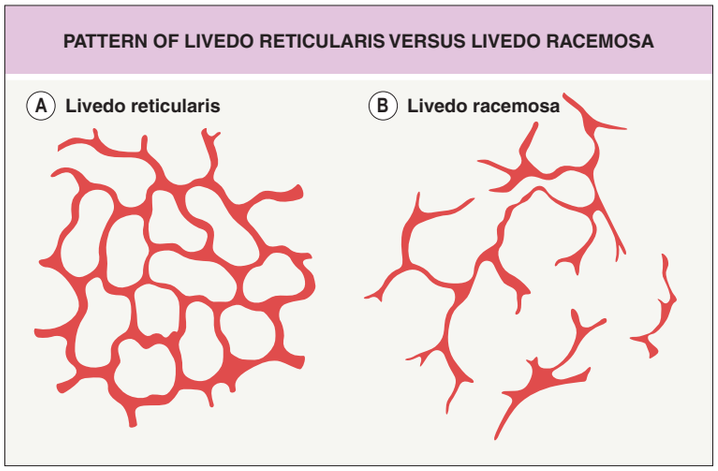

Fig. 106.2 Pattern of livedo reticularis (A) versus livedo racemosa (B).

Fig. 106.3 Livedo racemosa in a patient with lymphocytic thrombophilic arteritis. A more irregular, broken, and branching pattern is seen, as compared to livedo reticularis.

CAUSES OF LIVEDO RETICULARIS AND LIVEDO RACEMOSA

Livedo reticularis

Congenital

- Cutis marmorata telangiectatica congenita

Acquired

Vasospasm

- Cutis marmorata/physiologic livedo reticularis
- Autoimmune connective tissue diseases (e.g. SLE)
- Raynaud phenomenon/disease

Intraluminal pathology

- Increased normal blood components
  - Thrombocythemia
  - Polycythemia vera
- Abnormal proteins
  - Cryoglobulins
  - Cryofibrinogens
  - Cold agglutinins
  - Other paraproteins (e.g. IgM)

Livedo racemosa

Vessel wall pathology

- Vasculitis
  - Cutaneous polyarteritis nodosa (cutaneous arteritis)
  - Systemic polyarteritis nodosa
  - Cryoglobulinemic vasculitis
  - Autoimmune connective tissue disease-associated vasculitis (e.g. rheumatoid arthritis, SLE, Sjögren syndrome)
- Lymphocytic thrombophilic arteritis (macular arteritis, macular lymphocytic arteritis)
- Calciphylaxis
- Sneddon syndrome
- Deficiency of adenosine deaminase 2
- VEXAS syndrome
- Livedoid vasculopathy (also intraluminal obstruction)

Intraluminal pathology

- Thrombophilia/hypercoagulability (see Table 105.9)
  - Antiphospholipid antibody syndrome
  - Protein S and C deficiencies
  - Antithrombin III deficiency
  - Factor V Leiden mutation
  - Homocystinuria, hyperhomocysteinemia
  - Disseminated intravascular coagulation
  - SARS-CoV-2
- Thrombotic thrombocytopenic purpura
- Embolic
  - Cholesterol emboli
  - Septic emboli
  - Atrial myxoma
  - Nitrogen (decompression sickness)
  - Carbon dioxide arteriography
- Hyperoxaluria/oxalosis
- Intralymphatic histiocytosis

Additional causes of livedo reticularis and livedo racemosa

- Medications (e.g. amantadine, norepinephrine, gemcitabine, interferon)
- Infections (e.g. hepatitis C [vasculitis], *Mycoplasma* spp. [cold agglutinins], syphilis)
- Neoplasms (e.g. pheochromocytoma)
- Neurologic disorders (e.g. complex regional pain syndrome [reflex sympathetic dystrophy], paralysis)
- Moyamoya disease

Table 106.1 Causes of livedo reticularis and livedo racemosa. SLE, systemic lupus erythematosus; VEXAS, vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic.

Livedo reticularis due to intraluminal pathology

LRe can result from circulating proteins or cells that slow intravascular blood flow. Abnormal circulating proteins (e.g. cryoglobulins[10], cryofibrinogens, cold agglutinins, IgM paraproteins) can lead to increased blood viscosity. Additionally, an increase in normal blood components in disorders such as polycythemia vera[11] and thrombocythemia

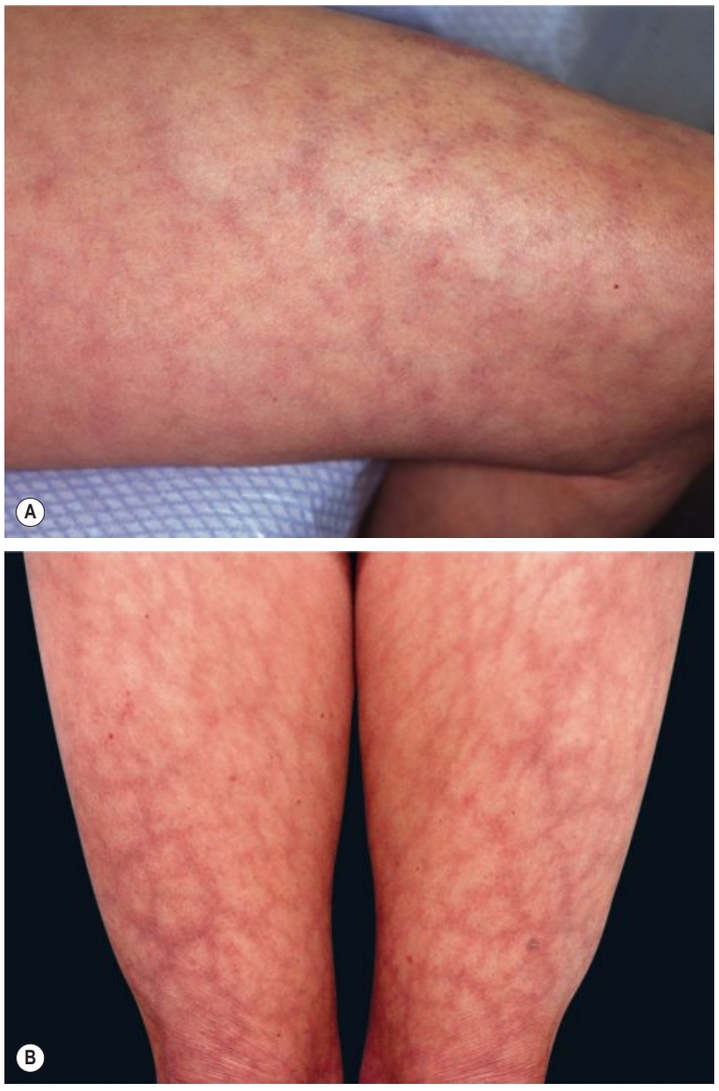

Fig. 106.4 Livedo reticularis. A An even, net-like pattern is seen on the thigh in physiologic livedo reticularis. **B** Livedo reticularis in a patient with systemic lupus erythematosus. *B, Courtesy Jeffrey P. Callen, MD.*

(essential thrombocytosis) may result in altered blood flow. LRe of the lower extremities is often seen in patients with neurologic conditions that lead to immobility of the lower limbs and intravascular stasis.

Livedo racemosa

Livedo racemosa due to vessel wall pathology

LRa results from more significant disruption of blood flow, either from narrowing or complete obstruction of vessel lumina. The most common cause is *vasculitis* involving the medium-sized arterioles at the dermal–subcutaneous junction or in the deep dermis. It is a characteristic finding in cutaneous polyarteritis nodosa (cPAN; more recently renamed cutaneous arteritis)[12], in which there is predominantly involvement of medium-sized arterioles, but can also be seen in systemic PAN and ANCA-associated vasculitides (see Ch. 24). In cPAN, the LRa often has a "starburst" pattern with scattered separate reticulated red–purple patches.

Lymphocytic thrombophilic arteritis, also known as macular arteritis or macular lymphocytic arteritis, often presents with widespread blanchable LRa (see Fig. 106.3)[4,5,13]. Additional clinical findings include patches of macular pigmentation and focal areas of cutaneous ulceration[4]. The vascular inflammation is lymphocytic rather than neutrophilic, and this allows distinction from cPAN. *Livedoid vasculopathy* may also be associated with LRa, but the vascular pattern is usually limited to the lower extremities (see Ch. 23)[14].

Sneddon syndrome is rare and is characterized by widespread LRa as well as multiple transient cerebral ischemic attacks and infarctions. The latter can lead to progressive neurologic impairment[6,7] (see Ch. 23). The LRa is often located on the trunk, buttocks, and proximal

Fig. 106.5 Calciphylaxis in a patient with end-stage chronic renal disease. There is retiform purpura and a large black eschar overlying cutaneous necrosis. Note the violaceous reticulated pattern on the inner thighs. Because the patient was also receiving warfarin, the differential diagnosis included warfarin necrosis. *Courtesy Alicia Little, MD.*

extremities, with a typically large branching pattern. Histologically, there is vessel wall thickening due to intimal smooth muscle proliferation and luminal narrowing. Because this thickening can be preceded by partial or complete vessel occlusion by fibrin thrombi, there is overlap with intraluminal pathology (see below).

ADA2 deficiency is due to homozygous or compound heterozygous mutations in *CECR1* which encodes adenosine deaminase 2 (see Ch. 45). This disorder is also known as vasculitis, autoinflammation, immunodeficiency, and hematologic defects syndrome (VAIHS). It usually presents during childhood and the vascular inflammation favors the skin and central nervous system; a PAN-like presentation with LRa and nodules is accompanied by early-onset cerebrovascular accidents (CVAs; see Fig. 45.11). In addition to hepatosplenomegaly, patients may have fevers, hypogammaglobulinemia, and cytopenias[15,16].

Calciphylaxis consists of calcium deposition within the walls of blood vessels (see Ch. 50). It is most commonly seen in the setting of end-stage chronic kidney disease complicated by secondary hyperparathyroidism. Calciphylaxis may initially commence with LRa that then becomes purpuric and subsequently necrotic (Fig. 106.5)[17].

Livedo racemosa due to intraluminal pathology

Complete obstruction of the vessel lumen can result from either emboli (e.g. cholesterol emboli derived from atheromata[18]) or thromboses within vessels due to thrombophilia (hypercoagulability). As outlined in Table 105.9, causes of thrombophilia include APS[19] and deficiencies of protein C[20], protein S, or antithrombin III[21]. Exposure to either heparin or warfarin can also lead to thrombosis-induced cutaneous necrosis. In patients with severe SARS-CoV-2 infection, a thrombotic vasculopathy can develop, with both LRe and LRa having been observed[22].

Intracellular crystal deposition is seen in hyperoxaluria and this also gives rise to luminal obstruction and LRa[23]. A patchy, discontinuous pattern is seen and it may subsequently become purpuric with areas of infarction and necrosis.

Other causes of livedo reticularis and livedo racemosa

There are numerous causes of LRe and LRa cited in the literature, and for most, one of the above mechanisms can generally be implicated. The other causes include drugs such as amantadine[24] and norepinephrine (noradrenaline), as well as infections. The latter can lead to: the production of cryoglobulins, cold agglutinins, or antiphospholipid antibodies; the induction of immune vasculitis; or septic vasculitis or septic emboli. Neoplasms may also be an underlying trigger via hypercoagulability or paraproteinemia as well as vasospasm (e.g. pheochromocytoma). Lastly, these vascular patterns may be seen in several neurologic conditions (e.g. complex regional pain syndrome) as a result of vasospasm or vasodilation (this is in addition to stasis arising from immobility).

Differential Diagnosis

Erythema ab igne is a heat-induced skin disease that begins as a reversible LRe, then with continued heat exposure, it evolves into a fixed reticulated hyperpigmentation. The sites of involvement reflect the source of exposure, e.g. heating pad, laptop computer, space heater. Various cutaneous eruptions may have a reticulated pattern and might be considered in the differential diagnosis, including reticulated erythematous mucinosis (favors mid central trunk) and some viral exanthems (e.g. erythema infectiosum). Poikilodermatous conditions may also have a reticulated pattern (e.g. dermatomyositis, mycosis fungoides); however, the presence of epidermal changes and telangiectasias help to distinguish these conditions.

Pathology

The histology of LRe and LRa varies depending on the underlying cause. In general, no specific abnormality is evident in LRe, but there may be ectasia of superficial blood vessels. With LRa, a number of abnormalities may be seen, including vasculitis, calcium deposition within vessel walls (calciphylaxis; see Fig. 50.6), intravascular eosinophilic plugging (monoclonal cryoglobulinemia; see Fig. 23.4), intraluminal thromboses (hypercoagulable states), cholesterol clefting (cholesterol emboli; see Fig. 23.5), and crystal deposition (oxalosis). In Sneddon syndrome, an occlusive vasculopathy is followed by subendothelial smooth muscle hyperplasia with partial or complete occlusion of affected arterioles. However, in order to find these histopathologic changes, it is necessary to sample the affected arterioles. An elliptical incisional biopsy from the paler central "hole" in the net pattern is necessary and serial sectioning may be required (see Fig. 106.1).

Treatment

Identification of the underlying cause or associated disorder determines the appropriate treatment options.

FLUSHING

Key features

- Flushing is a physiologic response, but in an exaggerated form causes clinical symptoms
- Common triggers (e.g. heat, emotion, exercise, some foods) will exacerbate flushing of any cause
- Causes of excessive flushing include exogenous medications, menopause, neurologic disorders, and systemic diseases (e.g. carcinoid syndrome)

Introduction

Flushing is the term used to describe transient and episodic reddening of the skin, most commonly of the face, and less often the neck, ears, and upper chest. It is the visible sign of a generalized increase in cutaneous blood flow. The greater visibility and capacitance of the superficial cutaneous vasculature of the face and adjacent areas accounts for the limited distribution[25]. In the evaluation of an affected patient, there are a number of causes to consider, including underlying systemic disorders (Table 106.2).

Pathogenesis

An increase in cutaneous blood flow occurs with relaxation of vascular smooth muscle. This may occur via the autonomic nervous system[26] (usually leading to active vasodilation), endogenous vasoactive agents (such as histamine and serotonin), or exogenous agents (Table 106.3). Alcohol-induced flushing may result from the direct effect of alcohol as well as cutaneous vasodilation from elevated blood levels of acetaldehyde; the latter occurs in those with alcohol dehydrogenase deficiency (prevalent in East Asians) and in the "disulfiram reaction" induced by some medications. Flushing from fermented alcoholic drinks may be caused by vasoactive substances such as tyramine. Vasodilation mediated by the autonomic nervous system is often accompanied by eccrine sweating due to a direct effect on both sweat glands and blood vessels (wet flush)[27]. Direct vasodilation by vasoactive agents is usually not associated with increased sweating (dry flush).

CAUSES OF FLUSHING

• Physiologic
• Exogenous agents (see Table 106.3)
• Menopause
• Neurologic disorders
  • Anxiety
  • Autonomic dysfunction, including CNS-driven*
  • Tumors (e.g. hypogonadal pituitary tumors)
  • Migraine
  • Frey syndrome (auriculotemporal syndrome)
• Dumping syndrome due to rapid gastric emptying
• Systemic diseases
  • Carcinoid syndrome
  • Mastocytosis
  • Pheochromocytoma
  • Medullary carcinoma of the thyroid
  • Thyrotoxicosis
  • POEMS syndrome
  • Pancreatic tumors (e.g. VIPomas)
  • Prostaglandin-secreting renal cell carcinoma

*May be rapidly fluctuating in the setting of increased intracranial pressure, head trauma, or benzodiazepine withdrawal-induced catatonia.

Table 106.2 Causes of flushing. Rosacea may be associated with pronounced flushing, but usually fixed erythema, papulopustules, edema, and/or telangiectasia are present to some degree. Patients with rubeosis facei diabeticorum may note facial warmth. CNS, central nervous system; POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein (monoclonal gammopathy), *s*kin changes; VIP, vasoactive intestinal polypeptide.

EXOGENOUS AGENTS THAT CAN CAUSE FLUSHING

• Alcohol
• Drugs
  • Angiotensin-converting enzyme (ACE) inhibitors
  • Calcium channel blockers
  • Calcitonin
  • Chlorpropamide*
  • Cholinergic agonists (e.g. pilocarpine)
  • Cyclosporine
  • Dupilumab*
  • Disulfiram*
  • Fumaric acid esters
  • Gold ("nitritoid reactions")
  • Hormone therapy (e.g. anastrozole, tamoxifen)
  • Hydralazine
  • Metronidazole*
  • Nicotinic acid
  • Nitrates (e.g. glyceryl trinitrate)
  • Opiates
  • Prostaglandins
  • Sildenafil, tadalafil, vardenafil
  • Tamoxifen
  • Topical calcineurin inhibitors*
  • Serotonin syndrome (usually combination of two drugs such as MAO inhibitor plus SSRI)
• Foods
  • Spoiled scombroid fish
• Food additives
  • Monosodium glutamate (MSG), sodium nitrite, sulfites

*With alcohol intake.

Table 106.3 Exogenous agents that can cause flushing. MAO, monoamine oxidase; SSRI, selective serotonin reuptake inhibitor.

Clinical Features

Blushing is a common emotionally triggered form of flushing associated with embarrassment and anxiety and is considered an exaggerated physiologic response. *Physiologic flushing* also occurs as part of normal

thermoregulation in response to heat or exercise. *"Hot flashes"* refer to flushing associated with menopause, which lasts for a few minutes and is usually associated with sweating[28].

Flushing of any cause may be exacerbated or triggered by a number of common factors such as heat, hot drinks, exercise, anxiety, food additives (e.g. sulfites), and alcohol. Affected patients often report a feeling of heat and burning of the skin during episodes and find the color change a social hindrance. Some patients become anxious that they will flush at inopportune times and this further exacerbates the problem. Repeated flushing may result in permanent "fixed" erythema and telangiectasias.

Carcinoid tumors that secrete vasoactive agents (e.g. serotonin) are associated with the carcinoid syndrome (Table 106.4). This syndrome includes flushing, which is often severe[29], and it may be precipitated by common triggers of flushing. The classic "carcinoid flush" occurs with ~10% of *midgut* tumors (small intestine, appendix, proximal colon), but only when there are associated liver metastases; it lasts minutes and consists of erythema and pallor as well as a cyanotic hue. Type III *gastric* carcinoid tumors are associated with a pruritic, patchy, bright red flush admixed with white patches and probably mediated by histamine. *Bronchial* tumors are associated with a prolonged (hours to days), intensely red to purple flush. Hindgut tumors (distal colon, rectum) are rarely, if ever, associated with the carcinoid syndrome and flushing, even with liver metastases.

An approach to the clinical assessment of flushing and relevant investigations are listed in Table 106.5.

SIGNS AND SYMPTOMS OF THE CARCINOID SYNDROME

• Cutaneous
  • Flushing
  • Vascular rosacea-like changes
  • Pellagra
  • Edema and induration of the face > extremities
• Bronchospasm
• Diarrhea
• Cardiac dysfunction (right-sided)
• Hypotension
• Peptic ulcers

Table 106.4 Signs and symptoms of the carcinoid syndrome.

CLINICAL APPROACH TO THE EVALUATION OF FLUSHING

1. Identify provocative factors
  • Direct questioning
  • Patient diary (food, medications, activities)
2. Check for associated symptoms
  • Sweating
  • Fever
  • Urticaria
  • Diarrhea
  • Bronchospasm
3. Investigation (not required in all cases)
  Indicated if flushing:
  • Of sudden or recent onset
  • Severe
  • Associated with systemic symptoms
  Investigations to consider:
  • Complete blood count with differential and platelets
  • Thyroid function tests
  • Serum estrogen, FSH, LH
  • Serum tryptase [M]; serum chromogranin A levels [C]; plasma free metanephrines [P]
  • 24-hour urine collection for:
  • Serotonin metabolites such as 5-hydroxyindole acetic acid (5-HIAA) [C]
  • Fractionated metanephrines (more specific but less sensitive than plasma) [P]
  • Histamine metabolites such as methylimidazole acetic acid (MeImAA) [M]
  • CT/MRI scans; octreotide/somatostatin receptor scintigraphy (using radiolabeled octreotide)
4. Elimination
  • Exclude suspected drugs and food additives

Table 106.5 Clinical approach to the evaluation of flushing. C, carcinoid; FSH, follicle stimulating hormone; LH, luteinizing hormone; M, mastocytosis; P, pheochromocytoma.

Differential Diagnosis

Fixed erythema, and sometimes telangiectasias, of the face and neck are seen in fair-skinned individuals with photodamage as well as patients with seborrheic dermatitis and photosensitive autoimmune connective tissue diseases (e.g. dermatomyositis). Affected individuals may complain of the persistent redness and burning of the skin rather than actual flushing. Rosacea may be associated with pronounced flushing, but usually fixed erythema, papulopustules, edema, and/or telangiectasias are present to some degree.

Treatment

The clinician should consider and eliminate any suspected exogenous cause (see Table 106.3). Underlying systemic causes, although rare, should be considered (see Table 106.2). Triggers of flushing are likely to be clinically relevant in most patients and should be avoided where possible. Non-selective β-blockers (e.g. nadolol, propranolol) or clonidine may be effective in idiopathic flushing. Anxiolytics may be helpful, particularly if emotional symptoms or anxiety are triggers. Menopausal flushing may respond to hormone replacement therapy, clonidine, or selective serotonin reuptake inhibitors (SSRIs). In troublesome cases unresponsive to these measures, transthoracic endoscopic sympathectomy may be considered.

ERYTHROMELALGIA

Synonyms: ■ Erythermalgia ■ Erythralgia

Key features

- Characterized by painful burning and erythema of the distal extremities (lower > upper)
- Precipitated by heat and relieved by cooling
- May be idiopathic, familial, or arise secondarily due to an underlying condition (e.g. thrombocythemia)

Introduction

Erythromelalgia is an episodic condition characterized by a burning sensation, erythema, and increased skin temperature. It affects acral sites, particularly the lower extremities. Classically, there are three major forms, including:

- type 1 – associated with thrombocythemia
- type 2 – primary or idiopathic form
- type 3 – associated with underlying causes other than thrombocythemia.

History

The term "erythromelalgia" was first coined by Mitchell in 1878. It was used to describe redness (erythros), involvement of extremities (melos), and pain (algos). The diagnostic criteria were established by Thompson[30] in 1979: (1) burning pain in the extremities; (2) pain aggravated by warming; (3) pain relieved by cooling; (4) erythema of affected skin; and (5) increased temperature of affected skin.

Epidemiology

In Norway, the estimated incidence of erythromelalgia is 0.25/100 000 with a prevalence of 2/100 000[31]. While types 1 and 3 usually appear during adulthood, type 2 may appear in childhood and may be familial. The female : male incidence varies from 2 : 1 to almost 3 : 1. In one study, the mean age of onset was 56 years (range, 5–91 years) with 4% having their symptoms begin during childhood.

Pathogenesis

While the discovery of *SCN9A* mutations in patients with primary familial erythromelalgia has provided insights into this disorder, in general, the pathogenesis of erythromelalgia is not entirely understood. Firstly, it may

vary depending on the underlying cause and between different patient subgroups. For example, in patients with thrombocythemia, the pathophysiology is likely to be related to both increased numbers of platelets as well as abnormalities in platelet function. Of note, one explanation for why type 1 erythromelalgia does not respond to heparin or warfarin is that the microthrombi that form do not require thrombin activation[32].

In other types of erythromelalgia, changes in vascular dynamics may be a factor. It has been proposed that hyperemia results from increased blood flow through arteriovenous shunts with a resultant reduction in blood flow within nutritional vessels, thus leading to cutaneous hypoxia[31,33]. Another proposed mechanism is vasoconstriction (as occurs in Raynaud phenomenon), but in erythromelalgia this is followed by a prolonged phase of hyperemia[34]. A temperature-triggered release of vasoactive substances and chemical pain mediators may also play a role.

In 2004, gain-of-function missense mutations in *SCN9A*, which encodes the voltage-gated sodium channel alpha subunit Nav1.7, were first described in patients with primary familial erythromelalgia[35]. Nav1.7 produces threshold currents and is expressed primarily within dorsal root ganglia of sensory neurons (especially nociceptors) and sympathetic ganglion neurons. Mutations lead to lowered thresholds and "over-excitability" of pain-signaling sensory neurons[36] while at the same time producing "under-excitability" of sympathetic neurons. Certain mutations that produce a lesser effect on sodium channel activation and subsequent neuron excitability are associated with a later onset of clinical signs and symptoms[37].

Another dominantly inherited pain syndrome, paroxysmal extreme pain disorder, has also been found to be due to gain-of-function mutations in *SCN9A*, whereas loss-of-function mutations in both copies of this gene lead to a recessively inherited insensitivity to pain[38]. Lastly, there exist additional families that are not linked to chromosome 2q31–32 (*SCN9A* locus), suggesting genetic heterogeneity[39].

Associations in secondary erythromelalgia include myelodysplastic syndromes, diabetes mellitus, peripheral arterial disease, vasculitis, systemic lupus erythematosus, and other autoimmune connective tissue diseases.

Clinical Features

Erythromelalgia is characterized by burning, erythema, and warmth of acral sites (Fig. 106.6). Attacks most commonly occur late in the day, last through the night, and frequently impair sleep. The symptoms are usually episodic, although occasionally they may be continuous. The feet are involved in 90% of patients, whereas the hands are affected in 25%. Less commonly, there is also involvement of the head and neck. Type 1 erythromelalgia may be unilateral and is more frequently associated with progression to ischemic necrosis. In contrast, the idiopathic form is more likely to be bilateral. The pain is precipitated by minor elevations in temperature (between 32°C and 36°C). Other exacerbating factors include exercise, standing, walking, fever, and limb dependency. Cooling and limb elevation generally reduce the symptoms.

The affected areas will often appear red and swollen. Other findings include acrocyanosis, livedo reticularis, facial flushing, cutaneous necrosis, and ulceration. In up to 40% of patients, the limb may appear normal between attacks. Prolonged immersion in water can lead to extensive maceration and contribute to ulcer formation.

Prognosis is variable. In one long-term study, ~30% of patients fell into each of three categories: worsening, no change, and improvement. A further 10% had complete resolution of their symptoms[40].

Pathology

In type 1 erythromelalgia, vessels may show intimal proliferation and occlusive thrombosis followed by complete fibrosis of the affected arterioles. In general, however, biopsies are not required and histology is nonspecific.

Differential Diagnosis

Complex regional pain syndrome (CRPS; reflex sympathetic dystrophy) may sometimes have features similar to erythromelalgia (see Ch. 6). Abnormal warmth, erythema, and burning pain may be seen in both, but CRPS does not have the characteristic close relationship to temperature and tends to be constant rather than episodic. Peripheral neuropathy may also cause tingling and burning and may require differentiation by nerve conduction studies. Calcium channel blockers, autonomic dysfunction, acrodynia, and mushroom poisoning, as well as occlusive vascular diseases such as thromboangiitis obliterans, may be associated with erythromelalgia-like symptoms. It is important to consider underlying causes of erythromelalgia – in particular, chronic myeloproliferative disorders – as erythromelalgia may be the first sign of the latter.

Treatment

Although numerous treatments have been reported as possible therapies for erythromelalgia, no single therapy is consistently effective and many cases can prove difficult to control. The assistance of a specialist pain clinic can be valuable. Various methods of cooling the limbs during attacks, such as fans, wet dressings, and ice packs wrapped in towels, should be explored and have often already been tried by the time of presentation. Frequent periods of leg elevation can be helpful in reducing both discomfort and leg edema, whereas prolonged periods of leg dependency should be avoided. Simple oral analgesia is also important.

Aspirin can be effective for type 1 erythromelalgia and treatment for the thrombocythemia with medications such as hydroxyurea and (based upon mutational analysis) JAK inhibitors should also be considered. Topical therapies include capsaicin cream, 1%–2% amitriptyline/0.5% ketamine gel, and lidocaine patches, while possible oral medications include SSRIs (e.g. venlafaxine), tricyclic antidepressants (e.g. amitriptyline), anticonvulsants (e.g. gabapentin, carbamazepine), calcium channel blockers (e.g. diltiazem), the prostaglandin analogue misoprostol, and especially

Fig. 106.6 Erythromelalgia. Red hot painful hand (**A**) and feet (**B**) in two patients with erythromelalgia. *A, Courtesy Agustin Aloma, MD.*

in primary inherited erythromelalgia, sodium channel blocking agents (e.g. mexiletine, flecainide)[41,42]. With the report of functional expression studies (based upon a specific mutation) correlating with clinical responsiveness to carbamazepine or mexiletine, the possibility exists of utilizing such assays in the future to guide therapy. Rizatriptan, a selective agonist of serotonin 5-HT_{1B} and 5-HT_{1D} receptors, can be used for acute pain attacks in patients with primary erythromelalgia. In addition, there are ongoing trials of Nav1.7 channel blockers, both oral and topical.

Several intravenous therapies have been used for more severe cases, including nitroprusside, prostaglandin E1, and lidocaine (combined with oral mexiletine). More invasive approaches include epidural infusions of bupivacaine and opiates, lumbar sympathetic blocks, and bilateral lumbar sympathectomies[43]. Oral medications should be tried initially, but more invasive procedures may be necessary for more severe cases.

TELANGIECTASIAS

Key features

- Telangiectasia is due to persistently dilated dermal vessels and not angiogenesis
- Can occur as a primary process, a result of cutaneous damage, or secondary to systemic disease

Introduction

Telangiectasia refers to abnormal, small, persistently dilated blood vessels visible in the skin (Fig. 106.7). Individual vessels can be discerned and range in color from light red to deep purple and will usually empty with pressure. They occur as a result of vascular dilation rather than new vessel growth and are thought to arise from capillaries, venules, or small arteriovenous malformations. Telangiectasias are seen in a range of clinical settings (Table 106.6).

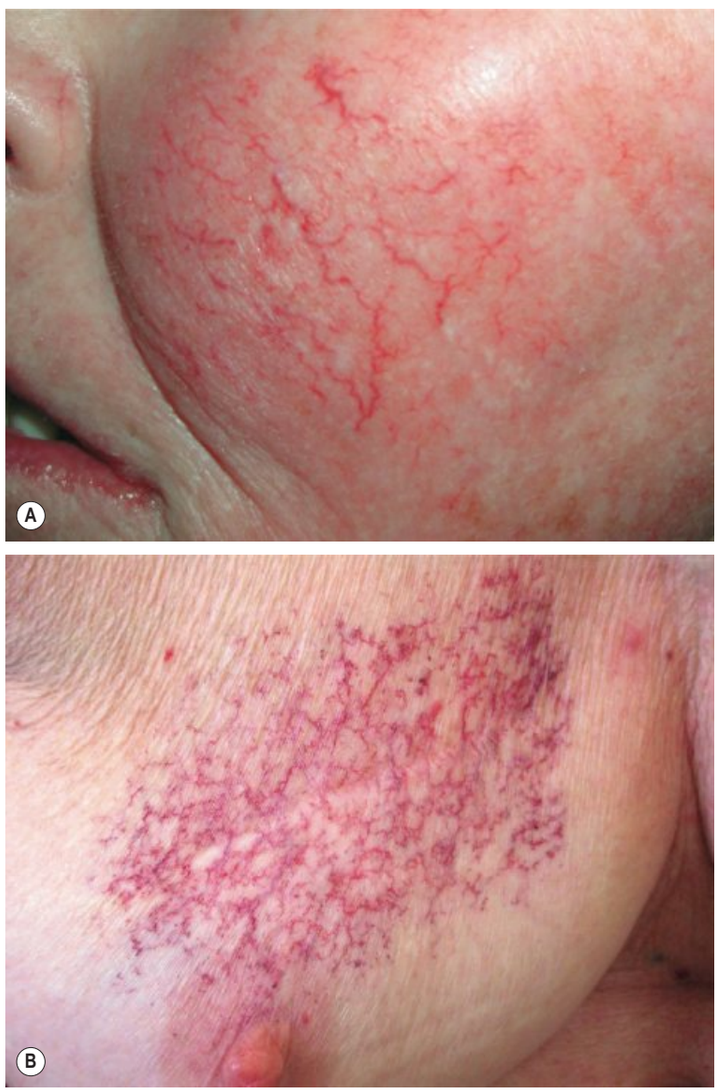

Fig. 106.7 Telangiectasias. A Sun-induced telangiectasias on the cheek. **B** Prominent telangiectasias on the breast following radiation therapy.

CAUSES OF TELANGIECTASIAS
Primary
• Spider telangiectasias (also associated with estrogen excess) • Hereditary benign telangiectasia (Fig. 106.8)* • Costal fringe • Angioma serpiginosum • Unilateral nevoid telangiectasia • Generalized essential telangiectasia • Cutaneous collagenous vasculopathy
Secondary to physical changes or damage
• Photodamage • Post radiation therapy • Traumatic • Venous hypertension
Skin disease
• Telangiectatic rosacea • Incipient or involuted infantile hemangiomas • Basal cell carcinoma
Hormonal/metabolic

• Estrogen-related
  • Liver disease
  • Pregnancy
  • Exogenous estrogens
• Corticosteroids (topical, systemic, Cushing syndrome)

Anti-neoplastic agents
• Tesirine† (e.g. loncastuximab tesirine-lpyl) • Ado-trastuzumab emtansine†
Systemic conditions

• Carcinoid syndrome
• Mastocytosis (telangiectasia macularis eruptiva perstans)
• Autoimmune connective tissue diseases
  • Lupus erythematosus
  • Dermatomyositis
  • CREST syndrome/systemic sclerosis
• Mycosis fungoides, including poikilodermatous
• B cell lymphomas
• TEMPI syndrome
• Angiolupoid sarcoidosis
• GVHD (in the context of poikiloderma)
• HIV infection (anterior chest)

Congenital malformations and genodermatoses
• Cutis marmorata telangiectatica congenita • Klippel–Trenaunay syndrome • Hereditary hemorrhagic telangiectasia • Ataxia–telangiectasia • Hypotrichosis–lymphedema–telangiectasia syndrome • Rombo syndrome • Bloom syndrome • Rothmund–Thomson syndrome • Poikiloderma with neutropenia • Dyskeratosis congenita • Xeroderma pigmentosum • Goltz syndrome (in lines of Blaschko) • GM1-gangliosidosis (also associated with angiokeratoma corporis diffusum) • Prolidase deficiency
*Childhood onset of multiple punctate, linear, or arborizing telangiectasias favoring sun-exposed areas of the face and upper extremities; the vermilion lips and palate are occasionally affected, but there is no visceral involvement. †Cytotoxic payload in monoclonal antibody drug conjugates.

Table 106.6 Causes of telangiectasias. GVHD, graft-versus-host disease; TEMPI, telangiectasias, elevated erythropoietin and erythrocytosis, monoclonal gammopathy, perinephric fluid collections, and intrapulmonary shunting.

Fig. 106.8 Hereditary benign telangiectasia. Fine linear and branching telangiectasias are seen on the cheeks bilaterally in this five-year-old boy. There is no associated visceral involvement. *Courtesy Julie V. Schaffer, MD.*

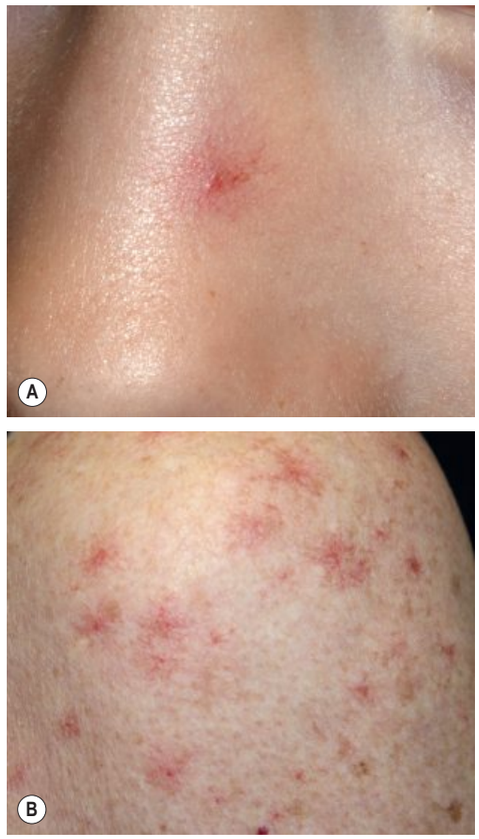

Fig. 106.9 Spider telangiectasia. They are characterized by a central arteriole with radiating telangiectatic "legs". **A** Single lesion on the nose of a young child. **B** Multiple lesions on the shoulder of an adult with liver disease. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Jeffrey P. Callen, MD.*

Treatment is often not required; however, options include cosmetic camouflage, light or fine wire diathermy, injection sclerotherapy, and laser or intense pulsed light therapies.

Spider Telangiectasia

Synonyms: ▪ Nevus araneus ▪ Spider nevus ▪ Spider angioma

This localized lesion has a slightly raised central red papule (which often becomes more prominent with time) and multiple small, radiating, dilated vessels ("legs")[44] (Fig. 106.9). The lesion can vary from several millimeters to more than a centimeter in diameter. They are commonly located on the face, neck, upper trunk, and hands.

Spider telangiectasias represent a form of telangiectasia with a central feeding arterial vessel. They are usually seen in otherwise healthy individuals, especially women and children. Lesions, often multiple, commonly occur with pregnancy, liver disease, and oral contraceptive pills (OCPs). Spontaneous resolution may occur, especially after pregnancy. Treatment options include electrosurgery or vascular lasers.

Generalized Essential Telangiectasia

This is a primary disorder that typically affects adult women but may commence during childhood. Initially, the limbs are affected, especially the distal lower extremities, with sheets of asymptomatic blanchable telangiectasias (Fig. 106.10)[45,46]. The involvement is usually symmetric. Over time, there is often a progression proximally such that the telangiectasias become more widespread. Although the telangiectasias are persistent, patients do not have associated systemic illnesses.

The differential diagnosis includes cutaneous collagenous vasculopathy; typically it is not confused with telangiectasia macularis eruptiva perstans. While improvement with vascular lasers is possible, the progressive nature must be considered and the cost of treating extensive involvement may prove prohibitive.

Fig. 106.10 Generalized essential telangiectasia. Bilateral sheets of asymptomatic blanchable telangiectasias. The initial site of involvement is usually the distal lower extremity. *Courtesy Jean L. Bolognia, MD.*

Cutaneous Collagenous Vasculopathy

Cutaneous collagenous vasculopathy (CCV) was first described in 2000[47]. Clinically, it can resemble generalized essential telangiectasia (GET). However, based upon the limited number of reported cases, there is not a female predominance, the telangiectasias may involve just the trunk and/or proximal extremities, and history of an "upward march" of lesions is lacking (Fig. 106.11A)[48]. The etiology is unknown and there is no clear association with any underlying systemic illness or medication.

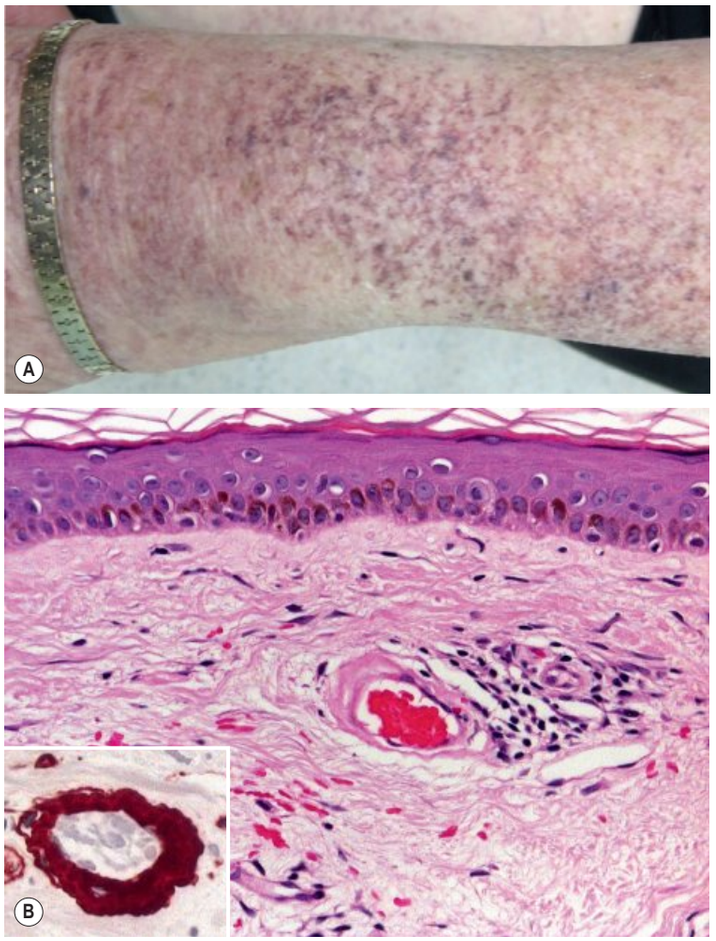

Fig. 106.11 Cutaneous collagenous vasculopathy – clinical and histologic features. A Multiple violaceous branching telangiectasias on the forearm; the patient also had involvement of the thighs, abdomen, and back. **B** In the upper dermis, there are some extravasated red blood cells and clumped RBCs within an ectatic blood vessel. Note the concentric hyaline deposits at the periphery of the affected blood vessel. Immunohistochemical staining with antibodies to collagen type IV highlight the deposits (inset). *B, Courtesy Lorenzo Cerrroni, MD.*

Fig. 106.12 Unilateral nevoid telangiectasia. Note the segmental, unilateral distribution pattern of discrete telangiectasias. *Courtesy Robert Hartman, MD.*

Fig. 106.13 Angioma serpiginosum. Grouped dark red puncta on the arm in a serpiginous pattern.

CCV does have unique histopathologic findings consisting of ectatic superficial blood vessels with hyalinized and laminated, concentric concretions surrounding the basement membrane of affected vessels. With special staining, this material is PAS-positive and diastase-resistant, and by immunohistochemistry, it reacts with antibodies against collagen type IV (Fig. 106.11B). Ultrastructurally, the deposits have been shown to consist of collagen with abnormal banding patterns (Luse bodies)[48].

This condition, like generalized essential telangiectasia, is benign in nature. There are scattered case reports of improvement following pulsed dye laser therapy.

Unilateral Nevoid Telangiectasia

Telangiectasias in this condition are usually confined to the trigeminal or upper cervical dermatomes (Fig. 106.12) and may follow the lines of Blaschko[49,50]. Congenital and acquired forms are recognized. It has been proposed that an increase in estrogen receptors on blood vessels in affected areas and/or an increase in estrogen levels is causative. Situations of relative estrogen excess such as pregnancy, puberty, and liver disease are associated with the acquired form.

Angioma Serpiginosum

Angioma serpiginosum is a rare vascular disorder with a characteristic appearance[51,52]. It is usually sporadic, but familial cases have been reported. Typically, the condition affects female patients and commences during the first two decades of life. Multiple, small, asymptomatic, non-palpable, deep-red to purple puncta occur in small clusters and sheets (Fig. 106.13). The arrangement and extension of the lesions may produce a serpiginous pattern. The extremities are most commonly affected, initially with a unilateral distribution; over months to years, the involvement may become more widespread. The palms, soles, and mucous membranes are not involved.

The puncta represent dilated, non-inflamed capillaries within the dermal papillae. These can be seen with dermoscopy. Incomplete blanching occurs with pressure, but lesions are not purpuric. The differential diagnosis includes pigmented purpuric eruptions, particularly the Majocchi variant (purpura annularis telangiectoides), which is more likely to be bilateral and on biopsy has perivascular lymphocytes and extravasated erythrocytes. Treatment is not necessary, but lesions can be improved with the pulsed dye laser.

Hereditary Hemorrhagic Telangiectasia

Synonyms: ■ Osler–Weber–Rendu disease ■ Osler–Rendu–Weber disease

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant condition in which there are multiple mucocutaneous and gastrointestinal telangiectasias (which are actually arteriovenous malformations)

as well as variable visceral involvement (lung, liver, and CNS). The diagnosis may first be suspected in children who have repeated episodes of epistaxis; however, the initial presentation can occur during the second or third decades of life. The characteristic mat-like and papular telangiectasias on the mucous membranes are first seen during adolescence[53]. Cutaneous lesions usually appear after puberty or even later in life.

Lesions, which increase in size and number as the patient ages, are most commonly seen on the face, tongue, lips, nasal mucosa, hands, and fingertips (Fig. 106.14). They frequently occur throughout the gastrointestinal tract and may result in obvious hemorrhage or iron deficiency anemia. Hemorrhage from vascular lesions in the lung, liver, CNS, spleen, and urinary tract may occur, as well as paradoxical emboli due to pulmonary arteriovenous malformations.

HHT can result from mutations in several genes, most commonly *HHT1* and *HHT2* which encode endoglin and ALK-1, respectively (see Table 104.2). Both of these glycoproteins are TGF-β receptors expressed by vascular endothelium, and they are thought to play a role in angiogenesis and vessel wall integrity.

Treatment of the mucocutaneous vascular lesions may not be required. Destructive treatments such as diathermy, cautery, or laser may be used to treat individual lesions. Surgical management or embolization may be required for uncontrolled hemorrhage from mucosal lesions or complications arising from visceral lesions. Initial and longitudinal evaluation of patients with HHT is outlined in Table 104.6.

Ataxia–Telangiectasia

Synonym: ■ Louis-Bar syndrome

Ataxia–telangiectasia was first described by Louis-Bar in 1941. It is an autosomal recessive disorder characterized by cerebellar ataxia, chromosomal instability (frequent translocations between chromosomes 7 and 14), growth retardation, oculocutaneous telangiectasias, pulmonary infections (including bronchiectasis), immunodeficiency, and the development of lymphomas[54].

It is covered in more detail in Chapter 60. Linear telangiectasias first appear on the bulbar conjunctivae between 4 and 6 years of age. Cutaneous telangiectasias favor the head and neck region, and they are most common on the malar prominences, ears, and eyelids in addition to the popliteal and antecubital fossae. Patients may have poikiloderma (hypopigmentation, hyperpigmentation, atrophy, telangiectasia), premature hair graying, and decreased subcutaneous fat.

Fig. 106.14 Hereditary hemorrhagic telangiectasia. The tongue and lips are a common location for the mat-like and papular telangiectasias that actually represent small arteriovenous malformations.

VENOUS LAKES

Venous lakes are small, dark-blue, slightly elevated, soft lesions that are predominantly localized on the lips (Fig. 106.15), ears, or face of older adults. They can usually be emptied of most of their blood content by persistent pressure[55,56]. Pathologically, venous lakes represent telangiectasias in the dermis. Either one great, dilated venule or several communicating dilated spaces that contain erythrocytes are seen. Thrombosis is sometimes present. Optional treatment with electrosurgery or a hemoglobin-targeting laser is usually effective.

NEVUS ANEMICUS

Nevus anemicus is a congenital pale area of skin, most commonly found on the upper to mid trunk. These patches have an irregular border and an average diameter of 5–10 cm (Fig. 106.16). Within the body of the lesion, local blood vessels are very sensitive to endogenous catecholamines and are permanently vasoconstricted[57]. The border and extent of the lesion become imperceptible with pressure (or diascopy) sufficient to cause blanching of surrounding skin. Conversely, application of heat or an ice cube will often accentuate the lesion; the border becomes hyperemic during warming, while the lesion stays pale. The pale appearance of the lesion (rather than an absence of pigmentation) and the results of the above clinical maneuvers allow nevus anemicus to be differentiated from vitiligo and nevus depigmentosus, respectively. Interestingly, islands of sparing may be present within the lesion, and skin transplanted within the nevus anemicus retains the characteristics

Fig. 106.15 Venous lake on the lip. The lesion is soft and, with compression, can be emptied of most of its blood content. *Courtesy Ronald P. Rapini, MD.*

Fig. 106.16 Nevus anemicus. Pale area of vasoconstriction with irregular borders on the back.

Fig. 106.17 Angiospastic macules (Bier spots). Multiple pale spots with an erythematous background on the forearm.

of the donor site (donor dominance). No histologic abnormalities have been reported. No treatment is required or effective. Of note, nevus anemicus can co-exist with vascular malformations and is seen in up to half of patients with neurofibromatosis type 1.

ANGIOSPASTIC MACULES (BIER SPOTS)

These were first described by Bier in 1898 and represent a pattern of vascular mottling consisting of white macular areas surrounded by a red to occasionally blue cyanotic background. Bier spots most commonly occur on the arms and legs of young adults (Fig. 106.17), but may also occur on the trunk. They are more noticeable in patients with lightly pigmented skin. Angiospastic macules may be induced by venous congestion and can be elicited by placing a limb in a dependent position or by placing a tourniquet around a limb. The spots disappear with limb elevation or release of the tourniquet. As with nevus anemicus, the border of the lesion becomes imperceptible with pressure (diascopy). The vascular pattern is thought to result from a benign physiological response consisting of vasoconstriction. Bier spots have also been associated with pregnancy, lymphedema, cryoglobulinemia, capillary malformation-arteriovenous malformation syndrome (especially type 2 due to *EPHB4* mutations), tuberous sclerosis complex, and aortic hypoplasia. *BASCULE* syndrome features *B*ier *a*nemic *s*pots, *c*yanosis (acral), and an *u*rticaria-*l*ike *e*ruption in association with orthostatic intolerance.

Key features

- Over time, cancer genomes gradually accumulate somatic mutations, and oncogenic driver mutations that increase cell fitness are selected in a process termed Darwinian cancer evolution
- Cancer evolution is also driven by complex chromosomal rearrangements (chromothripsis, chromoplexy) and mutational storms (kataegis) that occur in a single catastrophic cell division, a process called punctuated genome evolution
- Oncogenic driver mutations usually activate proliferative signaling, initiate cell division, and reprogram cellular metabolism to support cell growth and proliferation
- Mutations in tumor suppressor genes often deregulate cell cycle checkpoints, help cells evade physiologic mechanisms of cellular senescence and programmed cell death, and increase genome instability
- By deregulating developmental signaling pathways and cell–cell communication networks, cancer cells create novel tumor ecosystems
- Immune cells can sense DNA damage, specifically recognize mutated cancer cells, and enforce the adaptation and selection of cancer cell subpopulations with immune evasive phenotypes
- Chromosomal instability of cancer cells and a protumorigenic inflammatory microenvironment increase cancer cell plasticity, foster epithelial–mesenchymal transitions, and enable cancer cell invasion and metastasis
- Basal cell carcinomas (BCCs) arise as a result of oncogenic mutations in the Hedgehog signaling pathway, and they often have additional mutations in *TP53* and the Notch pathway
- Cutaneous squamous cell carcinomas (cSSCs) often carry loss-of-function mutations in the Notch pathway, *TP53*, and *CDKN2A*

INTRODUCTION

Worldwide, skin cancer is the most common type of cancer in fair-skinned individuals. This chapter will introduce our current understanding of the fundamental principles underlying cancer development. Notably, skin cancer research has provided significant contributions to the unraveling of the cellular and molecular mechanisms by which environmental carcinogens can cause cancer[1]. The following sections review the remarkable advances in cancer genetics, cancer biology, and cancer immunology made during the 21st century that have initiated a revolution in cancer therapy.

To facilitate our understanding of these novel insights, an increasing number of "hallmarks of cancer" have been defined[2,3]. As a conceptual framework, these hallmarks are presented along three dimensions of biologic organization: (1) the evolution of cancer genomes; (2) the biology of cancer cells; and (3) the development of cancer ecosystems (Fig. 107.1). This is followed by a review of recent insights into the molecular pathogenesis of keratinocyte carcinomas. The chapter concludes with a brief survey of ongoing technological advances that will shape the future of patient care, enabling improved prevention, earlier detection, and patient-specific therapeutic interventions.

THE GENOME PERSPECTIVE

The DNA Sequencing Revolution

Publication of the human genome sequence in 2001 and assembly of a reference sequence of the human genome in April 2003 provided a new foundation for biological research and launched a new era in biomedicine. The subsequent development of massively parallel DNA sequencing technologies (next-generation sequencing; see Ch. 3) has revolutionized genomic research. While completion of the human genome project took 13 years, today it is possible to sequence several whole human genomes in as little as a day.

A recent milestone in human genome research was a series of publications in 2020 by the Genome Aggregation Database (gnomAD) Consortium which delineated the sequences of 125 748 exomes (the protein-coding regions of the human genome) and 15 708 whole genomes[4]. This collection provided unprecedented insights into human genome variation at both the population and individual level. In the same year, the international ICGC/TCGA Pan-Cancer Analysis of Whole Genomes (PCAWG) Consortium published a landmark paper describing the generation and integrative analyses of 2658 cancer whole genomes (and matched normal tissues) across 38 tumor types[5]. Together with several companion papers, this resulted in new insights into the mechanisms of cancer development, extension of the list of oncogenes, and confirmation of the importance of oncogenic mutations in known cancer driver genes.

The ability to sequence and compare whole cancer genomes also revealed the significance of *structural* genomic alterations that affect the topology of the genome and alter "non-coding" sequences; the latter do not contain information for the production of proteins yet comprise 97% of the human genome. These aberrations include simple structural alterations such as deletions, tandem duplications, and unbalanced translocations, in addition to complex structural alterations that are rearranged in local clusters and inserted distantly in the genome. Structural aberrations are thought to play a previously underestimated role in driving cancer development via amplifications of oncogenes, deletions of tumor suppressor genes, creation of fusion genes, or aberrant insertion of oncogenes at transcriptionally active sites[6].

The number of DNA sequences generated from whole genomes of malignant and normal tissues of cancer patients, as well as from different tissues of otherwise healthy individuals, is increasing rapidly. At the same time, new tools for computational analyses are enabling increasingly sophisticated interrogations of large genomic data sets, thereby revealing an enormous complexity and heterogeneity of genomic alterations in cancer cells. These analyses have revealed large differences between different tumor types, between different patients with the same tumor type, and even between spatially or temporally distinct tumor regions in a single patient. In addition, an increasing number of variations in the human genome were associated with inherited cancer predisposition. However, this is just the beginning in our understanding of the functional implications of genomic alterations that underlie cancer development and the complex mechanisms that shape their evolution.

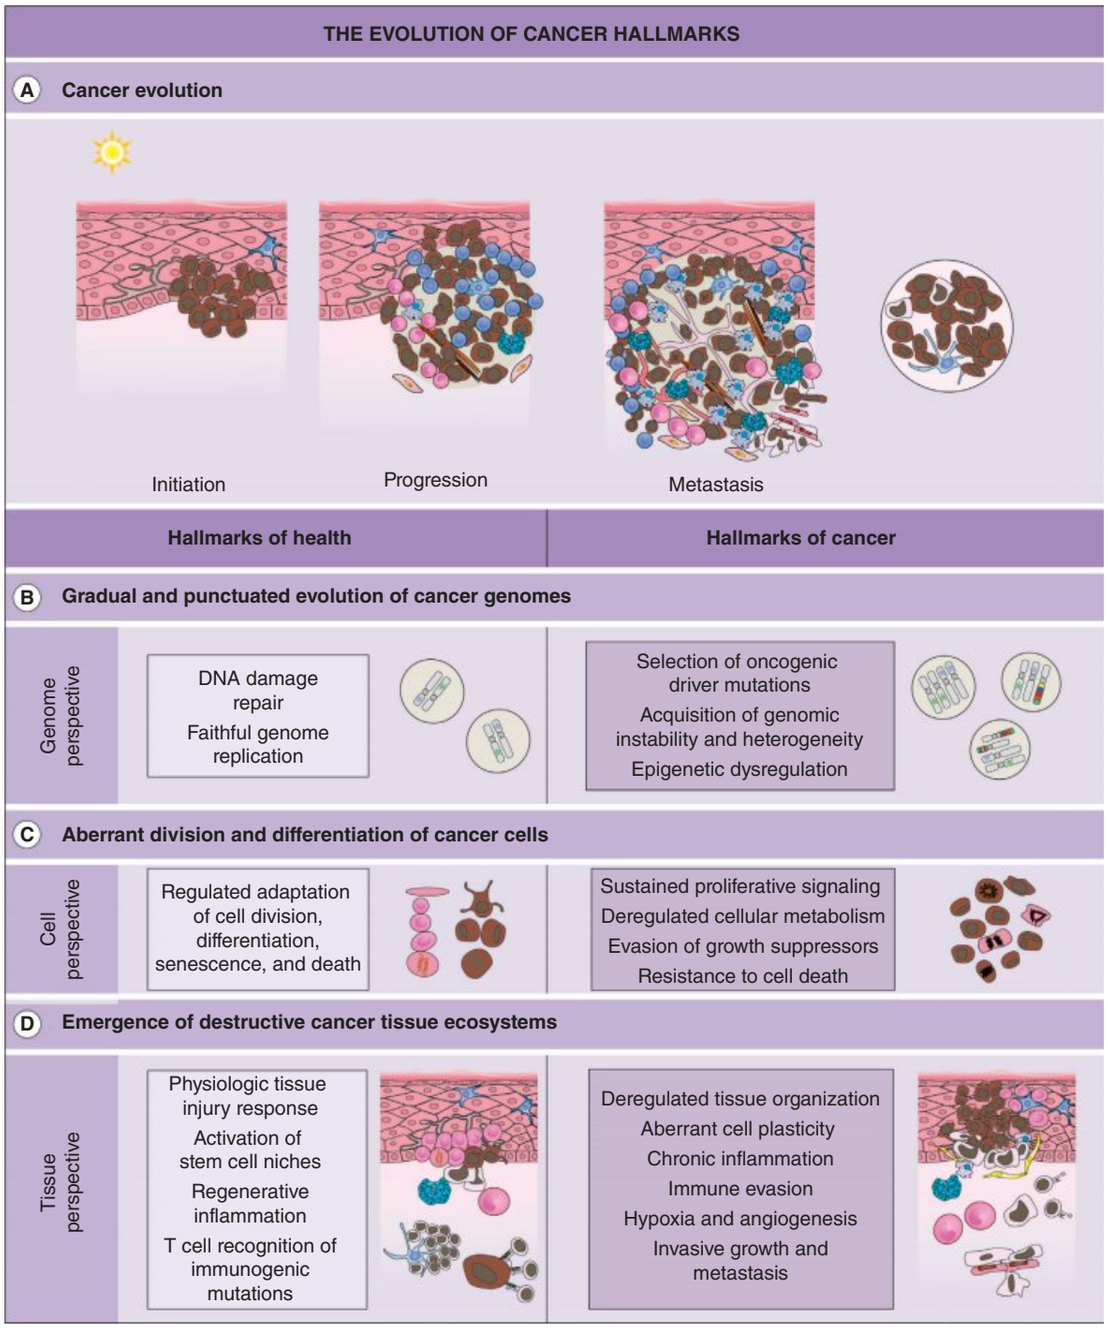

Fig. 107.1 The evolution of cancer hallmarks. A Schematic representation of the cancer initiation, local progression, and metastatic dissemination of skin cancer using melanoma as an example. **B–D** A simplified view integrating the concepts of cancer evolution and cancer hallmarks. Cancer development disrupts three principal levels of biological organization: genomes, cells, and tissues.

Types of Somatic Mutations

Cancer genomes accumulate a heterogeneous and complex array of somatic mutations

Cancer cells originate from normal precursor cells within tissues. In the process of malignant transformation, cancer cells acquire an increasing number of alterations in their genome, which are collectively called *somatic mutations*. Somatic mutations are distinguished from *germline pathogenic variants (mutations)*, which are already present in the fertilized egg and carry inherited information from both parents. Somatic mutations in cancer genomes are identified by direct comparison with the corresponding genomes of normal cells (usually obtained from blood). Mutations in cancer cells can be grouped into different categories according to their size[7]:

- *Single base substitutions* or point mutations are the most frequent alterations and correspond to single nucleotide variants (SNVs) in the germline. Cancer cells derived from tissues that are exposed to carcinogens (e.g. skin exposed to UV radiation) contain a high number of somatic single base substitutions.
- Small insertions or deletions of DNA (*indels*) are the second most frequent alteration and have a size of up to 50 base pairs (bps).
- *Structural variations* include alterations of larger DNA segments such as large insertions and deletions (>50 bps), somatic copy number alterations (SCNAs), and complex rearrangements.

Chromosomal alterations that are microscopically visible by cytogenetic techniques are a characteristic feature of cancer cells derived from patients with advanced disease. These include numerical and structural alterations of chromosomes (aneuploidy), gains and losses of chromosomal regions, and translocations (Fig. 107.2A). Such karyotype aberrations are uncommon in normal cells. Next-generation sequencing technologies have revealed numerous structural variations that are not detected by microscopic cytogenetic analyses, yet are important in cancer development and contribute to the heritable variation present in human genomes.

The Darwinian Model of Gradual Cancer Evolution

Rare oncogenic driver mutations are selected during cancer evolution

The generation of genome-wide catalogs of somatic mutations in various cancer types has provided new opportunities for studying the mechanisms by which somatic mutations arise in cancer genomes. Sequencing of single cell genomes revealed that a few mutations arise

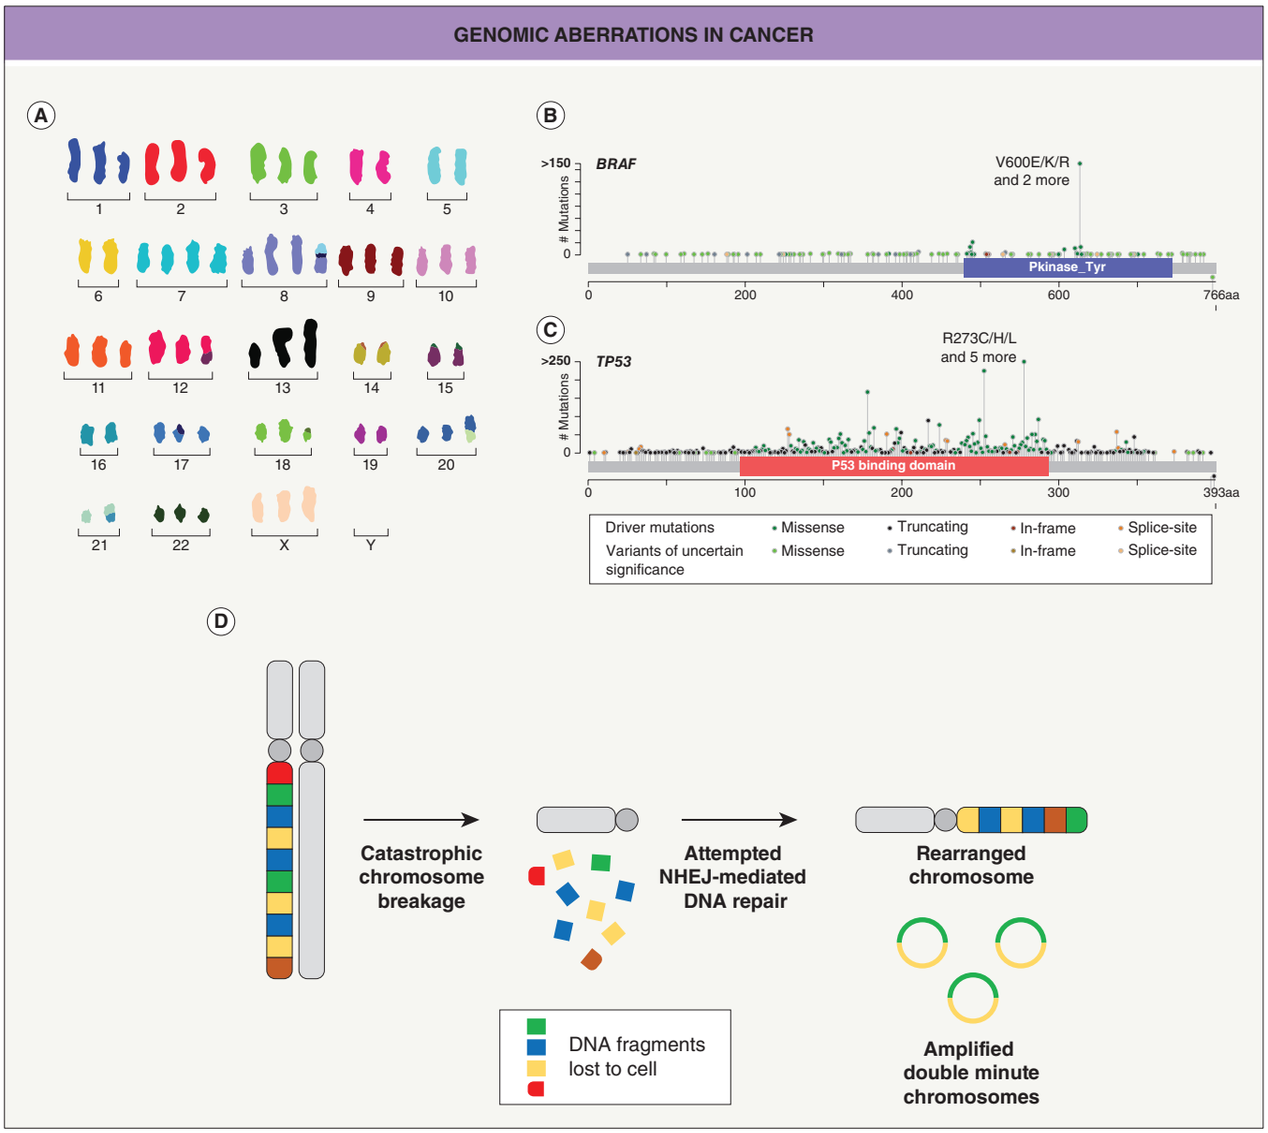

Fig. 107.2 Genomic aberrations in cancer. A Cancers often have highly abnormal karyotypes with extra copies of several chromosomes as well as various structural aberrations, which result from translocation events. **B** Mutations in *BRAF*, illustrating the typical mutation pattern in an oncogene. The vast majority of mutations affect valine at amino acid position 600 in the tyrosine kinase domain, resulting in a constitutively active protein. Mutations with low frequency are often of uncertain significance and without functional relevance. **C** Mutations in *TP53*, illustrating the typical mutation pattern in a tumor suppressor gene. Compared to an oncogene, the mutations are more widely distributed within the gene with hotspots affecting the p53 DNA-binding domain. Note that low frequency mutations are often truncating mutations resulting in a non-functional protein. **D** During chromothripsis, one or multiple chromosomes are fragmented into multiple pieces during a single cataclysmic event. Subsequently, these fragments are stitched together in a near-random orientation using non-homologous end joining or microhomologous repair mechanisms. This results in the generation of grossly altered chromosomes, double minute chromosomes, and loss of some DNA fragments. NHEJ, non-homologous DNA end-joining. *A, Adapted and redrawn from Lodish H, et al. Molecular Biology of the Cell, 9th edn. Austin: W. H. Freeman & Company, 2021 and from Abdel-Rahman WM, et al. Spectral karyotyping suggests additional subsets of colorectal cancers characterized by pattern of chromosome rearrangement. Proc Natl Acad Sci 2001;98:2538–43; B, C, Adapted from cBioPortal of Cancer Genomics; D, Adapted from Rausch T, et al. Genome sequencing of pediatric medulloblastoma links catastrophic DNA rearrangements with TP53 mutations. Cell 2012;148:59–71.*

spontaneously during each cell division due to errors by the molecular machinery of DNA replication. When cells are exposed to endogenous and exogenous mutagens, these errors are significantly accelerated because the resulting DNA damage is occasionally improperly repaired. Importantly, the efficiency of DNA repair can be compromised by inherited germline variants or by acquired somatic alterations in "*caretaker*" *genes* that coordinate DNA damage responses and DNA replication. As a result, each individual cancer genome carries a unique set of somatic mutations that have accumulated during aging and malignant transformation, reflecting the history of different DNA damage and repair processes.

Computational algorithms are able to discriminate at least 30 different mutational signatures and can reveal a history of exposure to exogenous mutagens and mechanisms of DNA repair defects[7]. A prominent example are skin cancer genomes, which bear large numbers of C-to-T and CC-to-TT transitions that are typically caused by UVB irradiation (see Fig. 86.15). Interestingly, the local density of mutations varies up to fivefold amongst different genomic regions, indicating an uneven distribution across the genome. Initial analyses found that this variance in mutational burden correlates with chromatin accessibility and modification, as well as replication timing.

In cancer genomes, the process of malignant transformation is reflected in non-random patterns of somatic alterations. For example, single base substitutions are recurrently detected at unique mutational hotspots within oncogenes (e.g. *BRAF*) and a significantly increased mutation density is seen in several exons of well-known tumor suppressor genes (e.g. *TP53*; Fig. 107.2B,C). In addition, copy number alterations accumulate with tumor type-specific patterns, most notably *amplifications* of genomic regions encoding oncogenes (e.g. *BRAF*, *MYC*, cyclins) as well as *deletions* of genomic regions encoding tumor suppressor genes such as *TP53* or *CDKN2A*[5].

The emergence of these mutational patterns can be explained by the concept of Darwinian evolution at the level of the cancer cell. According to this concept, somatic mutations arise accidentally as a result of

genome replication errors and the effects of exogenous or endogenous DNA mutagens. If a somatic mutation confers a competitive advantage for growth or survival within the population of tissue cells, it will be positively selected over time. In the context of cancer biology, positively selected mutations are called "*oncogenic drivers*", whereas somatic mutations that have no biological effects and are not selected are called "*passenger mutations*". To date, bioinformatic analyses have focused on mutational patterns that indicate a selection of oncogenic driver genes. These patterns include the clustering of base pair substitutions at hotspots or in small genomic regions that alter the structure of encoded proteins or deregulate their expression. Deciphering the functional impact of these somatic mutations on cellular functions has greatly contributed to our understanding of cancer biology.

Single Catastrophic Events in Genome Evolution

Complex chromosomal rearrangements can arise after a single catastrophic cell division error

Evidence is accumulating that during cancer evolution cells can acquire complex genomic rearrangements within very short periods of time, i.e. one cell division. One such process is termed *chromothripsis* and occurs in a single catastrophic cell division. Chromothripsis describes the shattering (thripsis in Greek) of chromosomes and the subsequent reassembly in a random order to produce derivative chromosomes with complex rearrangements (Fig. 107.2D)[8]. It can result from chromosome mis-segregation during cell division, and this can lead to the generation of small micronuclei with unstable nuclear envelopes that are prone to irreversible disruption. Chromosomes within micronuclei accumulate extensive DNA damage and are susceptible to shattering during the next mitosis. This generates multiple chromosomal fragments that are subsequently reassembled by DNA double-strand break repair to form derivative chromosomes (see Fig. 107.2D). Chromothripsis is observed with a frequency of 20% across various cancer types and in more than half of advanced melanomas[9]. A related process is termed *chromoplexy*, in which co-occurring double-stranded DNA breaks in different chromosomes are randomly reassembled, resulting in shuffled chains of rearrangements[5].

Another process, termed *kataegis* (Greek for thunderstorm), is a process of local hypermutations that results in clustered, strand-biased nucleotide substitutions[10]. The mutation clusters are typically several hundred bps long and alternate between a wide range of CT or GA substitutional patterns, suggesting that kataegis occurs in only one of the two template strands during DNA replication. Kataegis is observed with a frequency of 60% in various cancer types with a high prevalence in acral melanomas.

Gradual Cancer Evolution Versus Punctuated Evolution and Catastrophic Events

The discovery that complex genomic rearrangements with multiple somatic mutations can occur in cancer genomes during one or a few catastrophic cell divisions questioned the prevailing Darwinian theory of cancer evolution[11], as the latter assumes the sequential acquisition of mutations in a gradual fashion over time. Such evolutionary jumps have been postulated by evolutionary biologists as a means of initiating speciation in the heavily debated theory of punctuated equilibrium. In punctuated equilibrium, a few rapid changes result in the generation of novel species.

Nowadays, whole genome sequencing enables a partial reconstruction of the evolutionary history of cancer based upon the patterns of how somatic mutations accumulate, with the mutations serving as molecular clocks. These analyses revealed that long phases of gradual mutational "microevolution" (the Darwinian model of cancer evolution) can alternate with short periods of intense mutational "macroevolution" (single catastrophic events such as chromothripsis, chromoplexy, or kataegis), whereby cancer genomes can acquire multiple strong oncogenic driver mutations (Fig. 107.3)[11]. Using this approach, it was shown that phenotypically healthy skin already contains clonally expanded keratinocytes and melanocytes with a high burden of UVB-induced somatic mutations and positively selected oncogenic drivers, indicating that cancer genome evolution begins earlier than previously thought[12].

The relative importance of gradual versus punctuated cancer genome evolution differs between cancer entities. For example, a predominantly gradual genome evolution occurs in melanomas such as lentigo maligna that arise in photodamaged skin of older adults and carry a high mutational load. As noted previously, the observation that healthy skin already contains clonal populations of melanocytes harboring weakly oncogenic mutations indicates that the latter are acquired gradually over a lifetime, consistent with the Darwinian model. In contrast, a more punctuated genome evolution is found in acral and uveal melanomas as they harbor numerous structural variants and a significantly lower mutational load[13,14]. In the majority of melanomas, both gradual and punctuated genome evolution are thought to occur in a sequential manner, with oncogenic hotspot mutations generally occurring before copy number gains. The acquisition of complex genomic alterations and genomic instability that is frequently associated with a shift in mutational signatures promotes metastatic tumor progression.

THE CELL PERSPECTIVE

Functional Capabilities Acquired by Cancer Cells

Oncogenic driver mutations alter the physiologic behavior of cells

The comprehensive analysis of large numbers of cancer genomes has increased the number of oncogenic driver mutations within protein coding sequences to several hundreds. Mechanistic studies in cell culture systems and in model organisms have helped to understand how these alterations contribute to the malignant phenotype of cancer cells. Such endeavors have provided fundamental insights into the biology of cell behavior analogous to how the study of pathogens has elucidated the mechanisms of immune defense.

Many oncogenic driver mutations were found to alter the function of proteins that regulate cell division, faithful genome replication, and cell survival, confirming the concept that oncogenic driver mutations confer a selective growth advantage during cancer evolution. A limited number of oncogenic signaling pathways have emerged that control these essential cellular processes and serve as a map to functionally classify oncogenic driver genes. Prominent examples include the RTK–RAS–MAPK (receptor tyrosine kinase–RAS–mitogen-activated protein kinase) and the PI3K–AKT–mTOR growth factor signaling pathways (see Figs. 55.3, 55.4 & 113.1), in addition to p53–Rb cell cycle control (Fig. 107.4) and DNA damage response pathways[15].

To better illustrate the complex molecular mechanisms that contribute to malignant transformation, a set of hallmark capabilities has been defined that reflect the biologic consequences of oncogenic driver mutations, particularly aberrant proliferation and survival of cancer cells. Predominantly intrinsic cellular capabilities are sustained proliferative signaling, deregulated metabolism, evasion of growth suppressors, and resistance to cell death, as well as acquisition of replicative immortality and genome instability (see Fig. 107.1)[3]. This section reviews the fundamental principles of how oncogenic driver mutations compromise the physiologic regulation of cell division and genome replication, with a focus on the development of skin cancer.

Sustaining Proliferative Signaling

Oncogenic mutations constitutively activate growth factor signaling and drive cell division

Oncogenic driver genes that activate growth factor signaling were initially discovered as cellular homologs of genes identified in RNA tumor viruses[16,17]. The discovery that point mutations in *ras* also occur in human cancers led to an intensive effort to understand the underlying mechanisms by which these mutations promote uncontrolled cell growth. Functional analyses characterized Ras proteins as simple, binary, on-off switches that connect the activity of growth factors bound to their cell surface receptors to growth responses. For example, activation of *receptor tyrosine kinases* (RTKs) turns on Ras proteins, which then activate a cascade of *mitogen-activated protein kinases* (MAPKs) and subsequently a set of transcription factors in the nucleus (see Fig. 113.1).

Oncogenic mutations in *Ras* genes impair the GTPase activity of Ras proteins, which is tightly controlled in normal cells. Mutated

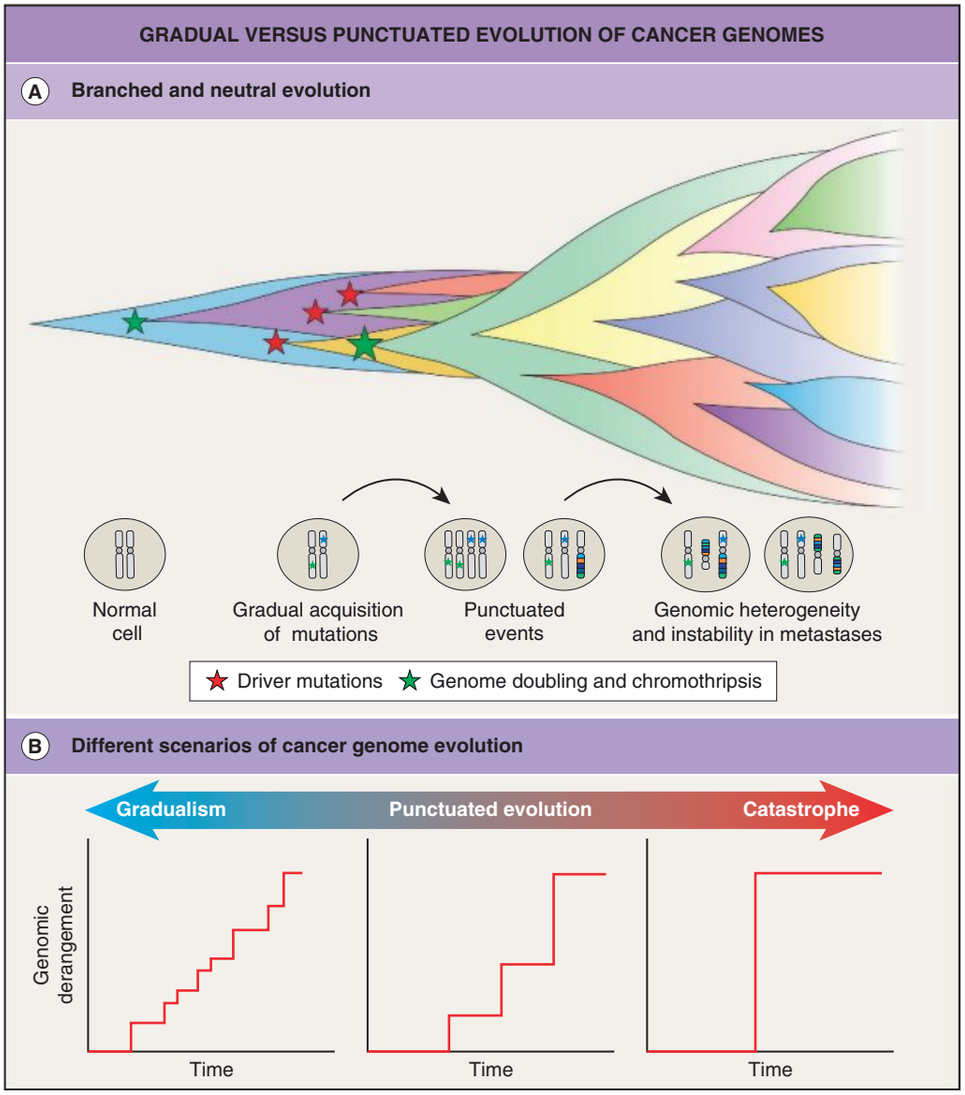

Fig. 107.3 Gradual versus punctuated evolution of cancer genomes. A Muller diagram of a hypothetical evolutionary trajectory of cancer genomes. The evolutionary progression of skin cells towards cancer often begins by acquisition of UV-induced mutations acquired during a lifetime in a gradual evolution. Once regulatory cell cycle checkpoints and DNA damage responses are impaired, gross alterations of the genome (e.g. genome doubling) or catastrophic single events (e.g. chromothripsis, kataegis) may occur. This leads to increased genomic heterogeneity, a key feature of advanced and metastatic cancer. **B** Illustration of different scenarios of cancer genome evolution. Left: oncogenic driver mutations accumulate gradually (Darwinian model of gradual cancer evolution). Middle: progression via punctuated events that induce more drastic chromosomal alterations such as chromoplexis. Right: cancer arising after a single catastrophic event such as chromothripsis. *A, Adapted from Niida A, et al. A unified simulation model for understanding the diversity of cancer evolution. PeerJ 2020;8:e8842; B, Adapted from Baca SC, et al. Punctuated evolution of prostate cancer genomes. Cell 2013;153:666–77.*

Ras proteins are locked in a constitutively active, GTP-bound state that signals independently of upstream activation of growth factor receptors. Genomic analyses revealed large numbers of diverse oncogenic driver mutations that deregulate different components of the RTK–RAS–MAPK pathway in many cancer types[5]. Proliferative signals generated by oncogenic mutations in the RTK–RAS–MAPK pathway ultimately activate several transcription factors that orchestrate cell cycle entry and progression. The development and clinical implementation of small molecule inhibitors of mutated BRAF to treat melanoma has unequivocally demonstrated the importance of oncogenic growth factor signaling in cancer cell proliferation (see Fig. 113.1).

Deregulating Cellular Metabolism

Oncogenic signaling reprograms metabolic pathways to support cellular proliferation

Oncogenic signaling has also been found to activate the molecular machinery required to synthesize the large amounts of RNA, DNA, proteins, and membrane lipids necessary to produce a new cell. This requires increased uptake of glucose, lipids, and essential amino acids[18]. The glycolytic conversion of glucose to lactate under oxygen-rich conditions (*aerobic glycolysis*) was first described by Otto Warburg nearly 100 years ago. Importantly, glycolytic metabolites not only provide a source for the generation of energy in mitochondria, but also serve as building blocks for the synthesis of many macromolecules.

The important role of an activated MAPK pathway in the metabolic activity of cancer cells is impressively demonstrated by the ability of BRAF inhibitors to abrogate the uptake of radiolabeled glucose as visualized in a PET-CT scan. Oncogenic driver mutations in the PI3K–AKT signaling pathway also support glycolysis via post-translational modifications and increased transcription of glucose transporters and glycolytic enzymes[19]. Understanding the metabolic adaptations and the alterations in protein translation during cancer progression is an emerging field of study that holds the potential for future novel therapeutic approaches[20].

Mutations in p53 and Rb Tumor Suppressor Pathways Deregulate Cell Cycle Control

Oncogenic mutations in growth factor signaling pathways initiate the cell cycle machinery that orchestrates the replication of genomic DNA and the subsequent segregation of chromosomes into two daughter cells[17,21,22]. In normal cells, cyclins, cyclin-dependent kinases (CDKs), and cyclin-dependent kinase inhibitors (CKIs) tightly control the following: the decision to enter the cell cycle at the G1/S checkpoint; the process of DNA synthesis during the S phase; the decision to initiate mitosis at the G2/M DNA damage checkpoint; and the process of chromosome segregation during the M-phase. A network of tumor suppressor genes tightly regulates the G1/S and the G2/M cell cycle checkpoints to ensure the generation and distribution of identical genomes (see Fig. 107.4), and it is frequently inactivated in cancer cells[21,22].

Central players in this network include p53, Rb, and p16 (one of the protein products of *CDKN2A*). p53 was initially thought to enhance growth of tumor cells but was later found to be primarily a tumor suppressor[23]. Loss-of-function mutations in *TP53* represent the most frequent oncogenic alteration across multiple tumor types[5]. Today, p53

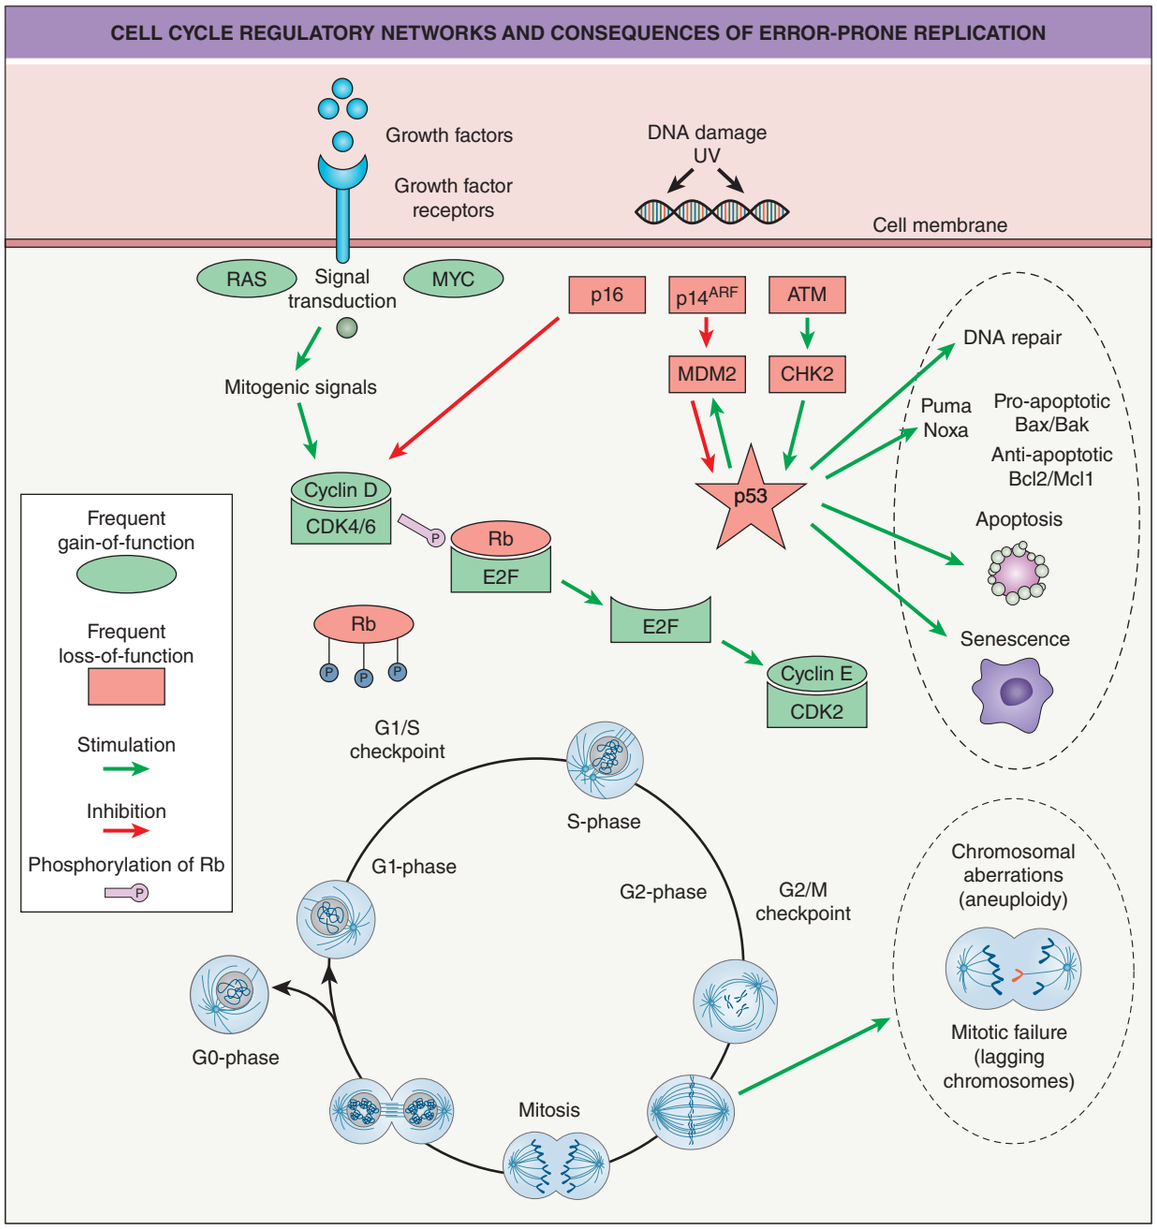

Fig. 107.4 Cell cycle regulatory networks and consequences of error-prone replication. Growth signals promote the activity of CDK4/6 and Cyclin D and drive cell cycle progression. DNA damage responses activate the p53–Rb network of tumor suppressors and arrest cells at the G1/S checkpoint of the cell cycle. If DNA damage is irreversible, cells enter a senescent state and ultimately activate the mitochondrial apoptotic signaling cascade leading to apoptotic cell death. Oncogenic driver mutations frequently deactivate the p53–Rb tumor suppressor network, thereby overriding cell cycle checkpoints. This predisposes cells to mitotic errors that can lead to chromosomal aberrations with numerical or structural aneuploidy.

is considered to be the *guardian of the genome* due to its important role in pathways that sense irreparable DNA damage and initiate programmed cell senescence or cell death (see Fig. 107.4). The *CDKN2A* and *RB* tumor suppressor genes, whose protein products control the G1/S cell cycle checkpoint, are also inactivated in the majority of cancer cells[22,24]. As a result, cancer cells do not exit from the cell cycle and continue to divide despite damage in their genomic DNA.

Resisting Cell Death

The proliferative capacity of healthy cells is tightly regulated by physiologic mechanisms of cell senescence and death. Cell senescence is a form of irreversible exit from the cell cycle in response to external or internal cellular stress and DNA damage. Senescence can be induced by carcinogens, reactive oxygen species, oncogene-induced replicative stress, or telomere attrition. At the molecular level, senescence is regulated by activation of the $p14^{ARF}$/MDM2/p53 and p16/pRb tumor suppressor pathways (see Fig. 107.4)[25,26]. Increased expression of p53 and p16 proteins are hallmarks of preneoplastic cells and represent a barrier for cancer development. Inactivation of these pathways allows cells to progress towards malignancy. Loss of p53 function also dysregulates the molecular machinery of programmed apoptotic cell death, which is critical for organismal development and the maintenance of tissue homeostasis.

In normal tissues, the balance between cell death and survival is maintained by tight regulation of members of the BH3-only and BCL-2-like families. In the absence of p53, the activity of the pro-apoptotic protein Bax is inhibited, thereby impairing apoptosis and promoting cell survival. Apoptosis is an important orderly process, which begins with the activation of orchestrating initiator caspases such as caspase 8 and 9. The latter in turn activate effector caspases, nucleases, and other lytic enzymes, resulting in the ordered degradation of genomic DNA and proteins including cytoskeleton components such as actin and lamins. Recently, multiple novel types of programmed cell death pathways such as ferroptosis, necroptosis, and pyroptosis have been described, with each exerting different effects on surrounding tissues[27].

Genome Instability and Mutation

Oncogenic alterations that disrupt the p53 and Rb tumor suppressor pathways impair DNA damage and repair responses, thus rendering cancer cells particularly susceptible to errors in DNA replication and chromosome segregation during mitotic division. For example, impairment of the mitotic spindle assembly checkpoint leads to chromosome mis-segregation and subsequently daughter cells with numerically and structurally altered chromosomes, a condition termed *aneuploidy*. A frequent early event during cancer evolution is whole genome doubling, which predisposes cancer cells with defective cell cycle

control to acquire additional chromosomal alterations and ultimately to develop chromosomal instability (see Fig. 107.4)[28–31].

The functional impact of aneuploidy on cancer progression is context-dependent[29]. Initially, leakage of DNA fragments from ruptured micronuclei into the cytosol, a frequent event in aneuploid cells, activates innate immune responses. This activation occurs via the cytosolic DNA-sensing cGAS–STING pathway and the production of interferons. Later during cancer evolution, the cGAS–STING pathway predominantly activates proinflammatory transcriptional responses that support immune evasion and metastatic dissemination[30,31].

THE TISSUE PERSPECTIVE

Architectures in Cancer Ecosystems

Oncogenic signaling alters the physiologic organization of cells in tissues and organs

A characteristic pathologic feature of advanced cancer is the disruption of normal tissue and organ architecture. Cancer cells often have increased morphologic heterogeneity, impaired cellular differentiation, and the phenotypic plasticity of their lineage progenitors[2]. The surrounding tumor microenvironment is frequently characterized by numerous inflammatory immune cells, newly formed vessels, and altered structure of the extracellular matrix. As similar features are observed in wound healing, cancer is thought to behave like a chronic wound that does not heal[32]. The identification of oncogenic driver mutations which dysregulate intercellular communication networks of ligands, receptors, and signaling mediators that have several functions – determining cell-fate decisions and morphologic patterning during embryogenesis, orchestrating tissue regeneration following injury or stress, and maintaining homeostasis in adult tissues – provides an explanation for this observation[33].

The evolution of cancer cells with increased transcriptional and epigenetic plasticity is critically shaped by reciprocal interactions with each other and with immune cells, endothelial cells, and fibroblasts within different niches of the tumor microenvironment[34]. The various cell phenotypes and their niches create a dynamic cancer tissue ecosystem that is coordinated by an altered intercellular communication network. Within this ecosystem, malignant and non-malignant cells dynamically adapt their phenotypes in response to the changing microenvironmental conditions during cancer progression and in response to therapeutic intervention. This includes the sensing of DNA damage in cancer cells by innate immune cells, as well as the subsequent genetic selection and phenotypic adaptation of cancer cells exposed to cytotoxic T cells that specifically recognize cancer mutations[30,35]. In addition, hypoxia promotes the release of angiogenic factors and initiates neovascularization. Inflammation and hypoxia promote cancer cell plasticity and epithelial-to-mesenchymal transitions that activate cellular migration programs and support invasive growth and metastatic spread[34].

Phenotypic Plasticity and Epigenetic Reprogramming

Increased cell state heterogeneity and plasticity is a hallmark of progressive tumor growth

The skin epithelium continuously self-renews through the activity of a long-lived population of adult stem cells that reside in microenvironmental niches. Adult stem cells undergo asymmetric cell divisions to give rise to transiently proliferating progeny and eventually to terminally differentiated cells that perform skin-specific functions. Keratinocytes, for example, continuously regenerate and eventually undergo programmed cell death to form the stratum corneum. Melanocytes and intraepithelial leukocytes have a longer lifespan and predominantly expand following tissue injury.

Physical damage, chemical toxins, and pathogens induce cellular stress and activate stem cell niches in the skin to increase their proliferative output, replace damaged cells, and restore tissue homeostasis. A typical example is the response to sunburning UV irradiation (Fig. 107.5). Importantly, tissue damage repair responses involve a transiently increased plasticity of stem cell states that allows precursor cells to adapt their differentiation pathways[36]. The underlying molecular mechanisms of tissue organization also govern the development of cancer and represent an additional bottleneck for the evolution of cancer genomes.

The accumulation of UV radiation-induced oncogenic driver mutations can only occur in cells that are capable of long-term self renewal and the generation of an entire cancer ecosystem. Lineage tracing experiments in genetically engineered mouse tumor models as well as in cancer-patient derived xenografts are beginning to reveal how somatic mutations that deregulate developmental signaling pathways in cancer cells increase the plasticity of stem cells and alter the differentiation trajectories of their cellular progeny. Reciprocal communication of keratinocyte carcinoma cells with fibroblasts as well as immune and endothelial cells through Hedgehog and Notch signaling are prominent examples in skin cancer (Figs. 107.6 & 107.7). These signals also orchestrate epithelial-to-mesenchymal transitions (EMT) during development and in response to tissue injury[37,38]. Both genetic and epigenetic dysregulation of these developmental signaling pathways promote tumor progression, from initiation and maintenance to metastatic spread and growth at distant sites.

Avoiding Immune Destruction

The cellular immune system can specifically recognize and eliminate mutated cancer cells

Based on experimental observations in the 1970s that immune cells can specifically recognize and eliminate virally induced cancer cells in mice, it was hypothesized that the immune system also controls the development of human cancer. In the first two decades of the 21st century this theory of cancer immunosurveillance advanced from wishful thinking pursued by very few scientists to a general principle in oncology.

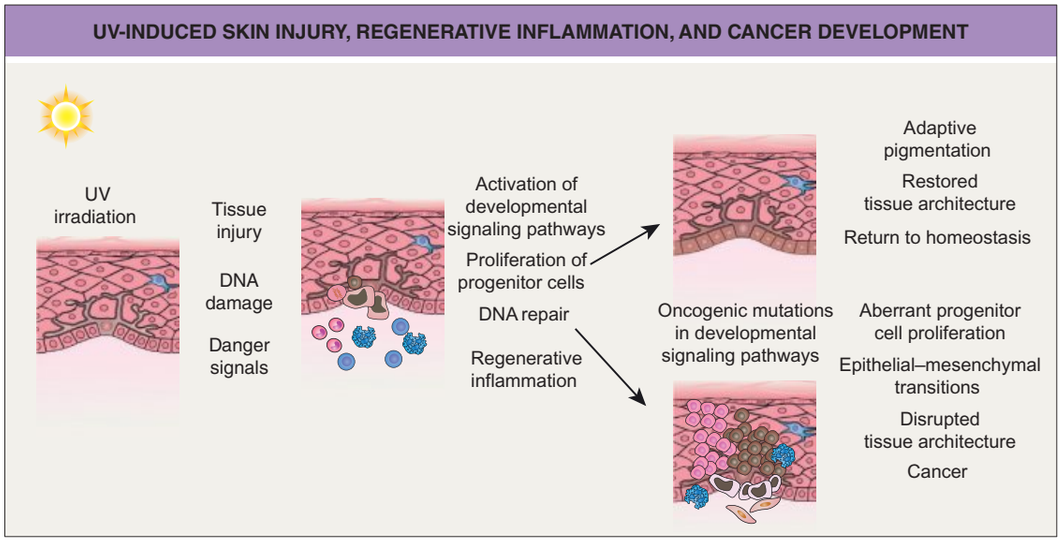

Fig. 107.5 UV-induced skin injury, regenerative inflammation, and cancer development. UV irradiation causes tissue injury and DNA damage. This results in the proliferation of progenitor cells and the activation of developmental signaling pathways that orchestrate tissue repair and restore tissue architecture. Oncogenic mutations in these signaling pathways promote aberrant proliferation of precursor cells within stem and progenitor cell niches, disrupt normal tissue architecture, and foster epithelial–mesenchymal transitions, thus leading to carcinoma.

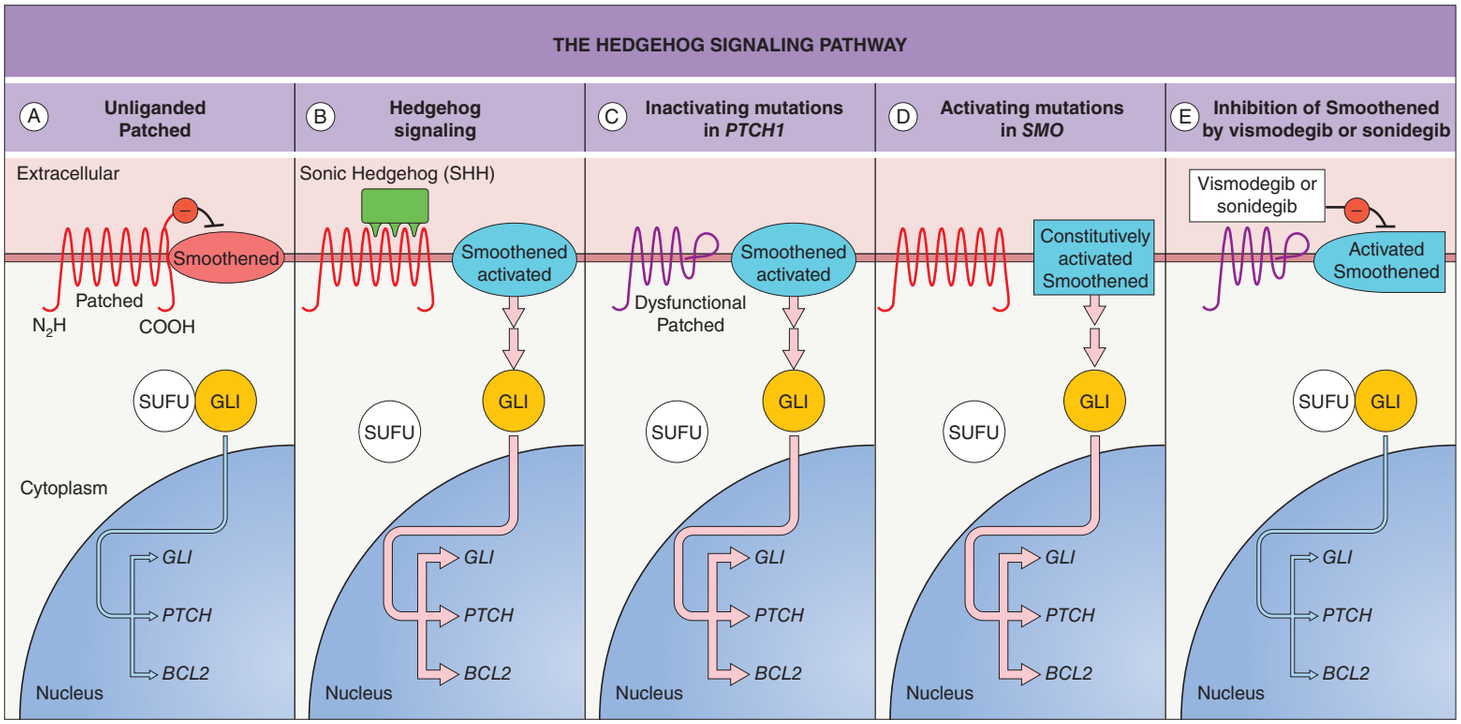

Fig. 107.6 The Hedgehog signaling pathway. A Unbound Patched silences Smoothened (SMO) signaling. **B** As Hedgehog binds to its receptor Patched, the repression of SMO is removed and signals are transduced via GLI to the nucleus. **C** Inactivating mutations in *PTCH1* (or rarely *PTCH2*) lead to dysfunctional Patched and this mimics Hedgehog binding and results in constitutive activation of GLI and downstream target genes. **D** An activating mutation in *SMO* results in constitutive signaling via GLI to activate downstream target genes. Such mutations are detected in sporadic BCCs in which *PTCH1* is intact. **E** Vismodegib and sonidegib are inhibitors of SMO that have been used to treat patients with BCNS as well as metastatic or locally advanced BCCs. At least 50% of advanced BCCs develop resistance to vismodegib, commonly via acquiring mutations in *SMO*.

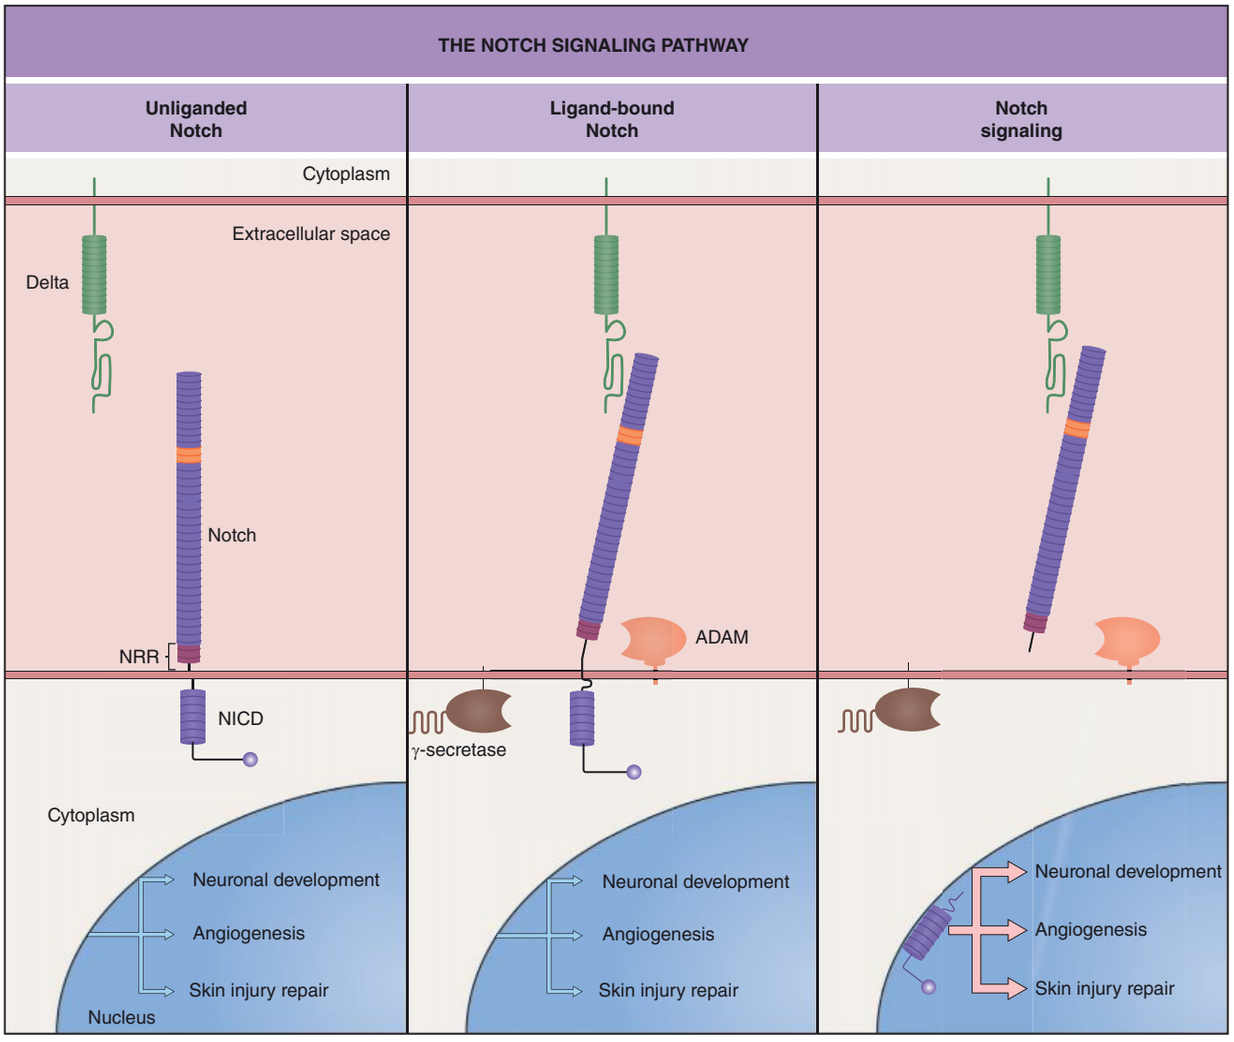

Fig. 107.7 The Notch signaling pathway. Notch signaling is inactivated in the majority of keratinocytes. The membrane-bound (juxtacrine) ligands of the Delta-like and Jagged family interact with the Notch receptor on the target cell and promote the cleavage of Notch both on the extracellular surface via ADAM (a disintegrin and metalloprotease) and on the intracellular surface via γ-secretase. The Notch intracellular domain (NICD) translocates into the nucleus and activates the transcription factor CSL. The extracellular, ligand-bound domain of Notch is repurposed by phagocytosis.

Initial proof-of-principle for the ability of T cells to specifically eradicate human cancer was obtained in studies where lymphocytes were isolated from melanoma metastasis tissues, expanded *ex vivo* and reinfused into patients. The clinical efficacy of monoclonal antibodies targeting the immunoregulatory receptors CTLA-4 and PD-1 (immune checkpoint blockade) on T cells represented a breakthrough for T cell immunotherapies and is currently changing the treatment of many cancer patients[39–41].

DNA damage in cancer cells triggers the cGAS–Sting pathway and alerts the innate immune system[30,31]. This also activates dendritic cells that take up cancer cell fragments and induces their migration to the regional lymph nodes (Fig. 107.8A). Here, dendritic cells present tumor antigens to naive T cells and stimulate their expansion and differentiation into effector T cells. These cells of the adaptive immune system home into tumor tissues where they can eradicate the malignant cell population[35,39]. The ability of tumor-specific T cells to broadly recognize mutated peptides, which stochastically arise as a consequence of genomic alterations in cancer cells, represents a cornerstone of modern tumor immunology. These mutated peptides (termed *neoantigens*) are presented to T cells in the binding groove of MHC molecules in a similar manner as viral antigens (see Ch. 4). This explains why the efficacy of T cell immunotherapies directly correlates with the mutational burden of cancer cells.

Tumor-specific T cells also recognize self-antigens derived from normal gene products that are expressed only in specific cell types. Melanosomal enzymes such as tyrosinase that are recognized by melanoma-specific T cells are typical examples of lineage differentiation antigens. Proteins of the *MAGE* gene family, which are physiologically expressed in embryonic tissues and are restricted to reproductive organs in adults (termed *cancer testis antigens*), represent another class of tumor antigens recognized by T cells and are frequently re-expressed in cancer cells due to epigenetic alterations[35,39].

Detailed immunohistopathologic investigations revealed that cancer tissues vary widely with respect to the infiltration of T cells and other immune cells. Recently, clinical and experimental evidence has accumulated that oncogenic driver mutations orchestrate the tumor immune landscape. For example, mutations that activate the Wnt signaling pathway or *MYC* promote evasion of cellular immunity by preventing T cells from entering tumor tissues, a phenomenon called *T cell exclusion*[42]. However, the interaction between tumor and immune cells is not unidirectional, and immune cells may also secrete cytokines that are conducive to cancer cell survival and proliferation.

Today, it is well documented that the anti-tumoral T cell response imposes a critical cell-extrinsic barrier to malignant transformation[43]. Current immunotherapies partially resurrect this barrier by reactivating

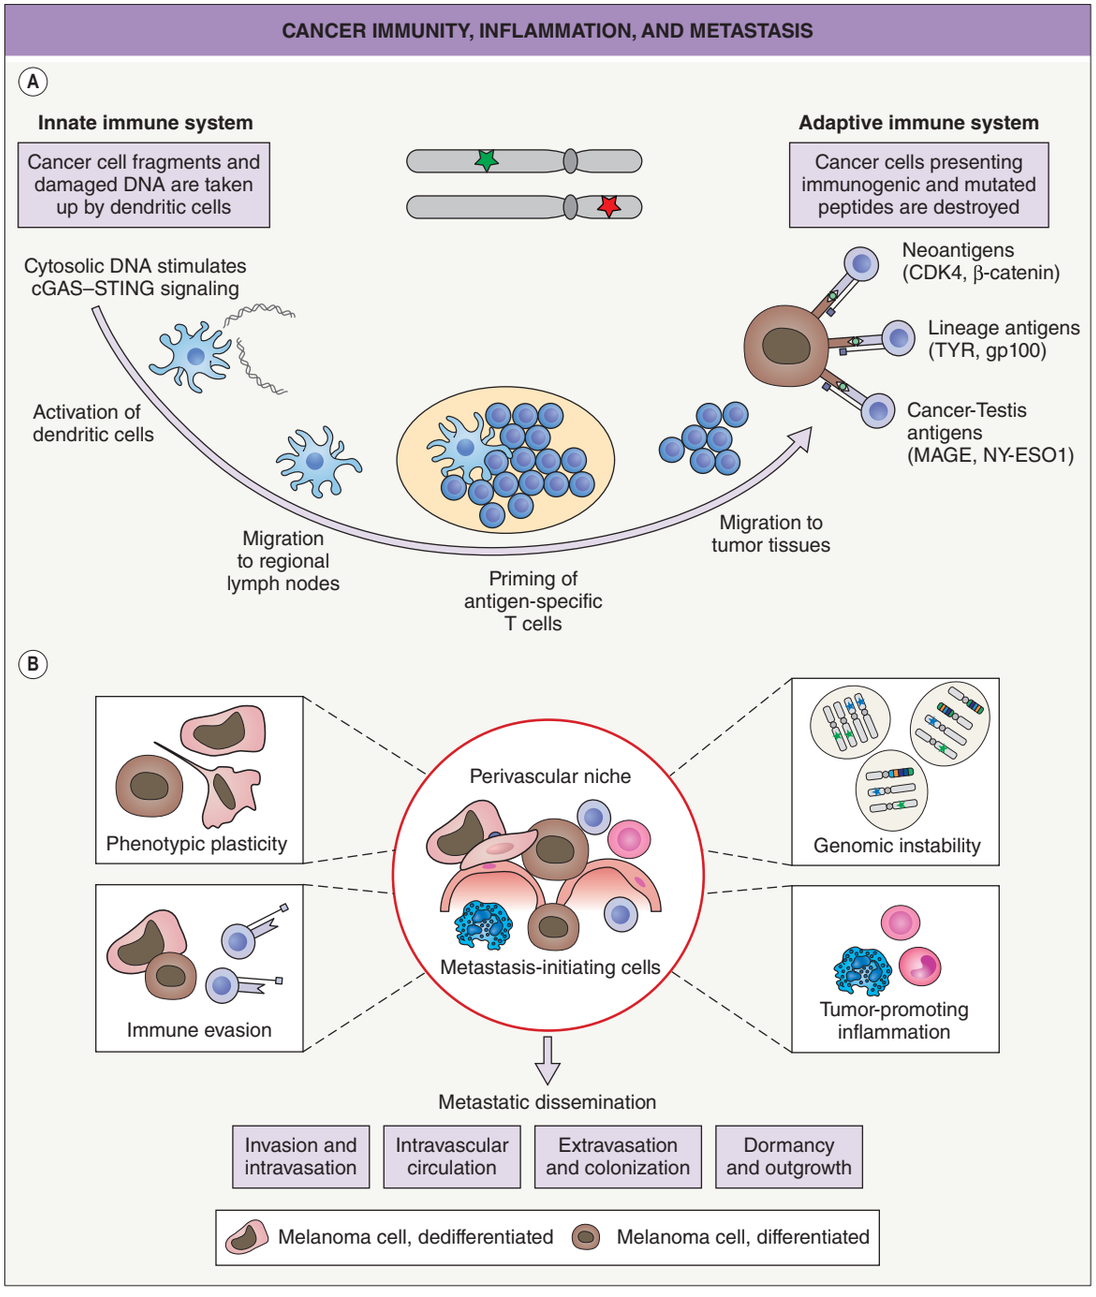

Fig. 107.8 Cancer immunity, inflammation, and metastasis. A Dynamics of innate and adaptive immune recognition of cancer cells by the cellular immune system. **B** In the process of metastasis, cancer cells depend on several cell-intrinsic and cell-extrinsic factors that support extravasation, survival in the circulation, dormancy at sites of organ colonization, and outgrowth to clinically apparent distant metastases. Shown here is the perivascular niche, which plays a key role in promoting cancer cell survival.

the effector functions of tumor-infiltrating T cells. However, cancer cells in turn evade T cell immunity through a variety of mechanisms, including transcriptional downregulation of genes involved in antigen presentation and the acquisition of dedifferentiated, stem cell-like phenotypes[44–46]. In this process, T cells drive phenotypic adaptations of cancer cells and shape their genomic evolution through Darwinian selection of subpopulations with genetically hardwired immune evasive properties, e.g. loss-of-function mutations in MHC molecules[43].

Cancer-Promoting Inflammation

A growth-promoting inflammatory microenvironment can drive cancer progression

Progressively growing cancer cells engage in dynamic reciprocal interactions with surrounding immune cells, creating a microenvironment that fosters their survival and proliferation[47]. This is driven in part by cancer cell-intrinsic oncogenic signaling and the secretion of growth-promoting, proinflammatory cytokines and chemokines. In addition, cancer-promoting inflammatory microenvironments can result from repetitive tissue injury due to the action of physical and chemical carcinogens. The potential role of inflammatory cells within cancer tissues in promoting malignant progression was already recognized by Rudolph Virchow in 1863 in his "irritation theory of cancer". This was experimentally verified using chemical carcinogens and UV irradiation as initiators and inflammatory promotors.

Chronic inflammation, both intrinsic and extrinsic to cancer cells, increases the recruitment of myeloid immune cell populations with T cell suppressive phenotypes that normally orchestrate tissue regeneration. DNA damage responses and genomic instability of cancer cells contribute to a protumorigenic inflammatory response, for example due to leakage of extrachromosomal double-stranded DNA into the cytosol, which activates innate antiviral immune responses via the cGAS–STING pathway. Activation of this signaling pathway in cancer-associated dendritic cells can stimulate antigen-specific T cells, while activation in cancer cells with chromosomal instability supports cancer cell survival and evasion of T cell immunity[30].

Inducing or Accessing Vasculature

Hypoxic environments activate proangiogenic signaling pathways

Increased blood supply of oxygen and nutrients is required for continuous tumor growth. The identification of vascular endothelial growth factor (VEGF) as one of the principle molecular regulators of tumor angiogenesis represents a milestone in cancer research[48]. Cancer cells produce VEGF in response to hypoxic conditions that stabilize and activate this hypoxia-inducible factor. Binding of VEGF to its receptor VEGFR2 on endothelial cells initiates the formation of new blood vessels through neoangiogenesis. Mechanistically, this is orchestrated by motile endothelial cells, called tip cells, that break down the surrounding extracellular matrix (ECM) and initiate the growth of new vascular sprouts. This process is tightly regulated by Notch signaling via the secretion of the delta ligand-like 4 (DLL4) by endothelial tip cells (see Fig. 102.7).

However, newly formed blood vessels in tumors are mostly abnormal, both structurally and functionally. Their architecture is chaotic, tortuous, and leaky due to a lack of normal pericyte coverage, resulting in irregular blood flow, decreased perfusion, and chronic hypoxia. The cross-talk between hypoxic cancer cells and endothelial cells is also critically shaped by proangiogenic and proinflammatory mediators secreted by cells of the immune system in the tumor microenvironment. For example, macrophages and neutrophils can secrete VEGF-A and other proangiogenic factors such as angiopoietin-1 (ANGPT1) and hepatocyte growth factor (HGF). Therapeutic inhibition of proangiogenic signaling has been shown to normalize the tumor vasculature and improve the efficacy of chemo- and immunotherapies. Conversely, effective immunotherapies can contribute to vessel normalization[49].

Activating Invasion and Metastasis

Phenotypic plasticity enables cancer cell invasion, migration, and metastasis

If cancers are detected early, patients can be cured by surgical excision. This is frequently achieved for cancers in the skin that are immediately visible. However, in some cases cancer cells are able to invade adjacent tissue, enter lymph and blood vessels, spread throughout the body, and colonize distant organs before they are locally resected. Histologically distinct cancer entities differ in their propensity and their patterns of metastatic dissemination. This was already noted in the late 19th century by the English surgeon Stephen Paget who proposed that the organ preference of cancer metastasis might result from favorable interactions between metastatic cancer cells and the unique tissue microenvironments in different organs. This "seed and soil" theory was complemented later to include the impact of mechanical factors such as the anatomy of vascular and lymphatic drainage from the site of a primary tumor. Research over the past several decades has provided insights into cellular and molecular mechanisms that drive cancer metastasis[50–52]. The characterization of cancer cell subpopulations that initiate and sustain the development of metastases represented a key conceptual advance. These rare metastasis-initiating cells display the stem cell-like phenotype and plasticity of their lineage progenitors that helps them to survive the adverse physical and metabolic conditions in the circulation and evade immune cell recognition and destruction[51].

Metastasis-initiating cancer cells undergo reversible epithelial-to-mesenchymal transitions and enter slow-cycling and dormant cell states during the metastatic cascade. The switch of adhesion molecules from epithelial to mesenchymal cell states, most notably from E-cadherin to N-cadherin, is regarded as a critical step in initiating migration and invasion of carcinoma cells. Inflammatory cells in the microenvironment contribute to the disassembly of the extracellular matrix (ECM) and its constituents via enzymes such as matrix metalloproteinases (MMPs), thereby facilitating invasive growth. Supportive interactions with endothelial cells promote cancer cell migration and proliferation along blood vessel surfaces, increasing the likelihood of intravasation and dissemination through the circulation. Dynamic adaptation of cell adhesion networks protects cancer cells from anoikis, a type of apoptosis-like destruction of cells that have lost their cell-matrix contact. Only very few circulating metastasis-initiating cells are finally able to colonize distant organs. Here, they survive and remain dormant for longer periods of time within perivascular niches, before they grow out as clinically apparent metastases (Fig. 107.8B)[51].

Despite impressive advances in our understanding of the biology underlying cancer metastasis, patients with metastatic disease frequently develop resistance to currently available treatments. Progressive growth of disseminated cancer cells remains responsible for the majority of cancer-associated deaths. Current large scale sequencing studies of cancer metastases reveal an increasingly heterogeneous and complex picture of genomic alterations at this late stage of cancer evolution. These studies found that the majority of oncogenic driver mutations occur before metastatic dissemination. However, chromosomal instability and copy-number variations such as whole genome doubling were more frequently observed in metastatic cancer cells from many tumor types[53]. Evidence is accumulating that the unique microenvironments in different organs, most notably the metabolic conditions and the immune cell composition that determine therapy responses, also shape the evolution of cancer genomes during metastatic progression. Integrated analyses of the whole cancer ecosystems are required to fully understand metastatic disease as a prerequisite for the development of patient-specific therapeutic strategies.

PATHOGENESIS OF KERATINOCYTE CARCINOMAS

Keratinocyte carcinomas derive from epidermal keratinocytes and worldwide represent the most common cancer type in fair-skinned populations. The majority of keratinocyte carcinomas are basal cell carcinomas (BCCs), which are locally destructive and only rarely develop metastases. Cutaneous squamous cell carcinomas (cSCCs) are less common, but more likely to metastasize and are responsible for the majority of deaths from keratinocyte carcinomas (see Ch. 108).

Genomic sequencing of keratinocyte carcinomas has revealed the highest mutational burden of any cancer type, with molecular signatures of UV-induced DNA damage. This is consistent with lifelong sun exposure as the most important environmental risk factor[54,55]. It is now known that epidermal keratinocytes in clinically normal-appearing, UV-exposed skin can tolerate a surprisingly high number of mutations in known cancer genes[12], indicating powerful mechanisms

that prevent malignant transformation at the tissue level. Recent experiments in genetically engineered mouse models suggest that oncogenic signaling induces keratinocyte differentiation and physiologic death as a mechanism of tumor suppression[56].

Molecular Pathogenesis of Basal Cell Carcinoma (BCC)

Genetic linkage studies in families with basal cell nevus syndrome (BCNS or Gorlin syndrome; see Ch. 108), a rare inherited disorder in which multiple BCCs develop comparatively early in life, provided an initial insight into the specific molecular pathogenesis of BCC – this was beyond the known mutations in *TP53* that are present in all keratinocyte carcinomas. These studies identified *PTCH1* as a tumor suppressor gene that is inactivated in BCNS patients and whose protein product is an inhibitor of the Hedgehog signaling pathway (see Fig. 107.6). Subsequent studies identified loss-of-function mutations in *PTCH1* as a frequent event in sporadic BCCs[57].

The Hedgehog signaling pathway was discovered in *Drosophila*, is highly conserved during evolution, and plays an important role in tissue patterning and cell fate during embryonal development. In the skin, Hedgehog signaling is responsible for the developmental regulation of hair follicles and sebaceous glands. In adult tissues, it is involved in epithelial and neural stem cell maintenance as well as in tissue repair responses. Oncogenic activation of Hedgehog signaling is observed in various types of cancer, including BCC, medulloblastoma, and pancreatic, breast, colon, ovarian, and small cell lung carcinomas. Experimental activation of Hedgehog signaling in epidermal keratinocytes from genetically engineered mice leads to skin tumors with a BCC phenotype, demonstrating the functional importance of this pathway *in vivo*[58].

Whole exome sequencing studies confirmed BCCs as the tumor entity with the highest number of mutations and provided a comprehensive picture of the landscape of oncogenic driver mutations in BCC metastases (Fig. 107.9A). In addition to driver mutations that activate the Hedgehog pathway in 85% of BCCs, these studies identified mutations in target genes of N-Myc as well as the Notch and Hippo-YAP pathways[54]. These findings are thought to provide an explanation for the phenotypic variation of BCCs. Recently, it was shown that in genetically engineered mice, combined experimental activation of the Hedgehog and Notch signaling pathways, together with overexpression of N-Myc, was able to drive progressive and unrestrained growth of BCCs[59]. These observations support a model in which the aggressive growth of BCCs is the result of multiple complementary genetic alterations, consistent with the concept of cancer evolution (Fig. 107.9B).

Molecular Pathogenesis of Cutaneous Squamous Cell Carcinoma (cSCC)

The pathogenesis of cSSC has been studied experimentally for decades in mice using mutagenic chemicals such as dimethylbenzanthrene (DMBA) and UV irradiation in two-stage carcinogenesis models. The identification of oncogenic *Hras* mutations in cSCCs arising in DMBA-exposed mice represents a milestone in skin cancer biology[1]. Subsequent murine studies demonstrated an important role for loss-of-function mutations in *p53* in Ras-driven cSCCs, enabling chromosomal alterations and genomic instability. Initial studies in a limited number of human cSCCs confirmed recurrent oncogenic driver mutations in *HRAS* and *TP53*. Deeper insights into the molecular pathogenesis of cSCCs and the identification of additional oncogenic drivers had to await the comprehensive characterization of a larger number of cSCCs using next-generation sequencing of whole exomes. Initial reports identified frequent mutations in genes of the Notch pathway[60].

The Notch signaling pathway was first described in *Drosophila* (see Fig. 107.7). More than a century ago, Thomas Hunt Morgan identified mutant fruit flies with a characteristic notching of their wings, giving the gene its name. In the 1980s, Notch genes were identified and found to orchestrate an ancient cell signaling pathway that is highly conserved within the animal kingdom. Notch signaling plays an important role in cell–cell communication during embryogenesis and is critically required for the development of many tissues and organs including the brain, the heart and vasculature, the hematopoietic system, and the skin. It promotes the self-renewal of stem and progenitor cells, orchestrates cell fate decisions, and regulates cell differentiation in a cell context-dependent manner. Notch signaling is maintained at a low level in adult organisms and is rapidly upregulated during repair responses following tissue injury.

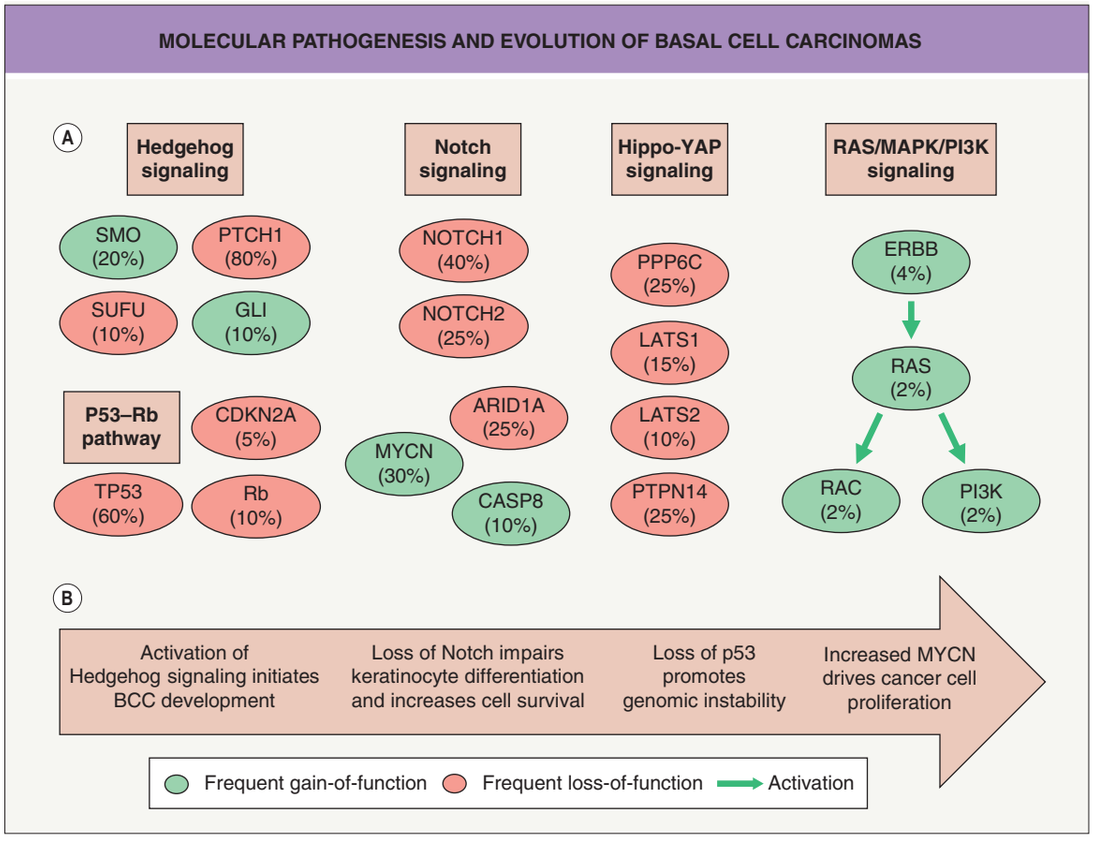

Fig. 107.9 Molecular pathogenesis and evolution of basal cell carcinomas (BCCs). A Genomic alterations in signaling pathways involved in BCC pathogenesis. **B** Hypothetical model of the evolutionary trajectory of BCC. *A, Adapted from Bonilla X, et al. Genomic analysis identifies new drivers and progression pathways in skin basal cell carcinoma. Nat Genet 2016;48:398–406.*

Importantly, mutations in Notch pathway genes are observed in a wide range of malignancies, most notably in multiple non-cutaneous carcinomas, leukemias, and brain tumors. The oncogenic activity of Notch signaling depends on the cellular context. Initial studies showed that increased Notch signaling is oncogenic in leukemias. In contrast, Notch signaling has tumor suppressor activity in the skin, most likely because it supports keratinocyte differentiation.

A recent comprehensive bioinformatics analysis of available genome sequencing data for cSCCs provided a comprehensive overview of the landscape of oncogenic driver mutations, confirming the important role of mutations in Notch pathway genes as the second most frequent group of oncogenic drivers after *TP53* and *Rb* (Fig. 107.10A)[55]. Today, sequential acquisition of oncogenic driver mutations in genes that encode proteins in the p53–Rb and Notch pathways, followed by mutations in epigenetic regulators and the acquisition of structural and numerical chromosome alterations, are thought to represent the evolutionary trajectory of cSCC development (Fig. 107.10B,C). Progressively growing carcinomas acquire chromosomal alterations, aberrantly activate the phenotypic plasticity of their stem and progenitor cells, recruit suppressive T cells that subvert anti-tumoral immunity, and engage with endothelial cells to support metastatic dissemination.

CURRENT DEVELOPMENTS AND FUTURE PERSPECTIVES

Mapping the Evolution of Cancer Ecosystems in Space and Time

Recent advances in single-cell and spatially resolved technologies have enabled analysis of tumor specimens at an unprecedented resolution. The next frontier in cancer research is to use these techniques to further understand the spatial and chronologic complexity of cancer. Current projects such as the NIH Human Biomolecular Atlas Program (HuBMAP) aim to generate references of human tissues by combining (epi-)genomic, transcriptomic, proteomic, and metabolomics analyses with single-cell and spatial resolution[61]. In analogy to the first human reference genome created more than 20 years ago, these frameworks may serve as invaluable tools for understanding the dynamics of tissue development.

Similar approaches focusing on cancer rather than healthy tissues are attempting to reconstruct the heterogeneity and complex interactions between cancer cells and their host organisms[62]. This wealth of information is already catalyzing the development of novel bioinformatical analysis tools and promoting the convergence of diverse scientific disciplines with the potential to once again revolutionize our understanding of cancer. The aforementioned projects may have the capability of answering some of the key riddles of cancer in the coming decade: the mechanisms of metastatic spread, the tissue specificity of oncogenic events, the cell(s) of origin of cancer, and the influence of the cancer microenvironment.

The Microbiome and Cancer

Although the discovery of microbiota influencing tumor development dates back more than 100 years, only recent discoveries have suggested a far deeper relationship between cancer cells and surrounding microbes. Due to the low biomass compared to the tumor cells themselves, and the diverse strains of microbiota colonizing different areas of the bodies and tumor types, the study of cancer-associated microbiota has proven to be challenging. However, recent technological advances have enabled their study, highlighting that microbiota have the capacity to modulate multiple aspects of cancer development, progression, and therapeutic response[63].

As an example, correlations have been observed between specific bacterial strains in the gut and responses to immunotherapy, suggesting that the microbiome profoundly influences host immune responses and thereby therapeutic efficacy. Additionally, metastatic dissemination has been shown to be influenced by intracellular bacteria. As lifestyle

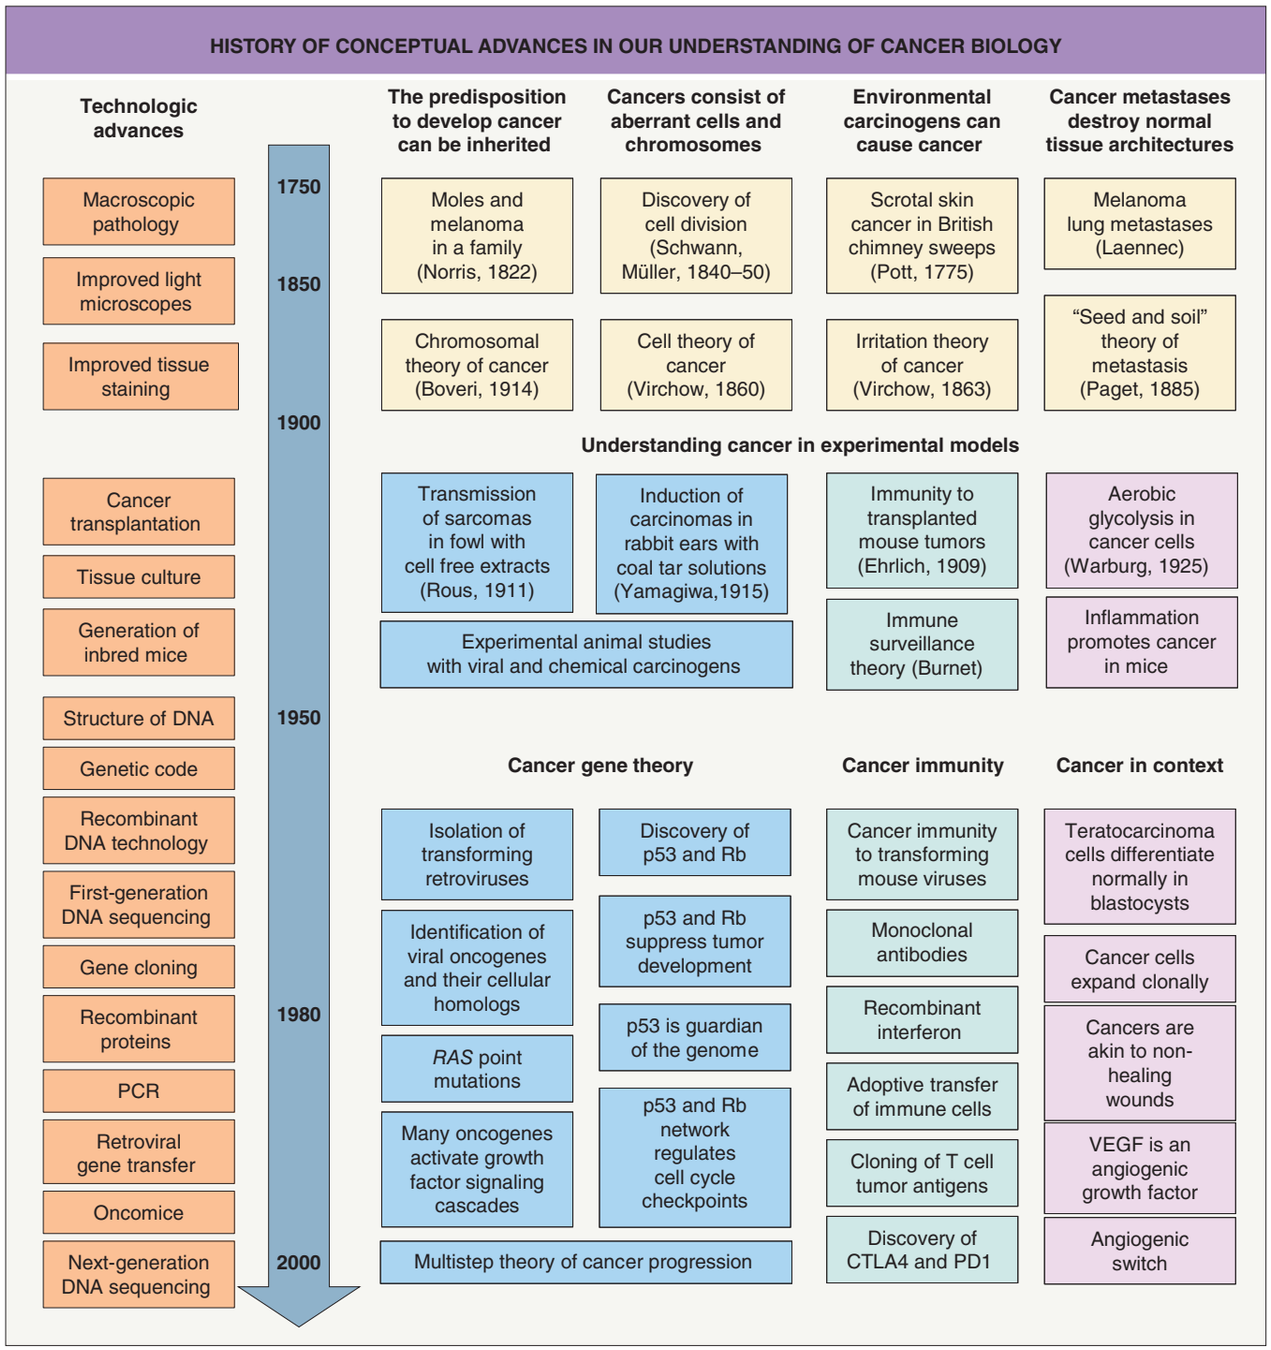
factors such as diet or smoking modulate the microbiome, these findings open new avenues of patient-centric therapeutic approaches. In the near future, synthetic biology approaches using engineered bacteria as cancer therapeutics may complement the current arsenal of targeted and immune therapies.



Future Perspectives for Clinical Translation

Despite the astounding technologic progress that has allowed the analysis of molecular profiles of tumors at an unprecedented depth, the clinical application of these methods is currently lagging behind. To bridge this gap, new projects are addressing the applicability and usefulness of molecular information in patient care. Studies such as the Tumor Profiler Trial are attempting to combine bulk and single-cell DNA and RNA sequencing, immunofluorescence, mass cytometry imaging, and pharmacologic analyses into a molecular research report that can be used to guide therapeutic decisions[64].

eFig. 107.1 History of conceptual advances in the understanding of cancer biology. Key technologic advances (left) are accompanied by a selection of groundbreaking observations in the fields of cancer biology, cancer genetics, and cancer immunology (right).

eFig. 107.2 Carcinogenesis: oncogenes versus tumor suppressor genes. A Under physiologic conditions, proto-oncogenes control the rate of cell cycle progression (left). Oncogenes are proto-oncogenes that have acquired activating mutations, represented by the yellow dot within the second allele (center) or gene amplifications (right). Oncogenes function in a dominant fashion, meaning that activating alterations in only one allele are sufficient for the gene to gain oncogenic potential. **B** A tumor suppressor gene acts as a brake on the cell cycle, decreasing cell proliferation. Tumor suppressor genes are inactivated by mutations in both alleles. Tumor suppressor genes function in a recessive manner, meaning that a mutation in only one allele is not sufficient for loss of gene function. eFig. 107.3 demonstrates the various mechanisms by which the "second hit" occurs in tumor suppressor genes.

eFig. 107.3 Mechanisms of loss of heterozygosity and inactivation of wild-type tumor suppressor genes. Mechanisms depicted by which both copies of a gene can be inactivated (bottom). With loss of heterozygosity (LOH), the resultant changes are best explained by the absence of wild-type protein. While translocations usually activate oncogenes or generate new fusion proteins, they can also be associated with microdeletions. An alternative mechanism exists (right) in which the wild-type allele is rendered non-functional. That is, some mutations can lead to expressed truncated proteins, and the latter may have dominant-negative effects or may be partially functional. An example would be the p53 protein. *Adapted and redrawn from Foulkes WD. Inherited susceptibility to common cancers. N Engl J Med 2008;359:2143–53.*

eFig. 107.4 Apoptotic pathways. Various triggering events are depicted within blue-colored boxes. Consequences of induced apoptosis are shown at the bottom of the figure within green-colored boxes. Fragmentation of genomic DNA by endonucleases results in a discrete ladder of DNA fragments of decreasing lengths as seen in the left two lanes compared to the DNA standard ladder in the right-most lane. Cyt, cytochrome; EGF, epidermal growth factor; TNF, tumor necrosis factor.

108 Actinic Keratosis, Basal Cell Carcinoma, and Squamous Cell Carcinoma

Ingrid H. Wolf, H. Peter Soyer, Erin K. McMeniman and Peter Wolf

Chapter Contents

Actinic Keratosis and Squamous Cell Carcinoma *1892*
Basal Cell Carcinoma *1900*

Synonyms: ■ Solar keratosis and senile keratosis are non-preferred synonyms for actinic keratosis (solar keratosis is abbreviated to SK, causing confusion with seborrheic keratosis) ■ Bowen disease: squamous cell carcinoma *in situ*, intraepidermal carcinoma ■ Basal cell epithelioma and rodent ulcer are antiquated synonyms for basal cell carcinoma ■ Basal cell nevus syndrome: nevoid basal cell carcinoma syndrome, Gorlin syndrome, Gorlin–Goltz syndrome

Key features

- Keratinocyte carcinoma, also referred to as non-melanoma skin cancer (NMSC), includes basal cell carcinoma (BCC), cutaneous squamous cell carcinoma (cSCC), and variants such as verrucous carcinoma; it represents the most common malignancy among White individuals
- The major risk factor for BCCs and cSCCs is exposure to ultraviolet radiation (UVR); other factors include exposure to ionizing radiation, arsenic or organic chemicals, human papilloma virus infection, immunosuppression, and genetic predisposition
- Prevention efforts are aimed at lowering incidence and morbidity via educational programs and sun protection campaigns
- If neglected or inappropriately managed, keratinocyte carcinomas can cause significant morbidity and even death
- Surgery remains a mainstay of treatment, but additional modalities include topical chemotherapy and immunomodulators, photodynamic therapy, radiation therapy, and systemic medications (e.g. targeted drugs, immune checkpoint inhibitors)

INTRODUCTION

Keratinocyte carcinomas, specifically basal cell carcinoma (BCC) and cutaneous squamous cell carcinoma (cSCC), represent the most frequently observed malignancy among White individuals. In individuals with fair skin, ~75%–80% of these malignancies are BCCs and up to 25% are SCCs[1]. The incidence of both continues to rise, leading to an increasing burden of disease. In this chapter, cSCC includes SCCs that arise on the lower vermilion lip.

HISTORY

In 1775, Sir Percivall Pott noted an etiologic relationship between SCC and chimney soot exposure in his short treatise *Chirurgical Observations Relative to the Cancer of the Scrotum*. During the Industrial Revolution, links to arsenic, coal tar, shale oil, and creosote were also identified. In the late 1800s, Paul Unna noted a connection to UVR, when he described skin cancer development in chronically sun-exposed sites in sailors.

Evidence of the basal cell nevus syndrome (BCNS), consisting of jaw cysts, syndactyly and bifid ribs, has been identified in Egyptian mummies almost 4000 years old. In the 1850s, Lebert first used the term "rodent ulcer" to describe untreated BCCs of long duration. Several years later, Sir Jonathan Hutchinson published a review of 42 cases of BCCs, identifying the tumor as a single entity with many different clinical and histopathologic forms. Krompecher first suggested that a BCC arose from the cells of the basal layer of the epidermis, but there were additional theories regarding the site of origin of this tumor, including from the hair follicle and other adnexal structures.

EPIDEMIOLOGY

Keratinocyte carcinomas occur worldwide in all races and ethnicities. They represent the most common malignancy in the US and are associated with substantial morbidity and a relatively small but significant mortality rate. An estimated 5.5 million NMSCs occurred in ~3.3 million individuals in the US in 2012[2], with one in five Americans developing skin cancer during their lifetime[3] (>95% will be NMSC). In a more recent analysis, the incidence of NMSC was noted to be significantly higher in Americans >65 years of age, with a rate of 45 individuals with NMSC/1000 persons and a case rate of 75 cases of NMSC/1000 persons[4].

The most important factor related to development of these neoplasms appears to be skin phenotype (Table 108.1)[5–12], but other factors also play a significant role. As an example, the incidence is about ten times higher in White versus Hispanic men and five times higher in White versus Hispanic women[13]. However, deriving precise data is hampered by the fact that these neoplasms are not routinely included in most state cancer registries and patients with NMSC are often treated in private offices rather than hospitals.

The average amount of annual UVR correlates with the incidence of skin cancer. There is also a direct relationship between incidence and latitude, in that the closer individuals are to the equator, the greater their exposure to UVR. In Australia, in 2002, the cumulative risk by age 70 years of having at least one BCC or cSCC was 70% for men and 58% for women. Incidence also increases with age, with a sharp increase in BCCs in men after the age of 60 years. In those under 40 years of age, the majority of NMSC is found in women, but, by age 80, the incidence in men exceeds that in women by a 2–3 : 1 ratio[13].

Actinic keratoses (AKs) are most often found in fair-skinned individuals, but can be seen in all races. AKs are so common that it has been estimated that up to 12% of individuals in the US have them[14]. AKs are also very common in other countries with large fair-skinned populations. For example, in Austria when 4449 outpatients >30 years of age were screened, an overall AK prevalence of 39% in men and 24% in women was observed, with prevalence increasing with age in both sexes[15].

Over 80% of AKs occur in sites with the most cumulative sun exposure, e.g. the bald scalp, superior helices of the ears, face, dorsal hands, extensor forearms. Risk factors include skin phototypes I and II, significant cumulative sun exposure, a prior history of AKs, increasing age, immunosuppression, and male sex[16]. AKs are also markers for an increased risk of developing invasive cSCC[17], but the rates of transformation are low and difficult to assess (see below)[18].

The demographics of *cSCC* are similar to those of AKs, with the majority of SCC occurring on the head, neck, upper extremities[19], or shins. In light-skinned populations, the degree of UV exposure is related to SCC development, while chronic irritation or injury can play a role in all populations. cSCC is found more frequently in men (M : F = 3 : 1), especially in younger age groups, and the incidence increases significantly after age 60 years[13]. The incidence of cSCC has been rising worldwide in all age groups over the last several decades at an estimated 3%–10% per year, with >400 000 cases of invasive SCC diagnosed annually in the US[20]. Similar incidence trends have been noted worldwide.

Weinstock[21] reported an age-adjusted mortality rate for confirmed cases of cSCC in Rhode Island of 0.26/100 000. SCC-associated mortality is

INFLUENCE OF SKIN PIGMENTATION ON EPIDEMIOLOGY OF NMSC AND CUTANEOUS MELANOMA		
Characteristic	**Lightly pigmented individuals**	**Darkly pigmented individuals**
NMSC – annual incidence per 100 000	230	3.4
BCC : SCC ratio	4 : 1	1.1 : 1 to 2 : 1
BCC male : female ratio	1.5 : 1	1.3 : 1
SCC male : female ratio	2 : 1 to 5 : 1	1.3 : 1
% of SCCs developing in scars and chronic non-healing ulcers	<2	30–40
NMSC incidence rates	Increasing	?
NMSC mortality rates	Decreasing until 2000; possibly increasing since 2010	Decreasing until 2000; possibly increasing since 2010
Melanoma – annual incidence per 100 000	29	1
Deaths due to melanoma – annual incidence per 100 000	4.3	0.2

Table 108.1 Influence of skin pigmentation on epidemiology of non-melanoma skin cancer (NMSC) and cutaneous melanoma. BCC, basal cell carcinoma; SCC, squamous cell carcinoma. From references 3,5–12.

higher in White individuals and older persons, and men have a 3 : 1 greater SCC mortality rate as compared with women[21]. In some studies, SCCs located on the ear, lip, and genitalia appear to have a higher risk of death. While melanoma among White individuals is responsible for 90% of skin cancer deaths before 50 years of age, in adults over 85 years of age, the majority of skin cancer deaths are attributable to cSCC[6]. A population-based analysis of CDC data revealed that mortality rates due to NMSC had been decreasing through 2000, were relatively stable until 2010, and then significantly increased by 44% through 2017[22]. Possible explanations included a true increase due to factors such as an aging population and an increase in immunosuppressed patients in addition to changes in cause of death documentation. For the period studied, the NMSC mortality rate was 1.24/100 000 persons/year (0.62, 0.38, and 0.23 for sun-exposed, genital, and perianal sites, respectively). At all three sites, mortality rates due to NMSC increased in White, but not in Black, individuals.

BCC is the most common skin cancer in humans, and men generally have higher rates of BCC than do women (1.5–2 : 1)[23]. Over the last 30–40 years, it is estimated that incidence rates have risen between 20% and 80%. In the US, a disproportionate increase has been observed in young women. Similar increases in incidence rates have been noted worldwide, with the incidence doubling in Finland and Switzerland and increasing in Wales by 50% over this time period.

Incidence rates for BCC also increase with age, and the median age at diagnosis is 68 years. In 2002, an incidence rate for BCC of 884 per 100 000 per year was observed in Australia. In this geographic location, cSCC typically occurs at half the rate of BCC among men and at about one-third the rate among women.

Mortality from BCC is quite rare and occurs primarily in immunocompromised patients and individuals with BCNS. Cases of metastatic BCC are more likely from tumors with aggressive histopathologic patterns (morpheaform, infiltrating, metatypical, basosquamous). Perineural growth, also referred to as perineural invasion, may be an indicator of aggressive disease[24]. Metastases often involve regional lymph nodes, lungs, bone, and skin. The mean age at the time of death is higher than with cSCC, and the age-adjusted mortality rate for BCC has been estimated at 0.12 per 100 000. Mortality risk is related to increasing age, lighter skin phototypes, and male sex (>2 compared with women).

PATHOGENESIS

See Chapter 107.

RISK FACTORS FOR THE DEVELOPMENT OF BASAL CELL CARCINOMAS (BCCs) AND CUTANEOUS SQUAMOUS CELL CARCINOMAS (cSCCs)		
	cSCC	**BCC**
Environmental exposures		
Exposure to UVR	+	+
Other exposures to UV light (PUVA, tanning beds)	+	+
Ionizing radiation	+	+
Chemicals, including arsenic, mineral oil, coal tar, soot, mechlorethamine (nitrogen mustard), polychlorinated biphenyls, 4,4′ bipyridyl, psoralen (plus UVA)[39]	+	+
Medications (e.g. voriconazole, azathioprine, BRAF inhibitors, hydrochlorothiazide*, hydroxyurea, other immunosuppressants)	+	(+)
Human papillomavirus (HPV)	+	(+)
Cigarette smoking	+	
Pigmentary phenotype		
Fair skin, always burns, never tans	+	+
Freckling	+	+
Red hair	+	+
Genetic syndromes

*Photosensitizing medication, but conflicting data.
**Both cSCCs (keratoacanthoma type) and BCCs typically have sebaceous differentiation.
†More often trichoblastomas.

Table 108.2 Risk factors for the development of basal cell carcinomas (BCCs) and cutaneous squamous cell carcinomas (cSCCs). UVR, ultraviolet radiation.

RISK FACTORS (TABLE 108.2)

Environmental Exposures

Ultraviolet radiation (UVR)

Exposure to UVR is the predominant cause of BCC and cSCC as evidenced by migrant studies, the correlation of incidence to latitude, and animal studies. There is, however, a difference in the type of UV

exposure. For BCCs, intermittent intense episodes of UV exposure and sunburns at any age appear to increase risk, whereas cumulative long-term UV exposure and childhood sunburns increase the risk for developing cSCCs and AKs[25,26].

Sun exposure early in life appears to have a greater influence on subsequent skin cancer risk than at a later age. For example, individuals born in countries with high ambient UV radiation such as Australia have significantly higher incidence rates of BCC and cSCC as compared to those with a similar genetic background (e.g. British, northern Europeans) who migrated to these areas later in life from countries with lower ambient UV radiation[25,27,28].

Indoor tanning usage

Multiple studies have demonstrated an increased risk for the development of BCCs and cSCCs in those who are exposed to artificial sources of UVR. Intentional tanning has been shown to increase the risk of SCC development[29] and Karagas et al.[30] demonstrated that any use of tanning devices was associated with odds ratios of 2.5 for SCC and 1.5 for BCC, even after adjustment for history of sunburns, sunbathing, and sun exposure. A systematic review and meta-analysis of 12 studies (n = 9328 cases of NMSC) fundamentally confirmed these findings[31]. In response, many countries have passed legislation aimed at regulating indoor tanning facilities. Notably, Australia has actually completely banned this commercial industry while some states in the US prohibit minors from indoor tanning[32].

Therapeutic UVR exposure

Individuals with psoriasis have been shown to be at increased risk for the development of keratinocyte carcinomas. Whereas long-term follow-up of psoriasis patients who were treated with UVR plus tar (Goeckerman) or narrowband UVB found no increased risk[33], long-term PUVA therapy was associated with a significant, dose-related risk of cSCC development (adjusted relative risk = 8.6 for an accumulated exposure of between 100 and 337 treatments)[34]. With prolonged PUVA therapy, a slightly increased risk for BCC development was noted as well. In addition to the direct effects of PUVA, PUVA-induced immunosuppression may also play a role.

Ionizing radiation

Exposure to ionizing radiation leads to a threefold increased risk for BCC and cSCC[35]. The risk is in proportion to the radiation dose. Larger fractionated doses (>12–15 Gy) are thought to be necessary to induce tumor formation, so the risk with a given total dose may be less if a larger number of smaller fractionated doses are given. Most SCCs and BCCs that arise after exposure to ionizing radiation do so after a long latency period of up to several decades, with most tumors appearing ~20 years after the initial exposure.

Treatment of tinea capitis with radiation (prior to the discovery of effective systemic antifungal medications) has been linked to the development of multiple BCCs. In a study of 2224 children given X-ray therapy for tinea capitis (compared with a control group of 1380 tinea capitis patients given only topical medications), the relative risk for developing BCC of the head and neck among irradiated White individuals was 3.6[36].

Patients with BCNS are exquisitely sensitive to ionizing radiation and it should be avoided if possible (see below).

Occupational risk factors

Persons with outdoor occupations have a higher risk of developing skin cancer[37]. Based upon decades-old evidence, airline pilots, who are also exposed to ionizing radiation at flight altitudes, have about twice the risk of developing keratinocyte carcinomas than the general population[38]. Other occupations associated with an increased risk for NMSC include agricultural workers, gardeners, sailors, and locomotive engineers.

Chemical exposures

Multiple organic chemicals have been associated with an increased risk for the development of keratinocyte carcinomas[39] (see Table 108.2). Occupational chemical exposures which can lead to skin cancer most commonly involve pesticides, asphalt, tar, and polycyclic aromatic hydrocarbons, and they typically result in SCC. The skin cancers induced by chemical exposures are usually localized as well as multiple, most often appearing on the arms[40].

Arsenic is a well-defined cause of SCC (see Ch. 88). A clue to arsenic exposure is the presence of palmoplantar arsenical keratoses. BCC has also been reported following extensive arsenic exposure. The typical latency period from exposure to tumor development is 20–40 years[41].

Human Papillomavirus Infection

Human papillomaviruses (HPV) represent a large group of DNA tumor viruses that infect the epithelia of both skin and mucosae, inducing hyperproliferative lesions, most commonly warts. HPV is associated with anogenital SCCs, particularly in HIV-infected patients. Individuals with the genetic condition epidermodysplasia verruciformis (EV) are known to have a significantly increased risk of developing SCCs, especially in sun-exposed sites. Infection with the HPV types referred to as EV- or beta-types (see Table 79.1) is also observed in the general population, in particular in immunosuppressed solid organ transplant recipients[42]. Because these specific HPV subtypes are thought to act as facilitators for the accumulation of UVR-induced mutations during the development of SCC[43], a goal is to design therapeutic HPV vaccines[44].

Immunosuppression

Organ transplantation

Solid organ transplant recipients have a markedly increased incidence of skin cancer, primarily cSCC. The incidence of BCC in organ transplant recipients is up to 5–10 times greater than in the general population, while the incidence of SCC is 30–250 times greater. Risk factors include skin phototypes I/II, cumulative sun exposure, previous history of skin cancer, age at transplantation, and the degree and the length of immunosuppression.

cSCC is a significant cause of morbidity and mortality in transplant recipients[45,46]. The pathogenesis of skin cancer in transplant recipients is multifactorial, involving decreased immunity, direct carcinogenic effects of immunosuppressive medications, and HPV infection in addition to UVR exposure. Transplant recipients are prone to developing numerous lesions and are more likely to suffer local and regional recurrences and metastases[45]. AKs and SCCs begin to appear with increasing frequency several years after transplantation. Lesions are often multiple and usually develop in sun-exposed areas. cSCCs from transplant recipients frequently contain HPV DNA, but it can be from a range of HPV strains including those that occur in common benign cutaneous warts (HPV types 1 and 2), EV (HPV-5 and others; see above), high-risk oncogenic warts (HPV types 16 and 18), and low-risk oncogenic genital warts (HPV types 6 and 11). Sometimes, several HPV types are detected within a single tumor. More recently, a role for polyomaviruses in the development of cSCCs has been proposed.

In one series of renal transplant patients from the US, 5% of the patients died of skin cancer. In another series of heart transplant patients from Australia, 27% died of skin cancer. Two-thirds of these deaths were due to cSCC. Several studies have shown that in renal transplant patients sirolimus, an mTOR inhibitor, reduced the development of cSCCs when compared to calcineurin inhibitors (e.g. cyclosporine, tacrolimus)[47]. However, the impact may be related to the number of previous SCCs[48]. More recently, belatacept, a fusion protein that prevents CD28 activation, was also observed to reduce skin cancer risk in renal transplant recipients[49]. Based upon currently available data, sirolimus and belatacept appear to be preferable in patients with a history of SCCs or strong risk factors. Additional interventions include reduction in immunosuppression, aggressive screening, discontinuing hydrochlorothiazide (HCTZ), and instituting acitretin. Of note, in Ireland a progressive decline in the incidence of keratinocyte carcinomas in organ transplant recipients from 1994 to 2014 was observed[50].

Patients who receive hematopoietic transplants do not experience this marked increase in skin cancer incidence (unless they have received long-term voriconazole), presumably because of a shorter duration of immunosuppression.

Immunosuppressive drugs

Use of immunosuppressive drugs, including systemic immunomodulators (e.g. TNF inhibitors, alemtuzumab, JAK inhibitors), increases the risk for the development of skin cancer. Risk of cSCC development is directly related to the length and degree of immunosuppressive drug usage. Given

the long-lasting mutations and increased risk of NMSC associated with thiopurines (e.g. azathioprine, 6-mercaptopurine)[51], their use in patients with significant photodamage should be avoided when possible.

HIV infection

Patients with HIV infection are at increased risk for the development of several cancers, including HPV-related SCC of the anus. These tumors can be aggressive and monitoring that incorporates anal cytology is recommended[52].

Other Risk Factors, Including BRAF Inhibitors

Up to 25% of patients receiving selective *BRAFV600 inhibitors* (e.g. vemurafenib, dabrafenib) can develop either cSCCs or keratoacanthomas (KAs). They develop primarily in individuals with cutaneous photodamage and can appear within weeks of beginning the kinase inhibitor. Fortunately, the combination of a selective BRAF inhibitor with a MEK inhibitor, as is routinely done nowadays, significantly reduces the incidence of side effects of both drugs, including the formation of SCCs and KAs. *Voriconazole* is also associated with the development of UVR-induced skin cancers, possibly a result of the phototoxic moieties of its metabolites. Due to the small, but statistically significant, increase in the risk of NMSC (hazard rate of 1.04 for SCC and 1.09 for BCC) associated with the use of *HCTZ*[53], the FDA revised its labeling in 2020.

Other possible risk factors include residence at high altitudes, thermal burns, chronic ulcers, and tobacco use[54]. While evidence from animal models suggested a relationship between fat intake and skin cancer incidence, results from subsequent epidemiologic studies were inconsistent and failed to show any strong evidence for either this association or for other dietary factors (e.g. vitamins, minerals)[55–57].

Genetic Risk Factors

Genetic predisposition

Phenotypic characteristics such as red hair, light skin, poor ability to tan, and freckling have been identified as risk factors for melanoma as well as NMSC[25]. Pigmentation is a polygenic trait, with polymorphisms in several genes leading to the variation observed in the human race (see Ch. 65). A key gene encodes the human melanocortin-1 receptor (MC1R) which is expressed on the cell surface of melanocytes. Population-based studies in diverse ethnic groups have shown that the coding region of the human *MC1R* is remarkably polymorphic. In White individuals, there is a strong association between nine common *MC1R* variant alleles and the red hair/fair skin phenotype, thus placing these individuals at higher risk of photocarcinogenesis[58]. Based upon genome-wide association studies and candidate gene studies (see Ch. 54), ~30 and at least 11 susceptibility loci for BCC and cSCC, respectively, have been identified, and they include multiple pigmentation loci.

Genetic syndromes associated with an increased risk of BCCs and/or cSCCs

Xeroderma pigmentosum

Xeroderma pigmentosum (XP) consists of a group of autosomal recessive disorders characterized by defects in unscheduled DNA repair (see Ch. 86). A markedly increased incidence of keratinocyte carcinoma and melanoma is observed in these individuals, if they are exposed to sunlight. cSCCs and BCCs appear at an early age (median age, 8 years), and in affected individuals who are <20 years of age the risk is 4800 times that of the general population. Strict UV avoidance can significantly decrease skin cancer formation.

Oculocutaneous albinism

Oculocutaneous albinism encompasses a group of autosomal recessive disorders in which there is a variable degree of pigmentary dilution of the skin, eyes, and hair (see Ch. 66). At a relatively early age, NMSC, especially SCC, and cutaneous melanoma develop with increased frequency. As in XP, strict sun avoidance for life can greatly minimize tumor development. However, for these patients metastatic cSCC is still a significant problem in areas of the world such as equatorial Africa.

Epidermodysplasia verruciformis

Epidermodysplasia verruciformis (EV) is a rare, usually recessively inherited disorder due to mutations in *TMC6* or *TMC8*, which encode transmembrane channels. There is widespread colonization of the skin by HPVs of multiple subtypes, most often 5 and 8 (see Ch. 79). Evidence for an association between cutaneous HPV infection and cSCC was first reported in these patients. One-third to one-half of patients will develop SCCs as adults, usually in sun-exposed regions, and several decades earlier than is typical for SCC development in the general population. Aggressive biologic behavior, including perineural spread, metastases, and death, have been reported.

Dystrophic epidermolysis bullosa

Dystrophic epidermolysis bullosa with significant scarring can result from both dominant and recessive mutations in the type VII collagen gene. cSCCs more commonly appear in the recessive forms, where they are the most common cause of death. Tumors usually develop during the third to fifth decades of life, are frequently multiple, and demonstrate aggressive behavior in terms of recurrences and metastases.

Basal cell nevus syndrome (BCNS)

BCNS is an autosomal dominant disorder due to an inactivating mutation in *PTCH1*[59] or rarely *PTCH2* while *SUFU* mutations can also lead to multiple hereditary infundibulocystic BCC syndrome (see Fig 107.6). Manifestations of BCNS include multiple or early-onset BCCs, odontogenic keratocysts of the jaw, palmoplantar pits, calcification of the falx cerebri, and skeletal anomalies (Table 108.3; Fig. 108.1). Affected individuals may also develop specific neoplasms such as medulloblastomas, bilateral ovarian fibromas, and cardiac fibromas. Recognition of the early clinical signs of BCNS such as macrocephaly and palmar pits allows for additional screening of at-risk individuals[59].

BCCs usually appear after puberty, but they may develop during childhood. The number of BCCs in a single patient varies from a few

DIAGNOSTIC CRITERIA FOR BASAL CELL NEVUS SYNDROME (BCNS)
Major criteria
1. One basal cell carcinoma (BCC) before the age of 20 years or excessive number of BCCs*
2. Odontogenic keratocysts of the jaw (proven by histology; detected by orthopantogram)
3. Two or more palmar or plantar pits (may be enhanced by soaking of the hands)
4. Lamellar calcification of the falx cerebri before the age of 20 years (on anterior–posterior skull X-rays)
5. Childhood medulloblastoma
6. First-degree relative with BCNS
Minor criteria
1. Macrocephaly (determined after adjustment for height; OFC >97th percentile)
2. Skeletal malformations (e.g. preaxial or postaxial polydactyly)
3. Vertebral/rib anomalies observed on chest X-ray and/or spinal X-ray: bifid/splayed/extra ribs; bifid vertebrae
4. Ocular anomalies (e.g. cataract, developmental defects, pigmentary changes of the retinal epithelium)
5. Cleft lip or palate
6. Ovarian or cardiac fibromas
7. Lympho-mesenteric or pleural cysts
*Need to take into account decreased risk in darkly pigmented individuals and increased risk in those with significant photodamage.

Table 108.3 Diagnostic criteria for basal cell nevus syndrome (BCNS). The diagnosis of BCNS requires *two major plus one minor or one major plus three minor criteria*. With the presence of one major criterion, identification of a heterozygous germline pathogenic variant in *PTCH1* or *SUFU* establishes the diagnosis. The occasional variants in *PTCH2* may not be conclusive and pathogenic variants in *SUFU* may not always cause typical BCNS (see text). Other skeletal abnormalities include frontal bossing, moderate or severe hypertelorism, Sprengel deformity (unilateral elevation of smaller-sized scapula), marked syndactyly of the digits, and marked pectus deformity. *Adapted from Varon R, Demuth I, Chrzanowska KH. Nijmegen Breakage Syndrome. 1999 May 17 [Updated 2017 Feb 2]. In: Adam MP, Mirzaa GM, Pagon RA, et al., editors. GeneReviews® [Internet]. Seattle (WA): University of Washington, Seattle; 1993-2022. www.ncbi.nlm.nih.gov/books/NBK1151 and ref. 59.*

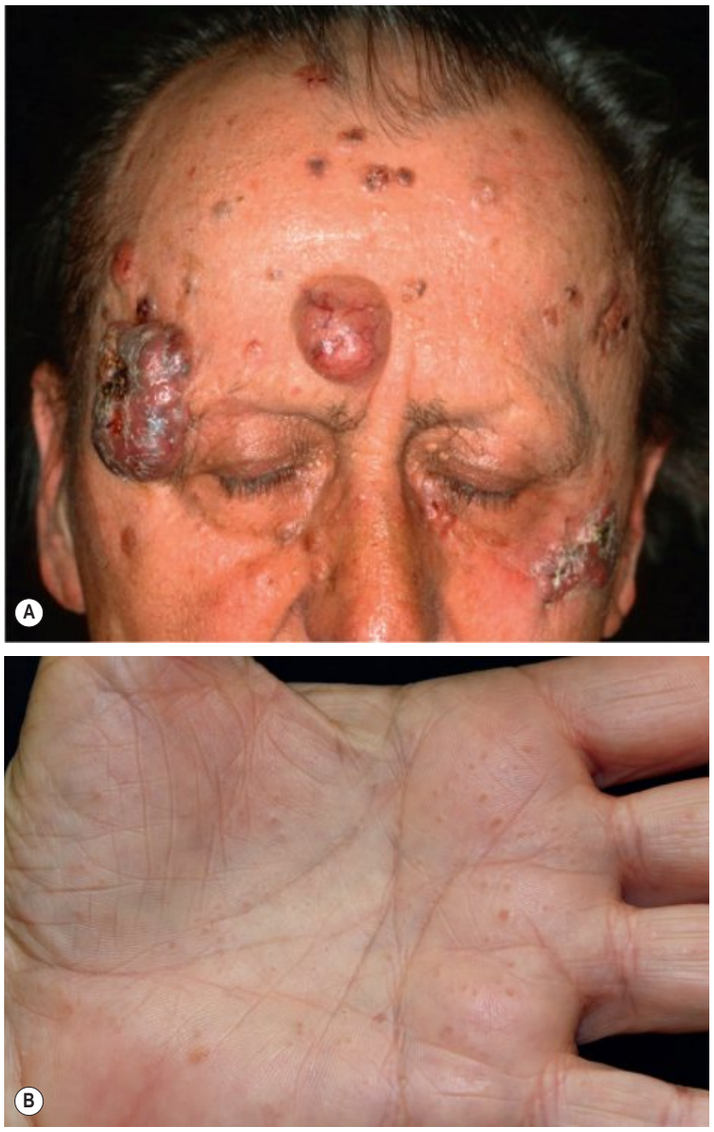

Fig. 108.1 Basal cell nevus syndrome. A Numerous small and several large nodular BCCs on the face. **B** Multiple palmar pits. *B, Courtesy Jeffrey P. Callen, MD.*

to more than a thousand and the size from pinpoint to >5 cm (see Fig. 108.1A). The BCCs favor the sun-exposed areas of the face, neck, and upper trunk, but may occur in sun-protected sites. As in the general population, nodular BCCs usually occur on the face, while superficial BCCs are found primarily on the torso. Individual lesions may be papulonodular, pedunculated, pigmented, eroded, ulcerated, or have a combination of these features. The pigmented BCCs are sometimes misdiagnosed clinically as melanocytic nevi (see Fig. 108.20). The clinical course of the cutaneous tumors is usually indolent prior to puberty, after which they enlarge and eventually ulcerate, as in the general population. Individuals with BCNS are exquisitely sensitive to ionizing radiation, and hundreds of tumors can develop in children within sites of radiation following radiotherapy for medulloblastoma. Additional cutaneous findings include epidermoid (infundibular) cysts and facial milia.

Bazex–Dupré–Christol syndrome and Rombo syndrome

Bazex–Dupré–Christol syndrome is a rare condition, consisting of follicular atrophoderma (usually occurring as circumscribed areas on the dorsal aspect of the hands and feet), hypotrichosis, localized hypohidrosis, milia, epidermoid cysts, and multiple, primarily facial, BCCs. The BCCs develop during the second decade of life and frequently have a trichoepithelioma-like histopathologic appearance. In most families, the inheritance pattern is X-linked dominant and mutations in *ACTRT1* have been detected, resulting in aberrant activation of the hedgehog signaling within primary cilia[60]. Sometimes a source of semantic confusion is the completely different Bazex syndrome (acrokeratosis paraneoplastica), in which psoriasiform plaques of the fingers, toes, ears, and nose are often associated with SCC of the upper aerodigestive tract.

The so-called *Rombo syndrome* has many of the features of Bazex–Dupré–Christol syndrome. Patients have an atrophoderma vermiculatum-like appearance on the cheeks, with evidence of sweat duct proliferation histologically. In addition, they often have hypotrichosis, blepharitis, peripheral (facial/acral) telangiectatic erythema, milia, trichoepitheliomas, and BCCs.

Bloom syndrome

Bloom syndrome (congenital telangiectatic erythema) is a rare autosomal recessive disorder due to mutations in *BML* which encodes the DNA helicase RecQL3 (see Ch. 87). In addition to malar erythema and telangiectasias, short stature and photosensitivity, patients can develop cSCCs as well as leukemia and malignancies of the gastrointestinal tract[61].

Rothmund–Thomson syndrome (RTS)

During the first few months of life, patients develop photodistributed erythema, edema, and vesicles of the cheeks and face (see Ch. 87)[61]. Additional cutaneous findings include gradual appearance of poikiloderma, thinning of scalp hair, and hypoplastic nails. While osteosarcoma develops in type II RTS (due to dysfunction of the DNA helicase RecQL4), NMSC can develop in both types. Mutations in *ANAPC1*, whose protein product mediates ubiquitination and controls progression through mitosis and G1 of the cell cycle, are responsible for type I RTS.

Keratitis–ichthyosis–deafness (KID) syndrome

In addition to congenital sensorineural hearing loss, patients present with a transient erythroderma at birth or during infancy followed by discrete plaques of erythrokeratoderma as well as palmoplantar keratoderma (see Ch. 57)[61]. Mutations in genes that encode connexins lead to KID syndrome (see Ch. 58); these gap junction proteins are expressed in ectoderm-derived epithelia of the inner ear, cornea, and epidermis. Patients have an increased susceptibility to viral, bacterial, and fungal infections and can develop the follicular occlusion triad, proliferating pilar tumors, and early-onset mucocutaneous SCCs (see Table 57.5).

Risk of Additional Cancers

Individuals who have had a BCC or cSCC are at increased risk for the development of additional BCCs and SCCs[62], compared to the general population. They are also at increased risk for developing cutaneous melanoma[63]. Based upon epidemiologic studies, persons with a history of BCCs or SCCs may be at increased risk for developing and dying from other (non-skin) cancers[64–66].

Field cancerization

In field cancerization, areas of the skin with significant photodamage (e.g. the bald scalp) have multiple clusters of p53-mutated keratinocytes[67] and they may or may not be clinically apparent. The presence of multiple actinic keratoses points to the diagnosis. Treatment regimens should focus not just on specific tumors but on the entire affected anatomical site (see below).

ACTINIC KERATOSIS AND SQUAMOUS CELL CARCINOMA

Clinical Features

Actinic keratosis

Actinic keratoses (AKs) were initially described as solar keratoses (due to their suspected cause) and senile keratoses (due to the age of onset). The term "actinic keratosis" is preferred over solar keratosis, partly because the abbreviation SK also stands for seborrheic keratosis.

AKs have historically been characterized as being "precancerous" or "premalignant" because the atypical keratinocytes within these lesions are confined to the epidermis. There is no risk of metastasis until these lesions evolve into invasive carcinoma, but AKs are viewed as potential precursors of cSCC. The likelihood of a solitary AK progressing into an invasive cSCC is difficult to predict, with estimates varying widely from 0.1% to 20%.

AKs present on sun-damaged skin of the head, neck, upper trunk, and extremities (Fig. 108.2A–D). Individuals at higher risk of developing

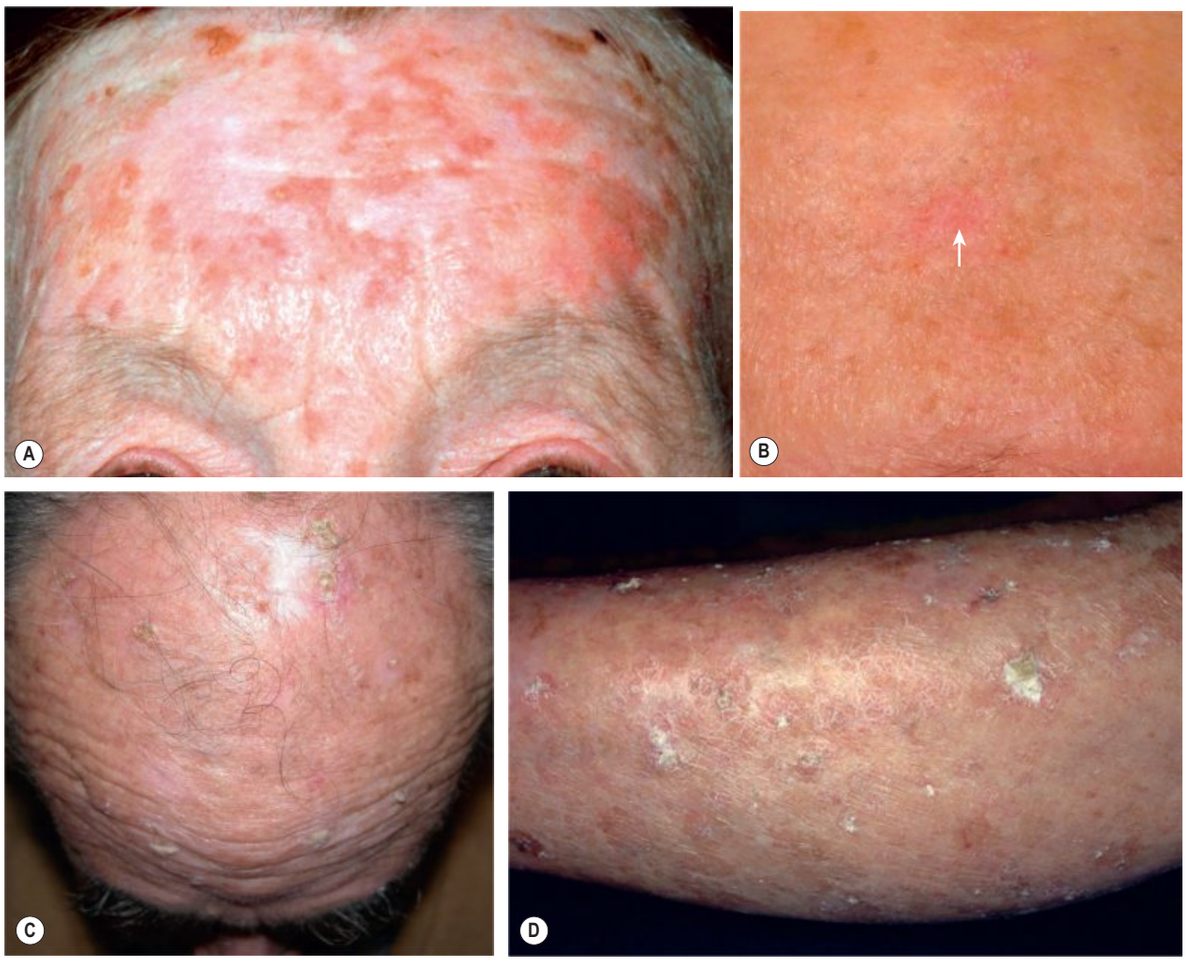

Fig. 108.2 Actinic keratoses (AKs). A Multiple AKs on the forehead of an elderly woman with fair complexion, blue eyes, and severe photodamage; the AKs vary in size from a few millimeters to over a centimeter. On the left forehead, the eroded pink plaque with scale represents a superficial SCC. **B** Pink-colored atrophic AK with minimal scale on the forehead. **C** Multiple AKs on the bald scalp, some of which are hyperkeratotic; the area of hypopigmentation represents a site of previous treatment and due to the field defect, recurrence at the edge is commonly observed. **D** Multiple, large hypertrophic AKs on the shin of an elderly woman; note the thick scale. *A, Courtesy, Medical University of Graz; B, Courtesy Iris Zalaudek, MD; D, Courtesy Jean L. Bolognia, MD.*

AKs include the elderly, those with lighter skin phototypes, and those with a history of chronic sun exposure. The typical lesion is a rough erythematous macule or papule with white to yellow scale. Patients may report tenderness, but this occurs more commonly with hypertrophic lesions (see Fig. 108.2D). AKs can range in size from a few millimeters to large confluent patches several centimeters in diameter, especially in patients with severe photodamage (see Fig. 108.2A). Dermoscopic features, such as the strawberry pattern seen on the face, can assist in diagnosis (see below).

One of the earliest signs is slight erythema with almost imperceptible scale (see Fig. 108.2B), although some lesions are devoid of visible erythema and present only as slight scale with indistinct borders. Advanced lesions are typically thicker and well-defined with more visible hyperkeratosis and erythema. Lesions are frequently clustered in areas of highest cumulative sun exposure, such as the superior helices of the ears, upper forehead, supraorbital ridge, nasal bridge, malar eminences, dorsal hands, extensor forearms, shins, and the bald scalp (see Fig. 108.2C). Of note, clinically, AKs may spontaneously regress, but then can reappear at the same site.

Visual inspection is best performed with simultaneous palpation to detect lesions that may not be readily apparent. This is especially true in individuals with significant background erythema from chronic sun exposure or rosacea. Clinical subtypes of AKs include the classic variant already described, hypertrophic (often hyperkeratotic), pigmented, lichenoid, atrophic, and actinic cheilitis.

Hypertrophic (hyperkeratotic) AKs are easily identified on visual inspection as papules and plaques with scale or scale-crust and an erythematous base (see Fig. 108.2D). The erythematous base often extends beyond the overlying hyperkeratosis. The hyperkeratotic scale can become white or yellow–brown over time. Due to their thickness, patients often find these lesions to be bothersome. Occasionally, a hyperkeratotic AK may develop a cutaneous horn that manifests as a column of thick cornified material that protrudes above the skin. The major entity in the differential diagnosis of a hyperkeratotic AK is a cSCC.

Pigmented AKs represent a subtype that often lacks associated erythema and has a hyperpigmented or reticulated appearance (Fig. 108.3). These lesions can at times be difficult to distinguish from reticulated seborrheic keratoses, lentigines, or even the lentigo maligna subtype of cutaneous melanoma. Dermoscopy may be a useful adjunct in these situations (see Ch. 0). Clinical clues are the location on sun-exposed skin, background solar changes, and hyperkeratosis that is sometimes appreciable by palpation. In cases in which the diagnosis is questionable, a biopsy is required to exclude the possibility of melanoma.

Lichenoid AKs have a clinical appearance similar to that of the classic form of AKs but with more erythema at the base of the lesion. Patients may relate pruritus or tenderness. Histology shows a lichenoid infiltrate in a pre-existing AK. The differential diagnosis includes a lichen planus-like keratosis, which also arises within areas of sun-damaged skin and can be pruritic, multiple, and even eruptive (see Ch. 109).

Atrophic AKs usually have minimal surface change and appear as pink to red, slightly scaly macules (see Fig. 108.2B). Histology shows an atrophic epidermis.

Actinic cheilitis is the term used to describe the characteristic changes that occur on the lower vermilion lip of individuals with moderate to severe photodamage. Actinic cheilitis may present as well-demarcated, erythematous patches or thin plaques with scale. In other patients, the erythema and especially the scale is more diffuse and can involve the entire lower vermilion lip; areas of leukoplakia may also be present (Fig. 108.4). The potential for evolving into invasive SCC is relatively higher than for AKs elsewhere (see Fig. 108.8).

Cutaneous squamous cell carcinoma in situ

cSCC *in situ* is commonly called Bowen disease (Fig. 108.5). The characteristic presentation of SCC *in situ* is an erythematous scaly patch or slightly elevated plaque that often arises within photodamaged sun-exposed skin. However, it can also develop in sun-protected sites (Fig. 108.6). The head and neck region and extremities are the most common sites, followed by the trunk. Lesions can become crusted and

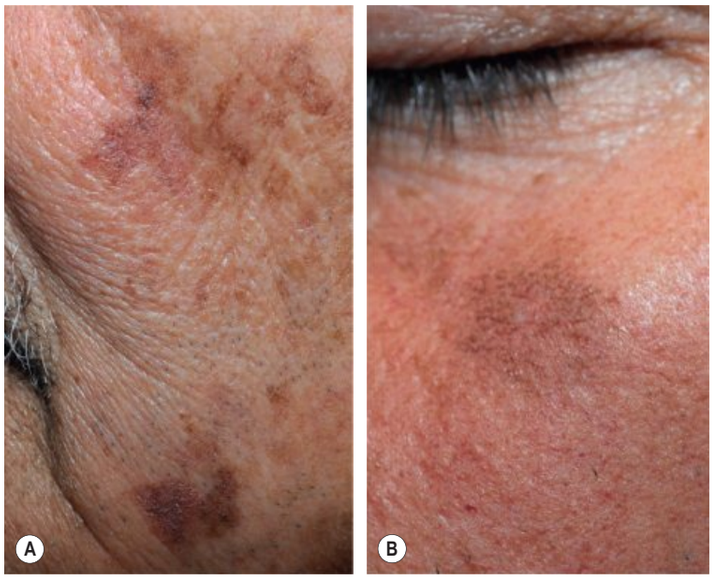

Fig. 108.3 Pigmented actinic keratoses. A, B The hyperpigmentation can have a reticulated appearance and there may be associated scale but an absence of erythema. *Courtesy Kalman Watsky, MD.*

Fig. 108.4 Actinic cheilitis. Erythema and scale of the entire lower vermilion lip with erosions and areas of leukoplakia. *Courtesy Kalman Watsky, MD.*

Fig. 108.5 Squamous cell carcinomas *in situ*, Bowen disease type. A Scaly red plaque on the chest with skip areas and background photodamage. **B** Erythematous plaque with thick yellow scale-crust on the distal lower extremity that may be misdiagnosed as psoriasis or dermatitis. **C** Larger broken-up pink plaque with scale-crust in the pubic region, a sun-protected site. This type of lesion is often misdiagnosed as dermatitis or psoriasis and treated with topical corticosteroids. **D** Bright red, well-demarcated plaque on the proximal nail fold with associated horizontal nail ridging; the possibility of HPV infection needs to be considered. **E** Dermoscopic findings of tiny dotted vessels in the upper half of the lesion combined with superficial scales. **F** Extensive involvement of the finger which was misdiagnosed clinically as an inflammatory dermatosis and treated for years with corticosteroid creams. *B, Courtesy Kalman Watsky, MD; E, Courtesy Iris Zalaudek, MD.*

erosions may be prominent within mucosal lesions in the anogenital region (see Ch. 73).

Clinical distinction of cSCC *in situ* from superficial BCC, psoriasis, or chronic eczema may at times be difficult (see Fig. 108.5B,F). Generally, superficial BCCs often have a more translucent quality with slight elevation of the leading edge as well as characteristic dermoscopic features (see Ch. 0). Patients with psoriasis and diffuse actinic damage can pose a diagnostic dilemma, as concomitant psoriatic papules and plaques may clinically resemble AKs and Bowen disease.

Arsenic-induced SCC in situ resembles the classic variant clinically but has a marked tendency to be multifocal and to arise in sun-protected areas of the trunk. Associated findings include palmoplantar keratoses and guttate hypopigmentation superimposed on hyperpigmentation (see Ch. 88).

Bowenoid papulosis is a squamous intraepithelial neoplasm linked to human papillomaviruses, most commonly HPV type 16 (see Table 79.1). The clinical appearance can vary from small brown papules of the penis to perianal pink papules to corrugated pink to brown plaques of the inguinal creases (see Fig. 73.13). It favors young adults and spontaneous regression can occur. However, the histopathologic findings are those of a high-grade squamous intraepithelial lesion or SCC *in situ*.

Other variants of SCC *in situ* include a pigmented variant often seen in individuals with darker skin types and a verrucous form. Pigmented SCC *in situ* may be mistaken for a superficial melanoma, and verrucous SCC *in situ* may simulate a seborrheic keratosis or a wart.

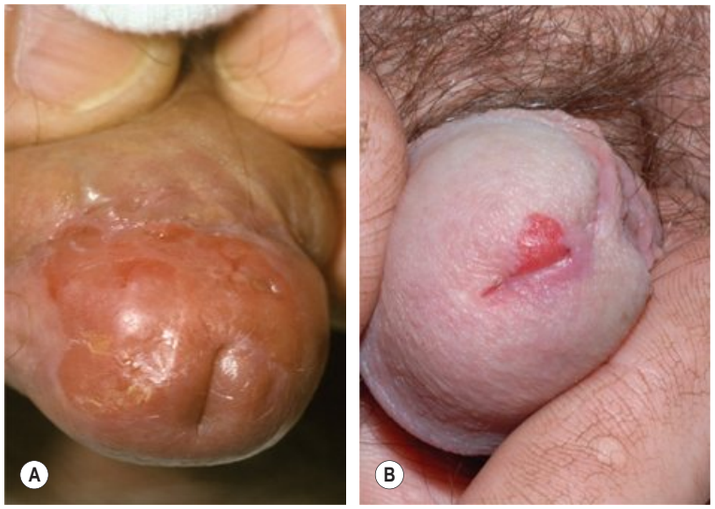

Fig. 108.6 Penile squamous cell carcinoma *in situ* (also referred to as erythroplasia of Queyrat). A Glistening, dull red, thin plaque of the glans penis. **B** Small, well demarcated paraurethral red plaque.

Invasive cutaneous squamous cell carcinoma

Invasive cSCC usually arises within a background of sun-damaged skin, most commonly on the bald scalp, face, neck, extensor forearms, dorsal hands, and shins (Fig. 108.7A,B). The color usually varies from erythematous to skin-colored; rarely there are pigmented variants. SCCs are often papulonodular, but can be plaque-like, papillomatous, or even vegetating (Figs. 108.7C,G and 108.8). The degree of scale varies, with some lesions becoming quite hyperkeratotic (Fig. 108.7E,F); secondary changes include crusting, erosions, and ulcerations (Fig. 108.7D,H). Dermoscopic features are outlined in Chapter 0.

The natural history of cSCCs also varies, from slowly enlarging to rapidly growing with significant tenderness and even pain. Of note, paresthesias, anesthesia, and pain may be signs of perineural invasion. The clinical differential diagnosis, in addition to hypertrophic AK, includes inflamed seborrheic keratosis or verruca vulgaris, atypical fibroxanthoma, prurigo nodularis, Merkel cell carcinoma, and hypertrophic lichen planus or cutaneous lupus. Staging is most often based upon the American Joint Committee on Cancer (AJCC) TNM system which focuses on cSCC of the head and neck (Table 108.4). Because the majority of cSCCs assessed by dermatologists do not have lymph node metastases, the major focus consists of determining if the primary tumor is T1, T2, or T3. In the Brigham and Women's Hospital staging system, high-risk factors are employed to further subdivide T2 into T2a

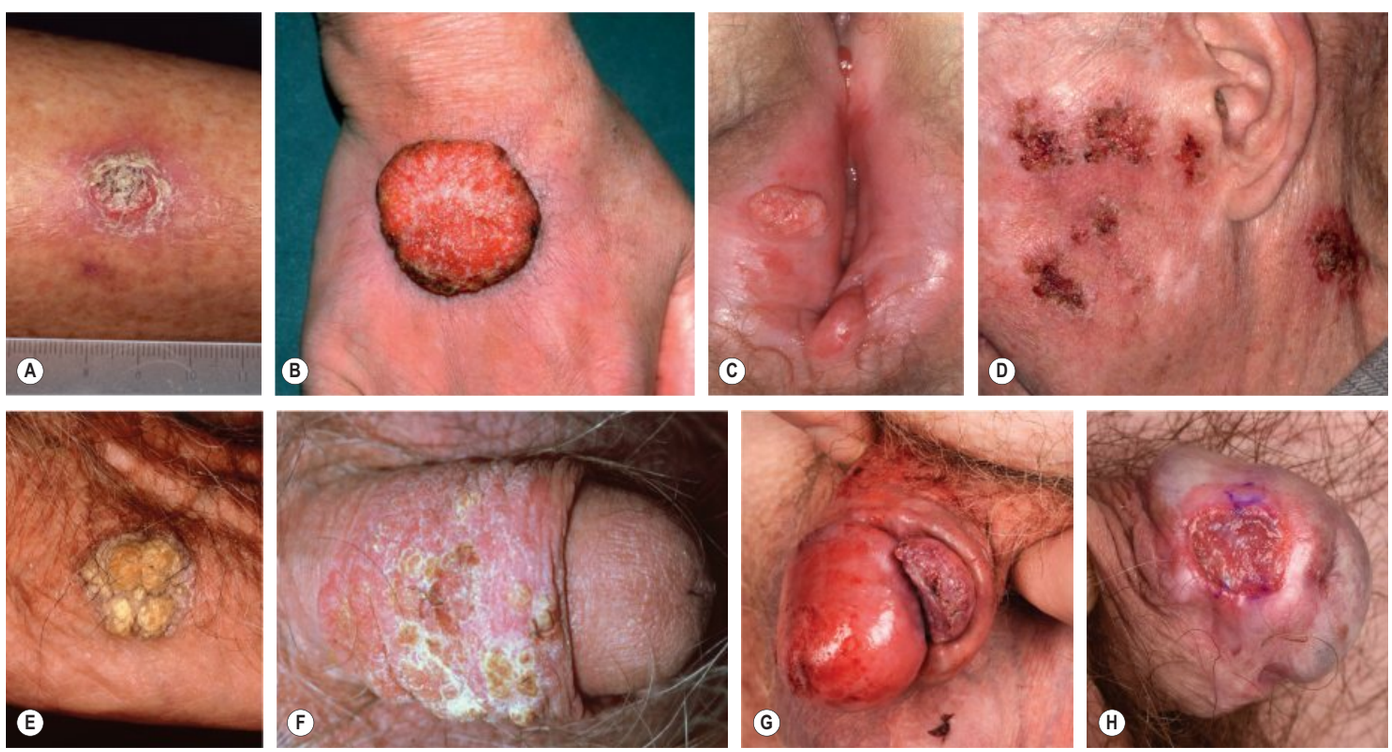

Fig. 108.7 Clinical spectrum of cutaneous squamous cell carcinoma (SCC). A Eroded and keratotic nodule that developed rapidly at the site of trauma on the shin. The differential diagnosis includes atypical squamous proliferation. **B** Large, fungating nodule on the dorsum of the hand. **C** Eroded, slightly vegetating, thick plaque arising within lichen sclerosis of the vulva. **D** Multiple eroded superficial SCCs in association with actinic damage and sites of previous treatment on the cheek and neck of an elderly man. **E** Keratotic verrucous nodule on the dorsal hand. **F–H** As in photodamaged skin, SCC of the genitalia can vary from a pink scaly plaque to an eroded nodule to an ulcer. *A, Courtesy Jean L. Bolognia, MD.*

Fig. 108.8 Squamous cell carcinoma (SCC) of the lower lip. A Extensive hyperkeratosis and leukoplakia of the lower vermilion lip; histopathologically, the SCC was superficially invasive and well-differentiated. **B** Verrucous and eroded nodule on the lower vermilion lip in a heavy smoker.

and T2b (Table 108.5)[68]. Nonetheless, clinical examination of patients with invasive cSCC includes palpation of regional lymph nodes for enlargement and firmness, followed by assessment of size if enlarged.

Keratoacanthoma

Keratoacanthomas (KAs) are considered by some to be a variant of cSCC and by others to represent benign tumors (i.e. a pseudomalignancy). The exact nosology is still uncertain, although there are some data that support its differentiation from "conventional" SCC. Typically, a rapidly enlarging papule evolves into a sharply circumscribed, crateriform nodule with a keratotic core over a period of a few weeks (Fig. 108.9A–D), and then it may resolve slowly over months to leave an atrophic scar. Most lesions occur on the head and neck or in sun-exposed areas of the extremities, with or without symptoms of pain or tenderness.

There are several distinct clinical presentations of KA, including solitary, multiple, grouped, keratoacanthoma centrifugum marginatum (Fig. 108.9E), giant (Fig. 108.9F), multiple spontaneously regressing (Ferguson–Smith), multiple non-regressing, and generalized eruptive (Grzybowski). Occasionally, KAs develop in a subungual, palmoplantar, or intraoral location. KAs are also seen in patients with Muir–Torre syndrome and they may have sebaceous differentiation (see Ch. 63). In addition, multiple KAs have been associated with chemical exposures, immunosuppression, BRAF inhibitors, and HPV infection.

By far the most common presentation is the solitary KA. While most of these tumors are small (5 to 15 mm), some KAs (e.g. keratoacanthoma centrifugum marginatum [see Fig. 108.9E]) may reach several centimeters in diameter, persist for months before resolution, and heal with prominent scarring. Grouped KAs may resolve more slowly than solitary KAs, while subungual KAs have been associated with underlying bony destruction.

STAGING OF CUTANEOUS SQUAMOUS CELL CARCINOMA (cSCC) OF THE HEAD AND NECK			
T, N, M			
Primary tumor (T)			
TX	Primary tumor cannot be identified		
Tis	Carcinoma *in situ*		
T1	Tumor <2 cm in greatest dimension		
T2	Tumor 2 cm or larger, but smaller than 4 cm in greatest dimension		
T3	Tumor 4 cm or larger in maximum dimension or minor bone erosion or perineural invasion or deep invasion*		
T4	Tumor with gross cortical bone/marrow invasion (4a); skull base invasion and/or skull base foramen involvement (4b)		
Regional lymph nodes (clinical) (cN)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension and ENE(–)		
N2	Metastasis in a single ipsilateral lymph node, >3 cm but <6 cm in greatest dimension and ENE(–) (2a); or in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension and ENE(–) (2b); or in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension and ENE(–) (2c)		
N3	Metastasis in a lymph node, >6 cm in greatest dimension and ENE(–) (3a); or metastasis in any node(s) and ENE(+) (3b)		
Distant metastasis (M)			
M0	No distant metastasis		
M1	Distant metastasis		
Stage			
	T	***N***	***M***
0	Tis	N0	M0

	T2	N2	M0
	T3	N2	M0
	T Any	N3	M0
	T4	N Any	M0
	T Any	N Any	M1

*Deep invasion is defined as invasion beyond the subcutaneous fat or >6 mm (as measured from the granular layer of adjacent normal epidermis to the base of the tumor); perineural invasion for T3 classification is defined as tumor cells within the nerve sheath of a nerve lying deeper than the dermis or measuring 0.1 mm or larger in caliber, or presenting with clinical or radiographic involvement of named nerves without skull base invasion or transgression.

Table 108.4 Staging of cutaneous squamous cell carcinoma of the head and neck. ENE, extranodal extension. *Adapted from American Joint Committee on Cancer (AJCC), 8th edition (2017).*

The Ferguson–Smith syndrome is an autosomal dominant condition due to mutations in *TGFBR1* which encodes TGF-β receptor type 1. Multiple KAs develop within sun-exposed areas, usually beginning during the third decade of life. Lesions typically regress over weeks to months, but rare examples of metastases have been reported. Multiple KAs of the Grzybowski type present as hundreds of papules resembling milia or early eruptive xanthomas. They develop rapidly and may slowly

resolve over a period of months. Patients often have scarring, ectropion, and a mask-like facies.

Verrucous carcinoma

Verrucous carcinoma is a rare, well-differentiated variant of SCC which tends to occur in middle-aged and older adults. It is considered a low-grade malignancy with three major subtypes: (1) epithelioma cuniculatum (plantar surface of the foot); (2) giant condyloma acuminatum of the genitalia (also known as Buschke–Löwenstein tumor; see Ch. 79); and (3) oral florid papillomatosis (oral mucosa). Of note, the "cuniculatum" refers to the rabbit burrow-like appearance with crevices.

Clinically, verrucous carcinomas present as large (sometimes huge), exophytic tumors with a papillomatous or verrucous surface (Fig. 108.10A,B). They are commonly associated with HPV infection, and distinguishing between a verrucous carcinoma and a large wart or condyloma acuminatum can be challenging. Gradual penetration of verrucous carcinomas into underlying tissues can result in destruction of subcutis, fascia, and bone. These tumors can arise within scars and amputation stumps (Fig. 108.10C) as well as in association with fistulae of osteomyelitis and chronic venous insufficiency. Verrucous carcinomas often recur after attempted removal, but they usually do not metastasize, except for recurrent or irradiated tumors with anaplastic transformation. Some authors consider subungual KAs, proliferating tricholemmal cysts (proliferating pilar tumors), and papillomatosis cutis carcinoides (which favors the shins and dorsal feet) to be subtypes of verrucous carcinoma.

HIGH RISK FACTORS FOR CUTANEOUS SQUAMOUS CELL CARCINOMA
• Vertical tumor thickness >6 mm
• Tumor diameter ≥2 cm*
• Location: ear, lips, oral or genital mucosa
• Histopathologic features: poorly differentiated*, presence of desmoplasia, invasion beyond subcutaneous fat*
• Perineural invasion of nerves with a diameter of ≥0.1 mm*
• Bone invasion
• Immunosuppression
*One of four high-risk factors (HRFs) in the Brigham and Women's Hospital grading system; T1 = 0 HRFs; T2a = 1 HRF; T2b = 2–3 HRFs; T3 = ≥4 HRFs or bone invasion.

Table 108.5 High-risk factors for cutaneous squamous cell carcinoma. *Adapted from Stratigos AJ et al.*[84]

Lymphoepithelioma-like carcinoma of the skin

Lymphoepithelioma-like carcinoma of the skin (LELCS) is an uncommon neoplasm that shows histopathologic similarities to lymphoepithelioma-like carcinoma (LELC), an undifferentiated nasopharyngeal carcinoma associated with EBV infection. LELCS has the potential for both sweat glandular and follicular differentiation. Clinically, it presents as a dermal papule or nodule arising in the head and neck region. In contrast to LELC, EBV genome integration is not found in LELCS, and metastases are rare. Evidence of HPV infection is also usually absent. LELCS is considered by some to be a variant of cSCC, while others view it as a type of cutaneous adnexal carcinoma.

Histologically, LELCSs are localized within the dermis or subcutis, with involvement of the overlying epidermis having been observed in only a few cases. The tumor consists of clusters of epithelial cells (with large vesicular nuclei and prominent nucleoli) intermingled with a prominent inflammatory infiltrate that sometimes forms germinal centers. However, classic signs of squamous differentiation such as

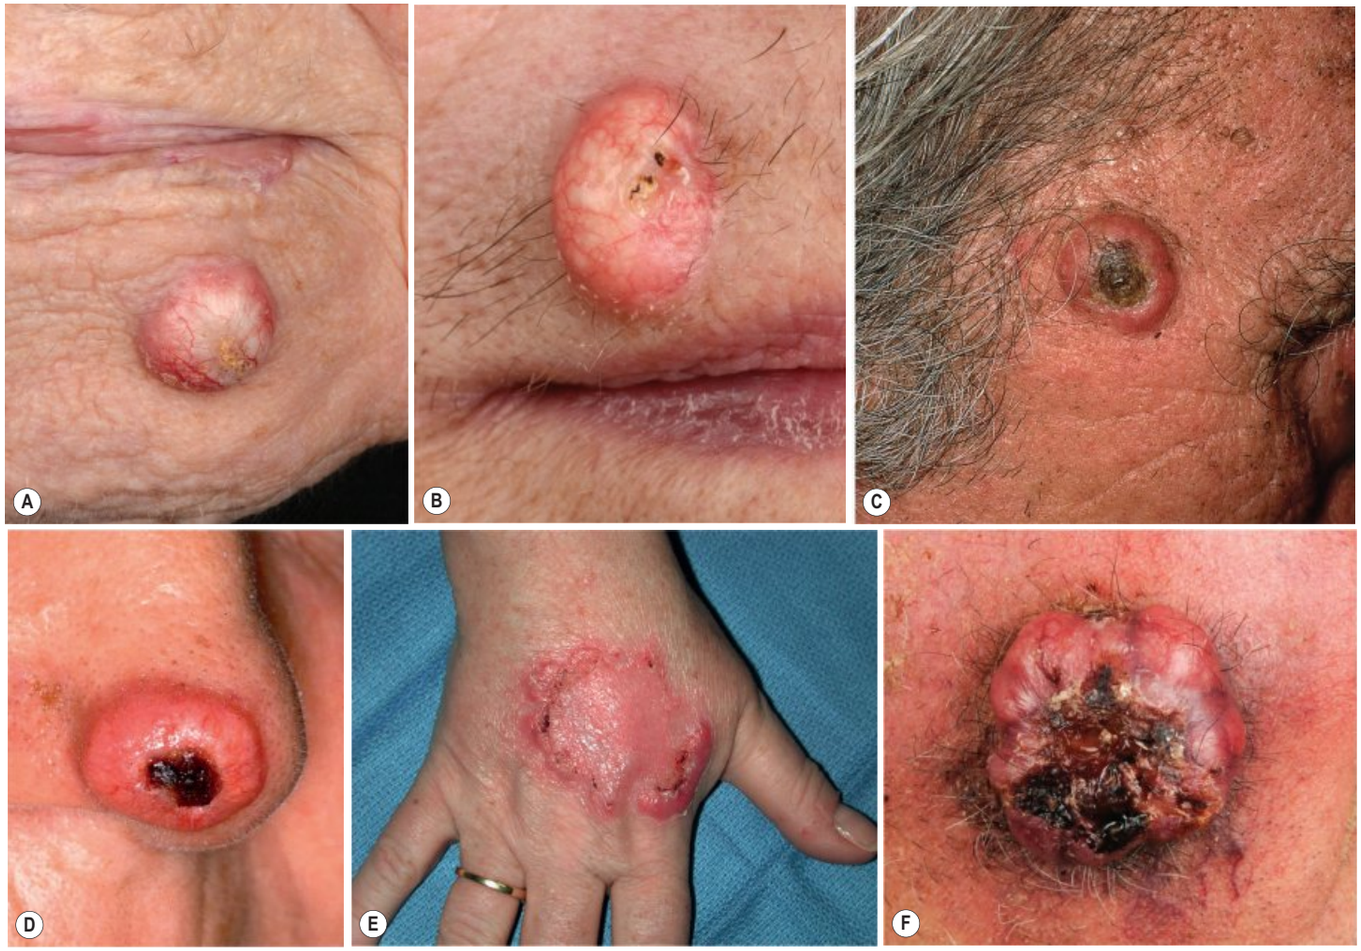

Fig. 108.9 Clinical spectrum of keratoacanthomas. A, B Erythematous nodules that are yellow–white centrally with a keratotic core; telangiectasias are also seen. **C, D** Rapidly growing, erythematous crateriform nodules with a rolled border and larger central keratotic core. The lesions may be tender. **E** Progressive peripheral expansion and central involution with residual atrophy characterize keratoacanthoma centrifugum marginatum. **F** Giant keratoacanthoma with a yellow–red color, multilobed rolled border, central ulceration, and a history of rapid growth.

Fig. 108.10 Verrucous carcinoma. A Longstanding large nodule on the plantar surface with a rabbit burrow-like appearance; such a tumor is also referred to as an epithelioma cuniculatum. **B** Keratotic and ulcerated plaque on the ventromedial aspect of the great toe. **C** A classic location in an amputation stump. In general, these well-differentiated SCCs enlarge slowly.

keratin "pearls", dyskeratotic cells, or intercellular bridges are absent. Neoplastic cells express cytokeratin and epithelial membrane antigen while stromal lymphocytes express leukocyte common antigen (CD45). The histopathologic differential diagnosis includes lymphocytoma cutis, follicle center lymphoma, and carcinoma with thymus-like differentiation.

In vivo Imaging Methods

Dermoscopy

Dermoscopy of invasive cSCC reveals linear-irregular vessels, elongated vessels resembling hairpins, dotted vessels, or a combination of these findings (polymorphous or atypical vascular pattern). Typically, vessels are surrounded by a whitish halo; the latter is the dermoscopic hallmark of all keratinizing tumors and is also found in KAs and in seborrheic keratoses (see Ch. 0). Ulceration and hemorrhagic crusts appear as red-, brown-, or black-colored surface blotches. Rare pigmented cSCCs may have a scaly surface, diffuse or homogenous blue pigmentation, and/or irregularly distributed blue–gray granular structures. AKs on the face can demonstrate a so-called "strawberry pattern" (an erythematous pseudonetwork surrounding hair follicle orifices filled with yellowish keratotic plugs; see Fig. 0.39H) as well as a "red starburst pattern" (central mass of keratin and hairpin vessels). In other body sites, AKs often display surface scales and dotted vessels. Bowen disease typically has a scaly surface and glomerular vessels (see Fig. 0.39D).

Reflectance confocal microscopy

Reflectance confocal microscopy (RCM) is an imaging technique which allows non-invasive horizontal imaging of the epidermis and superficial dermis at almost the same resolution as routine histology. However, RCM (and dermoscopic) features of keratinizing tumors are often difficult to visualize due to the surface scaling which obscures underlying structures. In AKs and cSCCs, key findings consist of areas with an irregular honeycomb pattern and atypia of keratinocytes; blood vessels display the "button hole" sign[69].

Pathology

Actinic keratosis

There is partial thickness involvement of the epidermis by atypical keratinocytes with nuclear pleomorphism, especially in the basal layer, as well as disordered maturation. Hyperkeratosis and parakeratosis are constant findings. Acrosyringia and acrotrichia are often *uninvolved*, resulting in orthokeratosis above the ostia of these structures (Fig. 108.11A). In the dermis, actinic elastosis is seen. A minority of dermatopathologists employ a grading system – early AK (grade I), AK involving the lower two-thirds of the epidermis (grade II), full-thickness atypia of the epidermis (grade III; SCC *in situ*) – but this classification has not gained widespread acceptance.

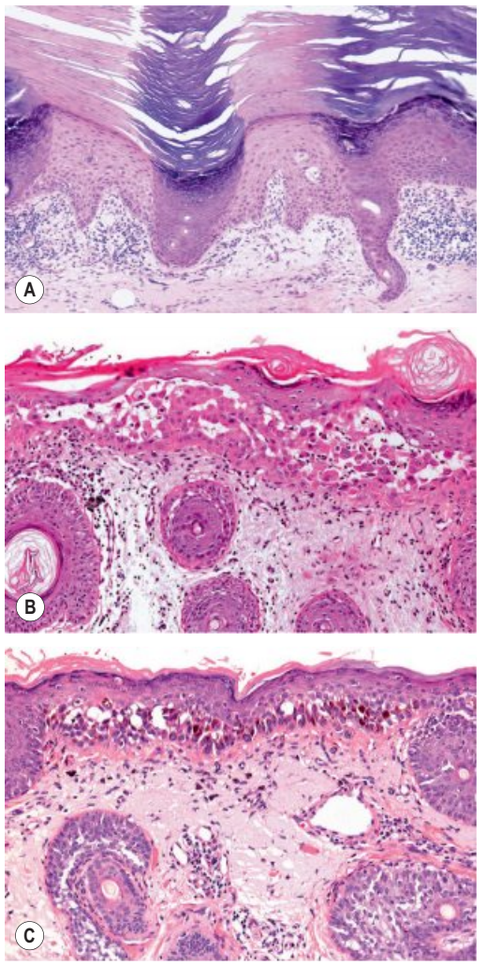

Fig. 108.11 Histopathology of actinic keratoses (AKs). A Hyperkeratotic AK with alternating pink and blue colors in the cornified layer; the pink-colored parakeratotic columns within the stratum corneum are located above the atypical keratinocytes in the spinous layer, while the blue-colored columns of orthohyperkeratosis are above the acrosyringia. Atypical epidermal keratinocytes also display a pinkish color that contrasts with the color of the basophilic, normal keratinocytes of the acrosyringia. **B** Acantholytic variant with clefts within the stratum spinosum. **C** Pigmented actinic keratosis with increased melanin pigmentation within the basal layer. Note the solar elastosis in the dermis. *B, C, Courtesy Lorenzo Cerroni, MD.*

In addition to atrophic and bowenoid AKs, several other histopathologic variants have been described, including acantholytic (Fig. 108.11B), hypertrophic (hyperkeratotic), pigmented, and lichenoid. In *hypertrophic* AKs, marked hyperkeratosis with associated parakeratosis is evident. If pronounced, this can lead to cutaneous horn formation. *Pigmented* AKs additionally show basilar pigmentation in a pattern similar to a solar lentigo (Fig. 108.11C). *Lichenoid* AKs demonstrate a band-like infiltrate of lymphocytes in the papillary dermis directly beneath the dermal–epidermal junction. *Actinic cheilitis* arises on the vermilion lips, primarily the lower one, and intraepithelial atypical keratinocytes, usually associated with inflammation, are observed.

Squamous cell carcinoma in situ

SCC *in situ* (Bowen disease), by definition, demonstrates full-thickness atypia of the epidermis over a broad zone (Fig. 108.12). Dyskeratosis, nuclear pleomorphism, and apoptosis are often more florid than in AKs, and mitoses are frequent. The epidermis commonly exhibits acanthosis. Atypical keratinocytes extend down the adnexa, and diffuse confluent parakeratosis is also observed. Lastly, in contrast to AKs, the basal layer of the epidermis is usually spared and, at least focally, is composed of small compressed basaloid keratinocytes arranged in a palisade.

Invasive cutaneous squamous cell carcinoma

In well-differentiated cSCC, there is a downward proliferation of lobules with aggregations of glassy, brightly eosinophilic keratinocytes containing nuclei with some degree of pleomorphism and mitoses (Fig. 108.13A). Keratin pearls and apoptotic cells are observed. The degrees of nuclear atypia and cellular differentiation vary within and among tumors (Fig. 108.13B). The pink quality of the cytoplasm arises from abundant high-molecular-weight keratin. The inflammatory infiltrate differs considerably in intensity and consists primarily of lymphocytes and plasma cells. At their margins, many well-differentiated

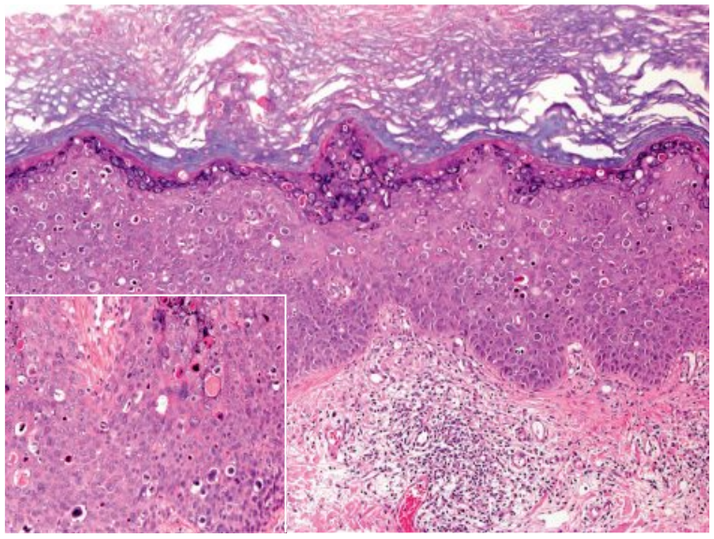

Fig. 108.12 Histopathology of Bowen disease (squamous cell carcinoma *in situ*). Irregular epidermal hyperplasia with atypical pleomorphic keratinocytes throughout the entire epidermal thickness. Note several necrotic keratinocytes (inset). *Courtesy Lorenzo Cerroni, MD.*

cSCCs exhibit contiguity with an AK. When invasive cSCC arises from Bowen disease, the intradermal tumor cells often have a more basophilic appearance.

Poorly differentiated cSCCs display progressive and overlapping features, ending in highly infiltrative tumors that lack overt keratinization and sometimes have a spindle cell morphology. Perineural infiltration (Fig. 108.13C) and desmoplastic or sclerotic stromal change become more common in these forms. Neurotropic SCCs behave in a more aggressive manner, with local recurrence rates approaching 50%. Poorly differentiated tumors (cytokeratin$^+$) generally require immunohistochemistry to distinguish them from spindle-cell melanoma (Melan-A$^+$, SOX-10$^+$, S100$^+$), atypical fibroxanthoma (cytokeratin$^-$, Melan-A$^-$, SOX-10$^-$, S100$^-$; CD10$^+$), leiomyosarcoma (smooth muscle actin$^+$, desmin$^+$), and other malignant tumors (exclusionary immunohistology).

There are several variants of SCC. The acantholytic type (Fig. 108.13D) and the related adenoid (pseudoglandular) SCC may have a worse prognosis, but this has been questioned[70]. Other variants of SCC include lesions with overlying cutaneous horn formation as well as bowenoid, clear cell, pseudovascular, desmoplastic, mucinous, adenosquamous, pigmented, and spindle cell types. The latter probably has a worse prognosis. Marjolin's ulcer is an SCC that occurs in a chronic wound or scar, including from a thermal burn.

A large, prospective study focusing on risk factors that predict metastasis and local recurrence in cSCC reported overall rates of 4% for metastasis and 3% for local recurrence[71]. Only tumors >2 mm in vertical

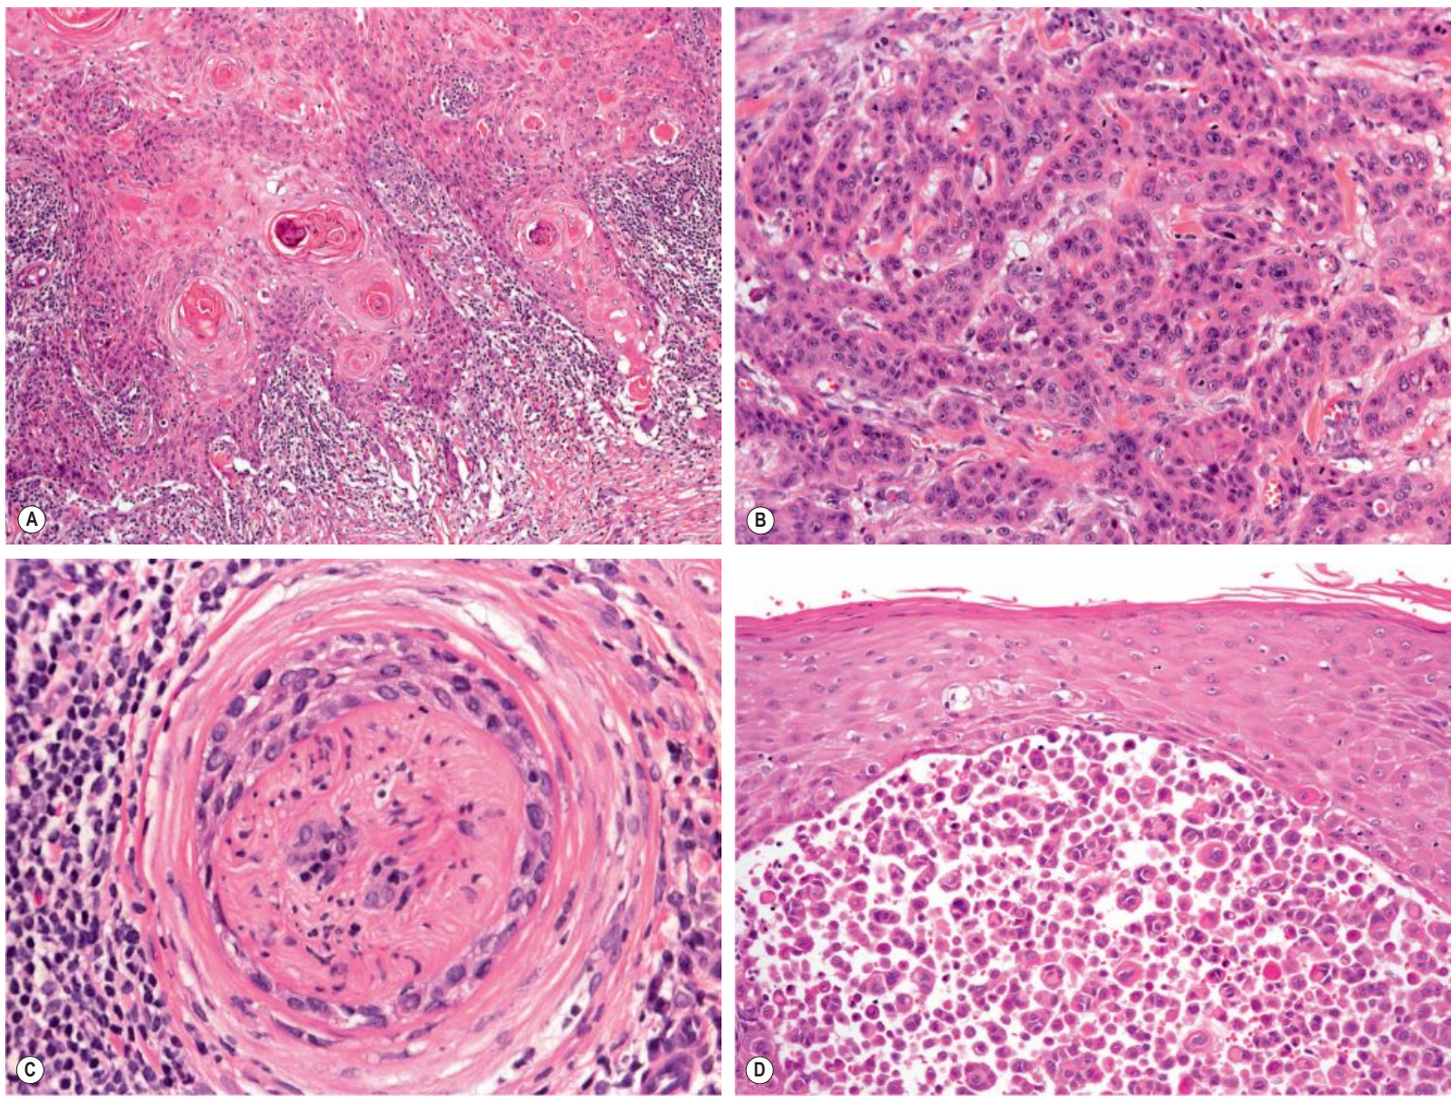

Fig. 108.13 Squamous cell carcinoma (SCC): range of histopathologic findings. A Well-differentiated SCC with numerous horn pearls (eosinophilic parakeratotic keratinization). **B** Poorly differentiated SCC with strands and cords of epithelial cells with prominent nuclear atypia and no signs of keratinization. **C** Perineural growth and neurotropism of a poorly differentiated SCC. **D** Acantholytic SCC characterized by epithelial aggregations composed of atypical keratinocytes with acantholysis. *Courtesy Lorenzo Cerroni, MD.*

thickness had a significant risk of developing metastases. For SCCs whose thickness was between 2.1 and 6 mm, the metastatic rate was 4%, and it was 16% for lesions thicker than 6 mm. Other risk factors for metastasis included location on the ear or mucosa, increased horizontal size, and immunosuppression (see Table 108.5). Tumor thickness and the presence of a desmoplastic stroma were found to be risk factors for local recurrence. For example, of 51 patients with desmoplastic SCC, 24% developed local recurrences, compared to 1% of 564 patients with non-desmoplastic SCCs.

Keratoacanthoma

A keratoacanthoma (KA) typically has a "volcano-like" architecture. The tumor is comprised of well-differentiated keratinocytes with a brightly eosinophilic glassy cytoplasm, surrounding a core filled with cornified material (Fig. 108.14). An inflammatory infiltrate of lymphocytes, and often eosinophils, is usually present. Small intratumoral abscesses of neutrophils are common, and neurotropism may be observed. As the lesion regresses, the dome-shaped architecture flattens and fibrosis develops at the base of the lesion. Cytologic atypia is usually not pronounced in a KA. If hyperchromatic nuclei or abnormal mitoses are prominent, then the diagnosis of an invasive KA-like SCC should be rendered.

Verrucous carcinoma

Verrucous carcinoma is defined as a well-differentiated and distinct clinicopathologic variant of SCC (Fig. 108.15). However, this term should not be applied to every SCC that has a warty appearance. Cytologic atypia is minimal, and the tumor has a pushing border as opposed to an infiltrating invasive edge. Verrucous carcinoma can be associated with HPV infection, and histopathologic distinction from a large wart or condyloma is often difficult and may be impossible if the entire tumor is not available for microscopic examination. The major distinguishing features of a verrucous carcinoma are the massiveness and depth of the lesion, as well as the pronounced irregular architecture.

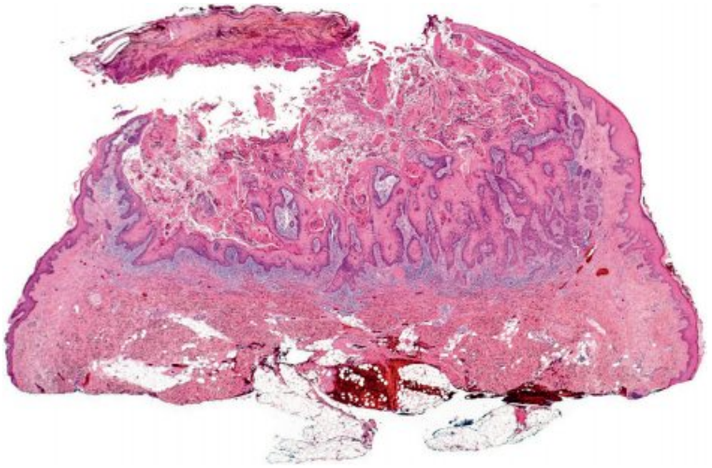

Fig. 108.14 Histopathology of keratoacanthoma. Scanning magnification of a stereotypical keratoacanthoma with a keratin-filled crater encompassed by epithelial lips. *Courtesy Lorenzo Cerroni, MD.*

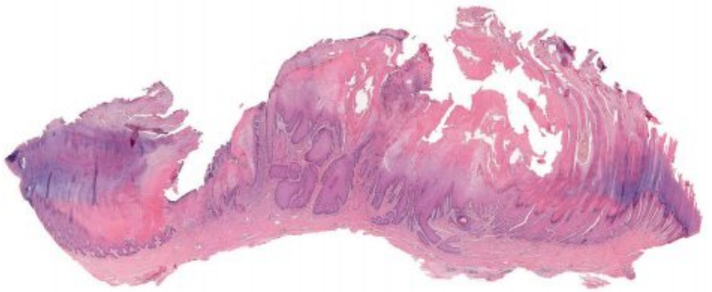

Fig. 108.15 Histopathology of verrucous carcinoma. A markedly irregular epithelial hyperplasia with prominent hyperkeratosis is seen. For the histopathologic diagnosis of verrucous carcinoma, the size of the lesion and architectural features are more important than cytomorphology, which usually does not show prominent atypia, thus emphasizing the need for large excisional biopsies in order to make a proper diagnosis. *Courtesy Lorenzo Cerroni, MD.*

Histopathologic simulators of SCC

There are a number of histopathologic simulators of SCC, including seborrheic keratosis, verruca vulgaris, inverted follicular keratosis, prurigo nodularis, hypertrophic lichen planus, hypertrophic lupus erythematosus, and the pseudocarcinomatous hyperplasia that can occur in a range of disorders (e.g. dimorphic fungal infections, healing wounds, tattoos, some non-keratinocyte tumors). Architectural pattern and recognition of cellular and nuclear features of malignancy are critical in establishing a diagnosis. In some cases, only clinical correlation allows a distinction between SCC and some of these conditions. Of note, SCC may occur in the setting of a pre-existing benign tumor (e.g. seborrheic keratosis) as well as within chronic pseudoepitheliomatous hyperplasia related to hypertrophic lichen planus or hypertrophic lupus erythematosus.

Atypical squamous proliferation

Atypical squamous proliferation (ASP) is a term used to describe the histologic findings found in papulonodules and thick plaques that develop within markedly sun-damaged skin, usually on the shins and following trauma. This term is preferred over keratoacanthoma-like squamous proliferations as they often lack a central keratotic core. Although ASPs are associated with less cytologic atypia than cSCCs[72], distinction can prove challenging. Immunohistochemical staining for p53 may be helpful with positivity in basal and immediately suprabasal layers in ASP, in contrast to full-thickness positivity in cSCC. Presumably growth factors released during wound healing, including following surgical excision, trigger proliferation of keratinocytes with UV-induced mutations.

BASAL CELL CARCINOMA

Clinical Features

Basal cell carcinoma (BCC) is a tumor that usually arises within sun-damaged skin. However, it may also develop in sites with minimal sun exposure, e.g. inner canthus, retroauricular; rarely BCCs occur on the palms, soles, and mucous membranes. Currently, despite the description of multiple subtypes of BCC, a universally accepted classification scheme is lacking, but a standardization of terminology has recently been proposed[73]. Nonetheless, four major distinctive clinicopathologic types are commonly recognized, namely, nodular, superficial, morpheaform, and fibroepithelial (also referred to as fibroepithelioma of Pinkus)[74]. Combinations of the latter three types with nodular BCC can occur. While all types of BCC may ulcerate, ulceration is observed more often in the nodular type. Also, variable amounts of melanin may be present within these tumors, even though the majority of BCCs are amelanotic; pigmented BCCs are observed more commonly in those with darker skin phototypes. When one attempts to classify BCCs, a significant confounding factor is the number of different histopathologic patterns that become entwined with clinical subtypes. Examples are cystic, mucinous, micronodular, and basosquamous BCCs. Although these patterns may be seen in all four major clinicopathologic types of BCC, they are observed more frequently in the nodular type.

Nodular basal cell carcinoma

Nodular BCC is the most common subtype, accounting for ~50% of all BCCs. Lesions typically present as a shiny, pearly papule or nodule with a smooth surface and the presence of arborizing telangiectasias (Fig. 108.16). With time, the tumor can enlarge and ulcerate (rodent ulcer, phagedenic ulcer), but an elevated rolled border usually remains and is a clinical clue to the diagnosis. A variable degree of pigmentation may be seen within the tumor (Fig. 108.17A–C). Sites of predilection are the face, especially the cheeks, nose, nasolabial folds, forehead and eyelids, but nodular BCCs may arise in any hair-bearing area of the skin. They rarely occur in non-hair-bearing sites, e.g. oral or genital mucosa, palms and soles.

The clinical differential diagnosis of non-ulcerated lesions includes adnexal neoplasms (see Ch. 111), fibrous papules, intradermal melanocytic nevi, lichen keratoses, and amelanotic melanomas; for ulcerated lesions, see Table 45.3 and Fig. 105.1.

Fig. 108.16 Clinical spectrum of nodular basal cell carcinoma. A Translucent papulonodule with prominent telangiectasias on the infraorbital cheek. **B** Classic presentation with a pearly rolled border and central hemorrhagic crust. **C** Larger plaque with rolled borders and multiple telangiectasias. **D** Nodulo-ulcerative tumor of the preauricular region with translucent rolled borders, most obvious at "12 o'clock"**. E** Depressed scar on the nose. **F** Dermoscopy of a nodular basal cell carcinoma of the forehead. The arborizing telangiectasias are in sharp focus (inset). *A, Courtesy Stanley J. Miller, MD; E, Courtesy Kalman Watsky, MD.*

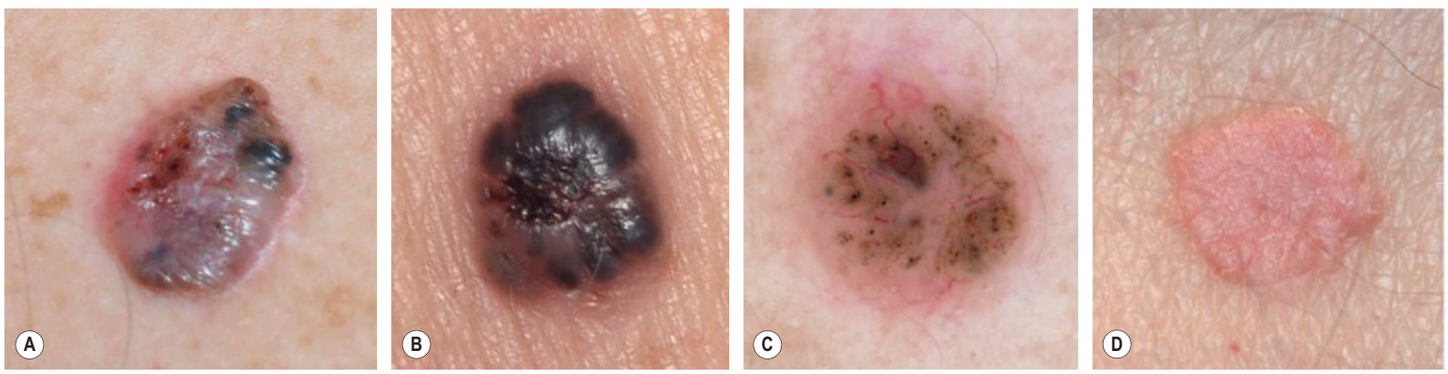

Fig. 108.17 Additional variants of basal cell carcinoma (BCC) – pigmented and fibroepithelial (fibroepithelioma of Pinkus). A, B Pigmented nodular BCCs with varying degrees of melanin pigmentation that may clinically resemble cutaneous melanoma. However, the glassy translucency, in concert with characteristic dermoscopic features such as arborizing telangiectasias and multiple blue–gray ovoid globules (**C**), point to the diagnosis of pigmented BCC. **D** A soft, skin-colored to light pink, broad, sessile plaque on the lower back is a classic presentation for a fibroepithelial BCC. *A, Courtesy Kalman Watsky, MD; C, Courtesy Giuseppe Argenziano, MD; D, Courtesy Oscar Colegio, MD.*

Superficial basal cell carcinoma

Superficial BCCs typically present as a well-circumscribed, erythematous, macule/patch or thin papule/plaque, with the diameter varying from a few millimeters to several centimeters (Fig. 108.18). Additional findings include focal crusts and/or scale, a thin rolled border, and variable amounts of melanin; in larger lesions, areas of spontaneous regression may be present, characterized by atrophy and hypopigmentation. The mean age at diagnosis is in the mid 50 s, a younger age than for other types of BCC, and in younger age groups, superficial BCC is the most common subtype. This BCC variant favors the trunk and extremities; less often, it occurs in the head and neck region. Multiple lesions may be present.

The growth pattern of superficial BCCs is primarily horizontal, but tumors may occasionally become deeply invasive, with induration, ulceration, and nodule formation. Subclinical lateral spread accounts for the significant recurrence rate of these tumors after routine surgical treatment. The clinical differential diagnosis includes solitary lichenoid keratosis and Bowen disease (more scale) as well as inflammatory diseases such as psoriasis, dermatitis, and cutaneous lupus erythematosus.

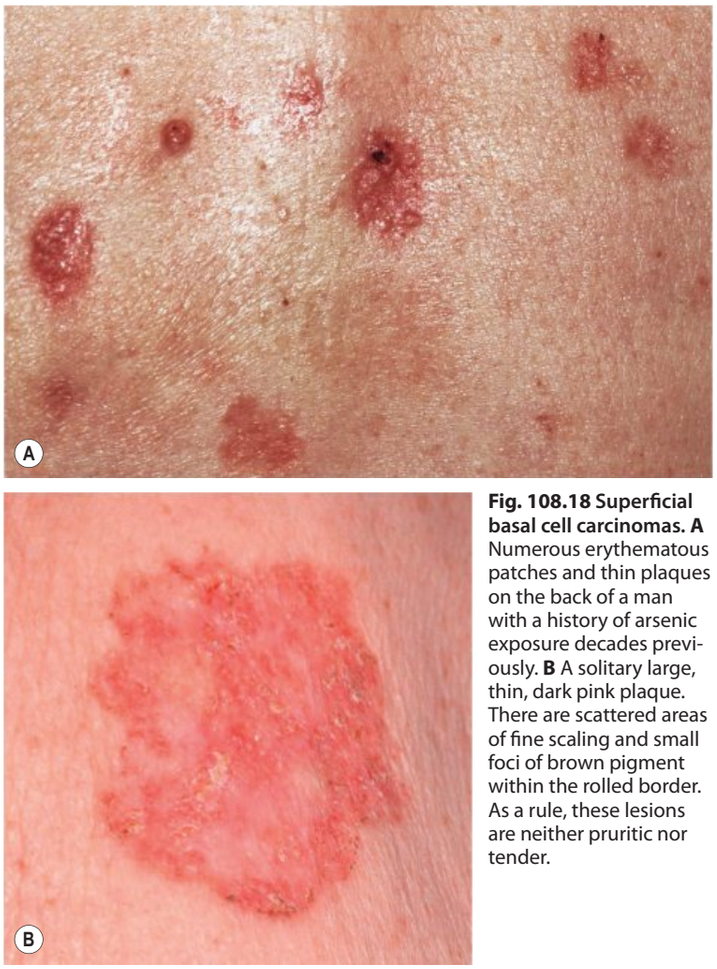

Fig. 108.18 Superficial basal cell carcinomas. A Numerous erythematous patches and thin plaques on the back of a man with a history of arsenic exposure decades previously. **B** A solitary large, thin, dark pink plaque. There are scattered areas of fine scaling and small foci of brown pigment within the rolled border. As a rule, these lesions are neither pruritic nor tender.

Fig. 108.19 Morpheaform basal cell carcinomas. A Recurrent tumor two years after microscopically controlled surgery; note the scar-like appearance with superimposed glassy pink and brown papules. **B** Oval hypopigmented firm plaque that resembles a scar (e.g. post electrodesiccation and curettage). While there is a light pink color between 9 and 12 o'clock, no translucency or rolled border is present. **C** A classic example with indistinct borders and scar-like appearance.

Fig. 108.20 Dermoscopy of pigmented "nevoid" basal cell carcinomas of the abdomen in a patient with basal cell nevus syndrome. There are pigment globules, maple leaf structures, and one arborizing telangiectasia as well as a pink background color (inset).

Morpheaform basal cell carcinoma

This less common subtype of BCC frequently presents as a slightly elevated to even depressed area of induration that is usually light pink to white in color and has ill-defined borders; it may resemble a scar or plaque of morphea (Fig. 108.19). The surface of the lesion is typically smooth, although crusts with underlying erosions or ulcerations as well as superimposed papules may be observed. While an elevated pearly border is typically absent, telangiectasias may be present. The biologic behavior is usually more aggressive, with extensive local destruction.

Fibroepithelial basal cell carcinoma (fibroepithelioma of Pinkus)

This rare variant of BCC usually presents as a skin-colored or pink, sessile plaque or pedunculated papulonodule with a smooth surface (Fig. 108.17D). It favors the trunk, especially the lower back. Fibroepithelial BCCs often occur in individuals with multiple superficial BCCs. The clinical differential diagnosis includes an intradermal melanocytic nevus or large fibroepithelial polyp (skin tag). Of note, some experts believe that fibroepithelioma of Pinkus is a variant of trichoblastoma (not BCC).

In vivo Imaging Methods

Dermoscopy

Dermoscopy provides a demonstrated benefit in the diagnosis of non-pigmented and pigmented BCCs[75]. The dermoscopic hallmark of BCC is the presence of well-focused arborizing vessels in conjunction with foci of microulceration (see Fig. 108.16F). Additional findings with a high specificity for BCC include large blue–gray ovoid nests, multiple blue–gray globules, leaf-like structures, and spoke-wheel areas (Fig. 108.20; see Ch. 0); a pigment network is absent. Short, fine superficial telangiectasias as well as concentric structures and multiple, "in-focus" blue–gray dots have also been described.

Reflectance confocal microscopy (RCM)

The following reflectance confocal microscopy (RCM) features have been described for all BCCs, regardless of subtype (Fig. 108.21)[69]: (1) variable architectural disarray of the epidermis; (2) a streaming pattern of elongated monomorphic nuclei that are polarized along the same axis; (3) tightly packed cells in the papillary dermis with a nodular/cord-like growth pattern; (4) palisading of tumor cell nuclei; (5) peritumoral dark cleft-like spaces (representing peritumoral mucinous edema); and (6) the presence of bright dendritic cells and melanophages (in pigmented BCC). RCM can also be used to determine surgical margins prior to excision.

Pathology

All types of BCC have, as a least common denominator, the presence of aggregations of basaloid keratinocytes within a variably fibromyxoid

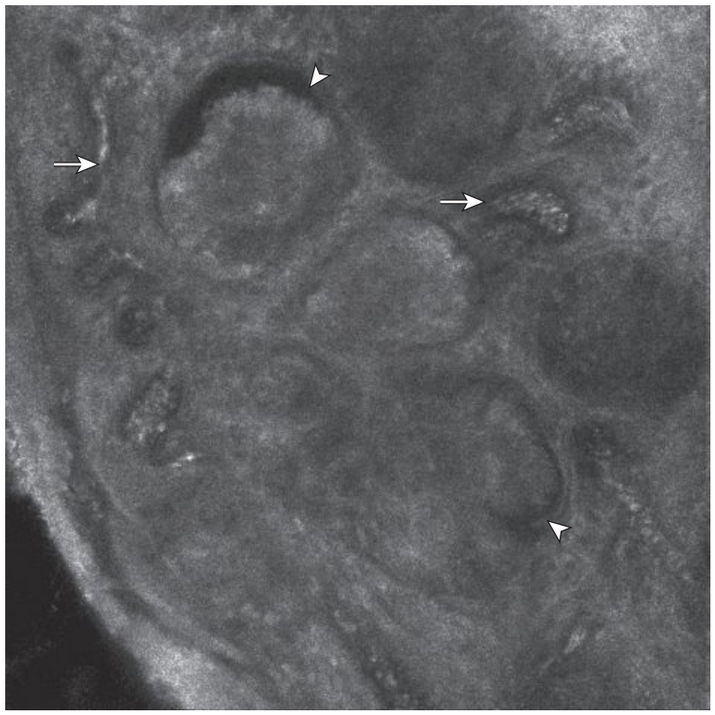

Fig. 108.21 Reflectance confocal microscopy of a basal cell carcinoma. A 0.5 × 0.5 mm image at a depth of 85 microns. Aggregations of basaloid cells with hyporeflective cleft-like peritumoral spaces (arrowheads) and dilated tortuous blood vessels can be seen (arrows). *Courtesy Claudia Curchin, MBBS.*

stroma. A connection to the epidermis is usually observed, at least focally (Fig. 108.22A). The tumor cells have large, relatively uniform nuclei and scant cytoplasm; cellular borders are indistinct and desmosomes are inapparent. Apoptotic cells are common. The fibromyxoid stroma is intimately associated with the tumor islands, often showing increased cellularity. A characteristic feature of BCC is retraction of the stroma around the tumor islands, creating microscopically visible clefts (Fig. 108.22B). Although this latter feature may not be seen in all instances, when present it is useful in differentiating BCCs from histopathologic simulators.

In *nodular BCC*, large, round or oval aggregations of basaloid keratinocytes extend from the epidermis into the dermis (Fig. 108.22C). Overlying ulceration with an associated inflammatory response may be present. Peripheral palisading is usually prominent and peritumoral clefts are often conspicuous in nodular BCC (Fig. 108.22D). Centrally, the nuclei lack organization and are more randomly distributed. In larger tumor islands, central areas of necrosis may develop, leading to the formation of cystic spaces. *True cystic or nodulocystic BCCs* contain mucin pools within the tumor islands (Fig. 108.22E). Micronodular BCCs are composed of tumor islands much smaller than those of nodular BCC (Fig. 108.22F). The cellular features are similar.

Superficial BCCs are characterized by small, superficially located buds of basaloid cells extending no more deeply than the papillary dermis, with or without clefting (see Fig. 108.22A,B). In a given two-dimensional plane of section, there are skip areas along the epidermis, hence the synonym "superficial multifocal BCC". There is evidence that many of these multifocal buds connect in a net-like pattern, such that most tumors are not truly multifocal.

Pigmented BCCs usually have the overall architecture of a nodular BCC. They contain aggregates of melanin, often irregularly distributed, and sometimes an increased number of intratumoral melanocytes (Fig. 108.22G). Melanophages are frequently dispersed within the dermis.

Morpheaform, sclerosing and infiltrative BCCs share similar histopathologic features. A common finding is a pattern of strands and cords of basaloid keratinocytes extending between collagen bundles (Fig. 108.22H). These tumor islands may be composed of very few cells and may surround nerves. A peripheral palisaded pattern of tumor cells is absent and stromal retraction (cleft formation) is also frequently not evident.

Fibroepithelial BCC (fibroepithelioma of Pinkus) is a variant of BCC characterized by thin anastomosing strands and cords of tumor cells that project downward from the epidermis in a fenestrated pattern and are embedded in a fibrovascular stroma (Fig. 108.22I). Both peripheral palisading and peritumoral retraction are less prominent. The differential diagnosis includes eccrine syringofibroadenoma and reticulated seborrheic keratosis.

Infundibulocystic BCCs have cords of follicular germs with small infundibular cysts that display differentiation towards hair follicle structures. Although they can be difficult to differentiate from trichoepitheliomas or other follicular adnexal neoplasms, immunostaining for PHLDA1, a marker of epithelial follicular stem cells, is stronger and more diffuse in trichoepitheliomas[76]. Multiple hereditary infundibulocystic BCC syndrome has been associated with a germline mutation in *SUFU*.

Additional histopathologic subtypes of BCC

Basosquamous carcinoma

Basosquamous carcinoma (metatypical BCC, keratotic BCC) is a tumor that has histopathologic features of both BCC and cSCC (Fig. 108.22J). These tumors may behave biologically more like an SCC than a BCC, i.e. they have more aggressive behavior with a greater likelihood of both recurring after treatment and metastasizing. It has been estimated that this variant constitutes 1% of all keratinocyte carcinomas. When metastases occur, they may have the same microscopic appearance as the original tumor or may resemble a poorly differentiated SCC.

Micronodular basal cell carcinoma

This histopathologic term applies to BCCs in which smaller aggregations of basaloid cells infiltrate the dermis (see Fig.108.22F). Micronodular BCCs possess a destructive behavior, with subclinical spread and high rates of recurrence. Clinically, they may present as infiltrated macules, papules/nodules, or plaques and are basically indistinguishable from nodular BCCs. A recent consensus project suggested that infiltrating, sclerosing, and micronodular subtypes should be grouped together under the umbrella term "infiltrating BCCs"[73].

Histopathologic simulators of BCC

Other basaloid tumors that may simulate BCC include adnexal neoplasms, in particular trichoblastoma (Table 108.6). In contrast to BCC, clefts in trichoblastoma are located within the stroma and not in direct proximity to the basaloid tumor islands. In addition, follicular germs and papillae, simulating rudimentary hair follicles, are commonly found in trichoblastomas. Basaloid induction within dermatofibromas and reactive folliculocentric basaloid proliferation may also simulate BCC histopathologically.

TREATMENT

Several national and international organizations have established guidelines of care for BCCs and cSCCs. When available, these guidelines are based upon evidence but are oftentimes developed via expert consensus[77–79].

Evaluation and Risk Assessment

Evaluation of a suspected NMSC requires a history, physical examination, and biopsy of the suspicious lesion. The history should assess duration, rate of growth, and any prior therapy, as well as any personal or family history of prior skin cancers. Localized neurologic symptoms, although rare, may suggest the possibility of perineural involvement. Any history of prior radiation therapy to the area should be elicited. Current medical problems (e.g. chronic lymphocytic leukemia), medications (e.g. voriconazole, hydroxyurea), and allergies should be reviewed. Evidence of immunosuppression (e.g. organ transplantation, immunosuppressive medications, HIV infection) should be determined, and any of the risk factors listed in Table 108.2 identified.

Physical examination should include observation and palpation of the tumor to determine exact location and size, and whether it appears to have any connection to underlying structures such as muscle, cartilage, or bone. An assessment should be done of how well or poorly defined the tumor borders are, whether there is physical evidence of prior surgery or other therapeutic interventions (indicating the possibility of

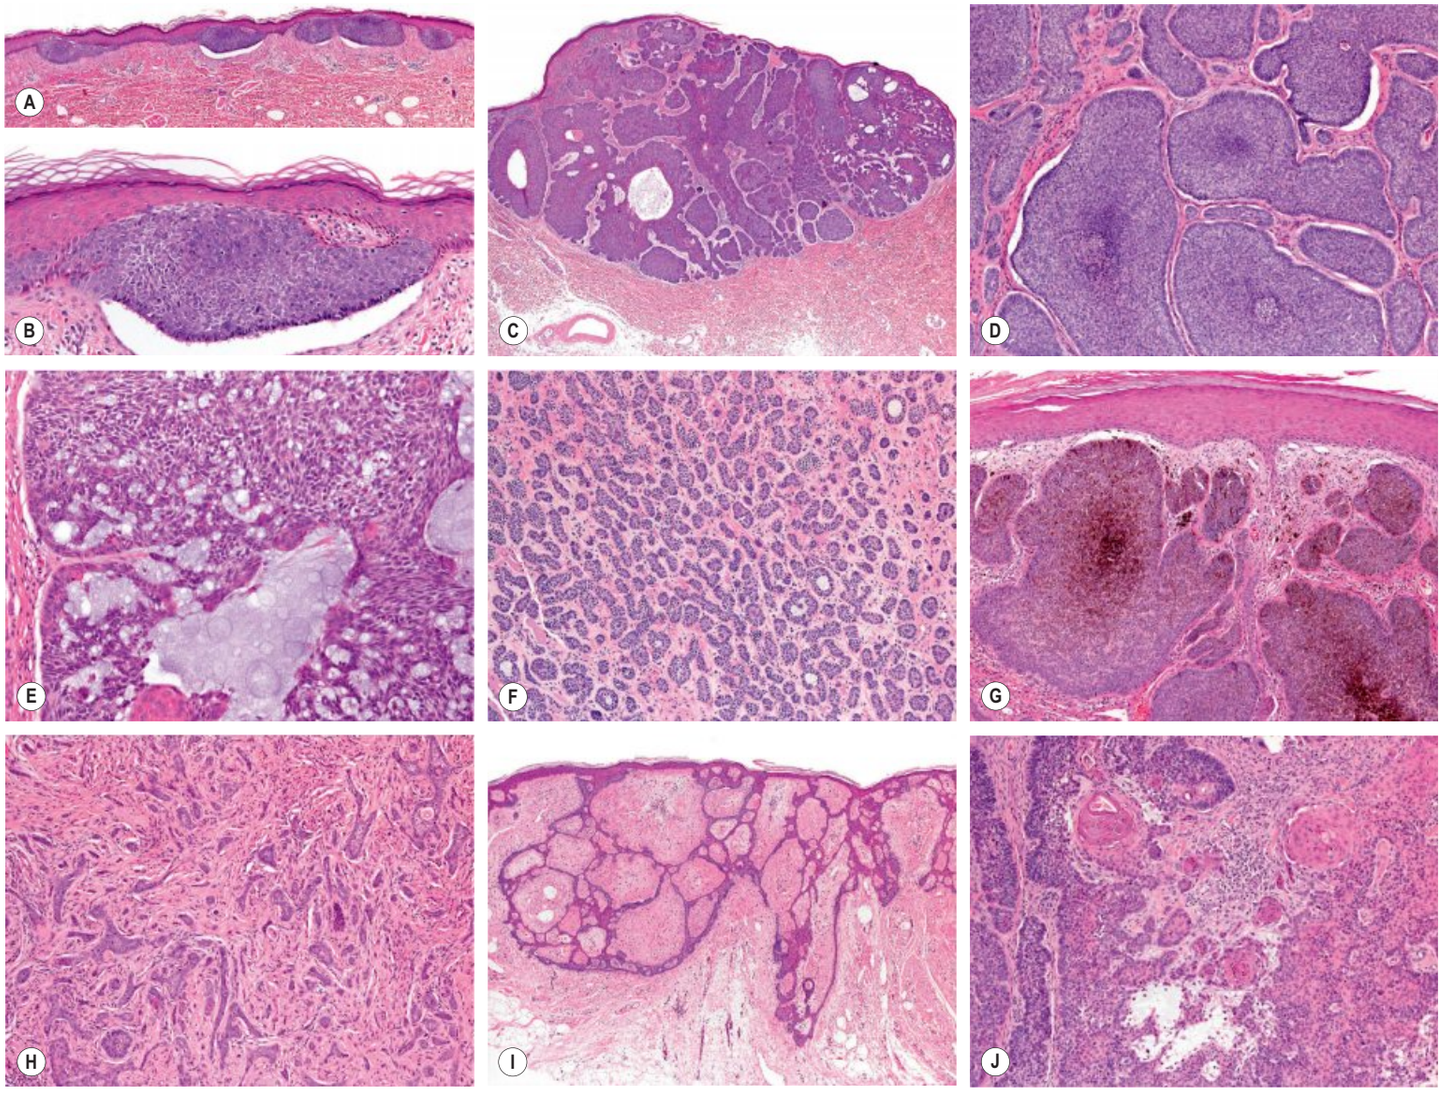

Fig. 108.22 Basal cell carcinoma (BCC): range of histopathologic findings. A *Superficial* type with a few basaloid buds and stromal retraction spaces. **B** A single basaloid aggregation with all the morphologic findings (e.g. peripheral palisading of nuclei, retraction between the tumor and surrounding stroma) characteristic of a *superficial* BCC. **C** *Nodular* BCC with large, partly confluent aggregations of basaloid cells as well as a few cystic spaces. **D** Nodular aggregations of basaloid cells with peripheral palisading and retraction spaces commonly seen in conventional *nodular* BCCs. **E** Nodular aggregations of basaloid cells with mucin deposition within the epithelial component, referred to as *mucinous* BCC. **F** *Micronodular* BCC characterized by numerous, densely packed, small nodular aggregations of basaloid cells. **G** *Pigmented* BCC with nodular aggregations of basaloid cells that contain brown melanin pigment. **H** *Morpheaform* BCC with numerous basaloid strands and cords with an irregular jagged outline embedded within a fibrous stroma. **I** *Fibroepithelial* BCC (fibroepithelioma of Pinkus) with a fenestrated pattern of anastomosing epithelial cords. **J** *Basosquamous* BCC in which both basaloid cells with peripheral palisading and eosinophilic cells with slightly pleomorphic nuclei and foci of keratinization ("horn pearls") are present. *Courtesy Lorenzo Cerroni, MD.*

recurrence), and if the tumor has developed within a site of chronic inflammation or scar. Careful inspection of the surrounding skin to exclude the presence of satellite lesions is necessary, as is examination of the draining lymph nodes, especially for high-risk tumors, since in-transit and distant metastases are more common in these patients. In all patients, a full skin examination is required, to exclude other cutaneous malignancies.

Skin cancers are often identifiable visually by an experienced clinician. Nevertheless, a properly performed biopsy is essential to the diagnosis and management of any lesion. Numerous biopsy techniques, including excisional, incisional, shave, saucerization, and punch, may be employed (see Ch. 146). For obvious skin cancers, especially in elderly patients, a tissue specimen is sometimes obtained at the same time as definitive therapy. If a superficial process (such as a superficial BCC or SCC *in situ*) is suspected, or if shallow therapy (such as curettage and electrodesiccation) is being contemplated, a shave biopsy is usually adequate for establishing a diagnosis. In most other instances, a punch biopsy or deep saucerization that extends to subcutaneous fat is preferred. AKs, on the other hand, are often treated without prior biopsy unless invasive NMSC is suspected; clinical judgment determines which AKs require treatment and which can be left untreated.

For both BCC and cSCC, the pathology report should include an assessment of the histopathologic subtype and status of the surgical margins. If present, ulceration and perineural or vascular involvement should be noted. In cSCC, the degree of differentiation and tumor depth should be assessed; the latter may consist of an anatomic estimate of depth or an actual measurement of tumor thickness in millimeters and can be prognostically useful. Even though clinical responses to immune checkpoint inhibitors have been observed irrespective of programmed cell death-ligand 1 (PD-L1) expression by the tumor cells of cSCC, immunohistochemical staining for PD-L1 is still oftentimes performed as several studies have observed a higher response rate in PD-L1$^+$ tumors[79a,79b].

Based upon clinical and pathologic parameters, a specific tumor may be stratified into a low-risk or high-risk category (Table 108.7). High-risk tumors, particularly SCCs (see Table 108.5), need to be treated aggressively. For larger and deeper tumors, preoperative radiographic imaging studies should be considered. Sentinel lymph node biopsy may provide additional prognostic information, but longer-term studies are needed to determine sensitivity, specificity, and any survival benefit. Because of the risk of post-therapeutic tumor recurrence and the elevated risk for subsequent skin cancers, patients are typically followed regularly for life.

HISTOLOGIC SIMULANTS OF BASAL CELL CARCINOMA (BCC)	
	Major distinguishing features
Adenoid cystic carcinoma	Cribriform pattern; EMA-positive
Ameloblastoma	Location in mouth
Basaloid follicular hamartoma	Multiple small papules; positive family history; loose to fibrotic stroma
Budding of atypical keratinocytes in actinic keratoses (may simulate superficial BCC)	No clefts around tumor complexes
Cloacogenic carcinoma	Anal location
Basaloid induction in epidermis overlaying a dermatofibroma*	Typical features of dermatofibroma in the dermis
Eccrine carcinoma	Small sweat ducts
Folliculocentric basaloid proliferation	Focal follicular budding
Merkel cell carcinoma and other neuroendocrine carcinomas	Punctate keratin (CK20-positive) in cytoplasm; positivity for Merkel cell polyomavirus (subset of cutaneous cases)
Metastatic breast carcinoma	History; single filing; expression of CK7, mammoglobulin, gross cystic disease fluid protein-15
Microcystic adnexal carcinoma	Small keratin cysts, absent stromal retraction, ductal differentiation
Mucinous carcinoma	Pools of mucin with floating basaloid islands
Nevus sebaceus	Basaloid induction; trichoblastomas and BCCs may arise within a nevus sebaceus
Sebaceous carcinoma	Adipophilin-positive sebocytes
Trichoblastoma	Clefts within the stroma; hair germs and papillae; PHLDA1-positive
Trichoepithelioma and desmoplastic trichoepithelioma	Horn cysts, absent stromal retraction, papillary mesenchymal bodies; PHLDA1 positivity; peritumoral CD34 positivity; positive family history when multiple
*Genuine BCC may rarely develop within a dermatofibroma.	

Table 108.6 Histologic simulants of basal cell carcinoma (BCC). CK, cytokeratin; EMA, epithelial membrane antigen.

RISK FACTORS FOR RECURRENCE OF NMSC		
	Low risk	**High risk**
Clinical risk factors		
Location (see Fig. 150.2) and size	Area L <20 mm	Area L ≥20 mm
	Area M <10 mm	Area M ≥10 mm
	Area H <6 mm	Area H ≥6 mm
Borders	Well defined	Poorly defined
Primary vs recurrent	Primary	Recurrent
Tumor at site of prior radiation therapy	Negative	Positive
Tumor at site of chronic inflammatory process (SCC only)	Negative	Positive
Rapidly growing tumor (SCC only)	Negative	Positive
Neurologic symptoms: pain, paresthesia, paralysis (SCC only)	Negative	Positive
Immunosuppression	Negative	Positive
Pathologic risk factors		
Perineural involvement	Negative	Positive
Subtype (BCC only)	Nodular, superficial	Micronodular, infiltrating, sclerosing
Degree of differentiation (SCC only)	Well differentiated	Moderately or poorly differentiated
Desmoplasia (SCC only)	Negative	Positive
Adenoid, adenosquamous, or desmoplastic (SCC only)	Negative	Positive
Tumor thickness (SCC only)	<2 mm	≥2 mm (see text)
Area L: low risk for recurrence: trunk, extremities. **Area M:** middle risk for recurrence: cheeks, forehead, neck, scalp. **Area H:** high risk for recurrence: "mask areas" of face (central face, eyelids, eyebrows, periorbital, nose, lips, chin, mandible, preauricular and postauricular skin/sulci, ear, temple), genitalia, hands, and feet.		

Table 108.7 Risk factors for recurrence of non-melanoma skin cancer (NMSC). BCC, basal cell carcinoma; SCC, squamous cell carcinoma. *Adapted from Miller SJ. The National Comprehensive Cancer Network guidelines of care for nonmelanoma skin cancers. Dermatol Surg 2000;26:289–92 and Brantsch KD, Meisner C, Schonfisch B, et al. Analysis of risk factors determining prognosis of cutaneous squamous-cell carcinoma: a prospective study. Lancet Oncol 2008;9:713–20.*

Surgical and Destructive Procedures

Standard excision

Cutaneous squamous cell carcinoma

Low-risk cSCC should be excised with a surgical margin of 4–6 mm. Standard excision without micrographic assessment of the complete margin (see Fig. 150.1) may be considered for select high-risk tumors, but strong caution is advised. US guidelines of care consider available data insufficient for evaluation of standard excision for high-risk tumors[78].

Basal cell carcinoma

Surgical excision is the standard treatment for most primary BCCs. In 98% of cases of non-morpheaform BCCs <2 cm in diameter, 4-mm margins are adequate for removal[79]. However, for facial lesions, simple excision with narrow margins is often not adequate for effective removal. For high-risk BCCs, US guidelines of care recommend Mohs micrographic surgery[77] while European guidelines recommend a surgical margin of 5–15 mm (depending on tumor characteristics) when micrographic surgery is not available[79].

Curettage alone

Barlow et al.[80] reported a 5-year cure rate of 96% when 302 biopsy-proven BCCs were treated by a single investigator with curettage alone. Minimal hypopigmentation and scarring was observed. If the deep margin of the shave biopsy specimen had >50% involvement with tumor, there was an increased risk of recurrence. Some clinicians combine curettage with application of topical agents such as imiquimod postoperatively.

Curettage with electrodesiccation

Curettage with electrodesiccation is frequently used by dermatologists to treat BCCs. Cure rates as high as 97%–98% have been reported[81], but careful selection of appropriate lesions (e.g. those without extension into the deep dermis) is necessary. In terminal hair-bearing sites, extension of neoplastic cells down follicular structures could also lead to incomplete removal. Curettage and electrodesiccation can be used for smaller SCCs *in situ* and well-differentiated primary SCCs <1 cm in diameter.

Mohs micrographic surgery

Mohs micrographic surgery results in superior histopathologic verification of complete removal of the tumor and allows for maximum conservation of tissue (see Ch. 150). Although Mohs micrographic surgery remains cost-effective when compared to either excisions done in a surgical center or hospital operating room or radiation therapy, it is more expensive than in-office standard excision. In one series of BCCs treated with Mohs micrographic surgery, a recurrence rate of only 1% over 5 years was observed. This was superior to all other modalities, including excision (10%), curettage and desiccation (8%), radiation therapy (9%), and cryotherapy (7.5%). However, percentages do vary

among studies, depending in part on the physicians involved and the types of lesions selected for inclusion.

Although direct comparison of different studies is difficult, Mohs micrographic surgery clearly has the highest cure rate when all tumor types as well as recurrent tumors are taken into consideration[82]. In one series of recurrent BCCs, Mohs micrographic surgery had a long-term recurrence rate of 5.6%, superior to all other modalities, including excision (17%), radiation therapy (10%), and curettage with electrodesiccation (40%). Mohs micrographic surgery is the preferred treatment for morpheaform, poorly demarcated, incompletely removed, or recurrent BCCs, as well as for those sites in which tissue conservation is paramount and there is a need for reliable clear margins. Mohs micrographic surgery is similarly indicated in cases of high-risk primary or recurrent SCC.

Radiation therapy

Radiation therapy is a therapeutic option for patients with a BCC or cSCC who are not well suited for surgery (see Ch. 139)[83,84]. Before choosing this therapy, both function and cosmetic outcome are considered. Advantages include avoidance of an invasive procedure in a patient who may not be able to tolerate surgery or is unwilling to undergo surgery. Disadvantages include lack of margin control, poor cosmesis in some patients, a prolonged course of therapy, and increased risk for future skin cancers. Scars from radiation therapy tend to worsen with time, in contrast to surgical scars, which improve over time.

Radiation is often used as an adjuvant modality following treatment of aggressive or high-risk cSCC with surgery, especially when perineural involvement is identified, to reduce local or locoregional recurrence[84a]. Verrucous carcinomas, which are well differentiated and rarely metastasize, are usually not treated with radiotherapy, since there is concern that cellular transformation may result in a worse prognosis. Radiotherapy is not well suited for morpheaform BCCs, as they are relatively radioresistant, or for patients with BCNS since X-rays can lead to mutations in the second *PTCH* allele, with subsequent tumorigenesis.

Cryosurgery

Cryosurgery is a mainstay of treatment for AKs, but has also been used to treat BCCs and cSCCs (see Ch. 138). It has the advantage of being a relatively easy to perform and quick procedure (particularly in the case of AKs) and is advantageous for those patients wishing to avoid invasive surgery. Complications may include hypertrophic scarring and postinflammatory pigmentary changes. A serious potential adverse outcome is recurrent carcinoma that can become extensive because of concealment by the fibrous scar tissue.

Photodynamic therapy

Photodynamic therapy (PDT) is FDA-approved for the treatment of multiple AKs (see Ch. 135). In the European Union and elsewhere, it is also approved for cSCC *in situ* and BCC. PDT is used primarily for superficial BCCs and occasionally as second-line therapy for nodular BCCs when surgery is not clinically recommended. Guidelines of care address clinical indications, photosensitizer administration, and light exposure specifications[85]. Daylight PDT, which is less painful than classic PDT, can be particularly useful in patients with numerous AKs and field cancerization. In organ transplant recipients, a systematic review found that PDT was the most effective treatment for AKs, when compared to topical imiquimod, ingenol mebutate, diclofenac sodium, and 5-fluoruracil[86]. However, in a randomized trial in immunocompetent patients, topical 5-fluorouracil was more effective than PDT, topical imiquimod, or topical ingenol mebutate for the treatment of AKs[87].

Laser

Laser surgery is an uncommon treatment for BCCs and cSCCs, with limited data in the literature and restriction to low-risk tumors.

Non-Surgical Treatments

Topical therapies

Table 108.8 outlines treatment options for AKs, including the dosing and side effects of FDA-approved topical agents.

5-fluorouracil (5-FU) is used primarily for the treatment of AKs and occasionally for superficial BCCs and selected cSCCs *in situ*. In a randomized trial in immunocompetent patients, 5-FU was more effective for the treatment of AKs than other standard therapies (see above)[87]. Side effects are usually limited to significant local skin reactions (see Ch. 129).

Diclofenac sodium, a nonsteroidal anti-inflammatory drug (NSAID), is also an effective option for the treatment of AKs. However, longer treatment cycles are required.

Imiquimod is a Toll-like receptor 7 agonist whose major side effect is a local skin reaction that can include erosions and crusting (see Ch. 129). The 5% formulation is FDA-approved for the treatment of superficial BCCs while 2.5%, 3.75%, and 5% formulations are approved for non-hypertrophic AKs on the face and scalp. Over a three-year period, imiquimod was superior to diclofenac sodium in clearing AKs and preventing histologic progression and recurrences. However, in a controlled trial evaluating AK treatments, it was less effective than topical 5-FU (see above)[87]. When compared to surgery in a randomly controlled trial of 501 patients with BCCs, tumor clearance was 82.5% in the imiquimod group versus 98% in the surgery group[88]. For SCC *in situ*, clearance rates of 73%–88% at 3–6 months have been reported[89].

Tirbanibulin, a drug that inhibits Src kinase signaling and tubulin polymerization, has been recently approved as a 1% ointment for the treatment of AKs. In two phase III trials, complete clearance of lesions after 5 days of application was observed in 44% to 54% of study participants[90].

Topical agents currently under investigation include the hedgehog pathway inhibitor ***patidegib*** for the treatment of BCCs[91]. Application of 2% or 4% patidegib gel has shown promising results, especially in patients with BCNS. Additional compounds under development for the treatment of AKs are ***sinecatechin***, which is derived from green tea leaves, and ***tuvatexib***, a hexokinase inhibitor.

Combination therapy

Combining more than one therapeutic modality has the potential advantage of enhancing the cure rate while minimizing adverse effects and maximizing cosmetic results. Both topical 5-FU cream and 5% imiquimod cream have been used to pretreat BCC sites prior to Mohs micrographic surgery, leading to a decrease in tumor size before surgical removal. Imiquimod cream has also been used, in conjunction with topical 5-FU cream, for the treatment of cSCC *in situ* in transplant recipients. Excellent cosmetic results have been reported when BCCs were treated with just curettage followed by 6 weeks of topical 5% imiquimod cream. In patients with AKs, combination therapy with calcipotriene (calcipotriol) 0.005% ointment plus 5% 5-FU cream twice daily for four consecutive days led to a response rate of 88%[92]. When PDT was combined with other topical agents (e.g. imiquimod), higher AK clearance rates were observed in comparison to monotherapy[85]; this approach has also been employed for actinic cheilitis.

Chemowraps

To treat multiple AKs, especially on the extremities and in the setting of field cancerization, wraps composed of zinc oxide-impregnated gauze can be used to occlude 5-FU cream[93]. In one series of 25 patients with widespread AKs, a response rate of 60% was achieved following weekly 5-FU chemowraps. Monitoring of patients for severe local reactions and systemic toxicity is recommended[94].

Intralesional treatment

There are reports describing the effectiveness of directly injecting NMSCs with cytostatic drugs such as methotrexate, bleomycin, and 5-FU, or injecting immunomodulators such as interferon alpha 2b, with response rates of about 80%[95]. Because of a limited level of evidence, the use of intratumoral agents should be considered in selected patients (Table 108.9).

Systemic Therapy

Treatment of advanced cutaneous SCC

Systemic therapy is utilized when tumors are neither surgically resectable nor curable by radiotherapy or when metastases have

COMMON TREATMENT OPTIONS FOR ACTINIC KERATOSES

Localized/lesion-targeted treatments*

Lesion-targeted treatment	*Comments*
Liquid nitrogen cryosurgery	• No cutting or anesthesia necessary • 10- to 14-day healing period • Risk of hypopigmentation
Curettage (> curettage + electrodesiccation)	• Requires local anesthesia • Risk of hypopigmentation and scarring (less so if curettage alone)
Shave excision	• Requires local anesthesia • Risk of hypopigmentation and scarring

Topical field treatments†,‡

Although these are the recommended FDA dosing schedules, if the patient develops significant burning with application or significant erosive erythema, the treatment should be held or discontinued

Topical agent	*Dosing*	*Comments*
5-Fluorouracil	• 0.5% cream – apply in the evening × 4 weeks • 1% or 5% cream – apply twice a day for 2–4 weeks • 2% and 5% solutions – apply twice a day for 2–4 weeks • When treating extensor extremities, pretreatment with a topical retinoid for 1–2 weeks may be required or occluded "chemowraps" may be used	• Warn of photosensitivity, which can be severe • Optimal results occur if treatment continues until there is significant inflammation or superficial erosions • Healing usually occurs within 2 weeks of stopping treatment • Solution is best for hair-bearing areas, such as the scalp
Imiquimod	• 2.5% or 3.75% cream – apply at bedtime for 2 weeks; take a 2-week break, and then repeat 2-week application cycle • 5% cream – apply 2 times per week for 16 consecutive weeks • Recommended treatment area is 25 cm^2	• May cause systemic flu-like symptoms • Not recommended if patient has an underlying autoimmune condition • May cause hypopigmentation at the treated site
Diclofenac sodium	• 3% gel – apply twice a day for 90 days • A maximum amount of 8 g daily should not be exceeded	• Do not use if patient is allergic to nonsteroidal anti-inflammatory drugs (NSAIDs) • Although it may have a less severe cutaneous reaction, compliance is an issue given a longer application period
Tirbanibulin	• 1% ointment – apply once daily for 5 consecutive days (face and scalp)	• May have less severe local cutaneous reaction

Procedural field treatments†,‡

Procedure	*Comments*
Photodynamic therapy (PDT; 5-ALA + blue light or red light or day light; MAL + red light or day light)	• Can be painful • Requires 24 hours of no outdoor exposure post-treatment • Relatively quick recovery over 1–2 weeks
Chemical peels (e.g. trichloroacetic acid)	• May require local anesthesia • May cause significant irritation and temporary discoloration • Healing typically over 7 days
Ablative laser techniques (e.g. ablative fractional lasers, erbium:YAG laser)	• Requires local anesthesia • Depending on the technique, recovery period varies • Hypopigmentation a potential complication

*Most appropriate for an isolated or limited number of actinic keratoses.
†Most appropriate for numerous or larger AK lesions.
‡In practice, combination or sequential therapy is sometimes used (e.g. liquid nitrogen to several thicker lesions followed by imiquimod or 5-fluorouracil applied to the entire forehead).

Table 108.8 Common treatment options for actinic keratoses. Addition of calcipotriene (calcipotriol) 0.005% to 5-fluorouracil may increase efficacy and shortens duration of treatment. Other compounds under development are sinecatechin, which is derived from green tea leaves, and tuvatexib, a hexokinase inhibitor. Ingenol mebutate has been removed from the market. ALA, 5-aminolevulinic acid. Daylight-activated PDT is discussed in Ch. 135.

developed. Currently, there are no consensus-based recommendations regarding the best treatment for advanced cSCC.

Immunotherapy with immune checkpoint inhibitors

Response rates of >40% in advanced cSCCs have been reported with anti-PD-1 antibodies including cemiplimab, pembrolizumab, and nivolumab[96]. For example, cemiplimab led to overall response rates (ORRs) of 44% and 45% for locally advanced cSCC and metastatic cSCC, respectively. As a result, cemiplimab is FDA approved for both indications. In patients who received pembrolizumab, ORRs of 42% and 32% were observed in patients with unresectable cSCC and recurrent or metastatic cSCC, respectively; it is now FDA-approved for the latter group of patients. Of note, in more than one study, patients with PD-L1$^+$ tumors had significantly higher response rates than those with negative tumors[79b], leading to the suggestion that immunohistochemical evaluation of PD-L1 be performed when considering immunotherapy. Use of cemiplimab as *neoadjuvant* therapy for stage II to IV cSCC led to a pathologic complete response rate of 51%[96a]. Side effects associated with immune checkpoint inhibitors are reviewed in Chapters 113 and 128.

In patients with advanced cSCC, anti-PD-1 antibodies have resulted in significantly better outcomes when compared to chemotherapeutic agents (e.g. carboplatin, paclitaxel, capecitabine) or tyrosine kinase inhibitors. The epidermal growth factor receptor inhibitor cetuximab, in combination with chemotherapy or radiation therapy, represents a potential second-line regimen for advanced cSCC.

Treatment of advanced BCC

Hedgehog signaling pathway inhibition

As with SCC, advanced BCC is defined as locally advanced or metastatic. When locally advanced, tumors are neither surgically

INTRALESIONAL ADMINISTRATION OF 5-FLUOROURACIL AND METHOTREXATE	
5-Fluorouracil (5-FU; 50 mg/ml)	• Maximum injection: 50–100 mg per lesion per session • Injection every week for 3–8 treatments
Methotrexate (MTX; 25 mg/ml)	• Check renal function prior to administration • Maximum injection: 1 ml per lesion per session • Injections every 2–4 weeks for 1–4 treatments
Both 5-FU and MTX	• Inject into base of lesion and lesion should blanch • Multiple injections into a single lesion may be required (e.g. each quadrant) • To avoid intravascular injection, pull back on syringe

Table 108.9 Intralesional administration of 5-fluorouracil and methotrexate.

resectable (e.g. due to involvement of vital structures) nor curable by radiotherapy. Inactivating mutations in *PTCH1*, *PTCH2*, or *SUFU* or activating mutations in *SMO* lead to activation of the hedgehog signaling pathway and have been associated with the development of BCCs (see Fig. 107.6); mutations in the first three genes can lead to BCNS. The hedgehog pathway inhibitors vismodegib (Fig. 108.23) and sonidegib are quite effective systemic treatments for advanced BCC.

Vismodegib was first reported to have antitumor activity in locally advanced or metastatic BCC in 2009[97]. Of the 33 patients treated with vismodegib in the phase I trial, two had a complete response (6%) while 16 had a partial response (48%). There was a reduction in the number of new BCCs as well as the size of existing BCCs. In further studies, individuals with metastatic BCC and locally advanced BCC had ORRs of ~30% and ~40%–45%, respectively. Nearly all patients in these trials reported adverse reactions (Table 108.10), leading to treatment discontinuation in about 30% of study participants. More recently two intermittent vismodegib regimens have been evaluated in patients with multiple BCCs and BCNS; these individual drug modifications (with non-dosing periods) led to equal efficacy but a lower rate of adverse events[98]. ***Sonidegib***, another hedgehog signaling inhibitor (via smoothened antagonism), also demonstrated efficacy in locally advanced and metastatic BCC.

Immunotherapy with immune checkpoint inhibitors

BCCs contain a high mutational tumor burden due to chronic UV-induced damage to DNA. This leads to an abundance of tumor neoantigens, providing a rationale for the use of immune checkpoint inhibitors, in particular anti-PD-1 antibodies[99]. Pembrolizumab, nivolumab, and cemiplimab have been investigated, and cemiplimab is currently FDA-approved for locally advanced or metastatic BCC in patients previously treated with a hedgehog pathway inhibitor or for whom a hedgehog pathway inhibitor is inappropriate. When cemiplimab was used as second-line therapy for locally advanced BCC (e.g. following development of resistance to hedgehog inhibitors), an ORR of 31% was observed[100]. Neoadjuvant immunotherapy may also be an option with the goal of reducing the size of the BCC thereby enabling subsequent surgical excision[99].

Prophylaxis

In high-risk patients, the most commonly used agents are low-dose acitretin to reduce the number of cSCCs[101] and nicotinamide to reduce the number of AKs and NMSCs[102]. However, in a study of immunosuppressed organ-transplant recipients, oral niacinamide did not lead to a reduction in the number of AKs and NMSCs[102a]. Other options include celecoxib and low-dose capecitabine, an oral prodrug of 5-FU[77–79]. However, the degree of efficacy of these agents remains controversial.

Reduction of immunosuppression

Reduction or cessation of immunosuppressive drugs has been associated with a decrease in the number of skin cancers and improved outcome in patients with pre-existing skin cancers[103]. When immunosuppression is essential, e.g. in organ transplant recipients, use of sirolimus or belatacept can lead to a reduction in NMSCs (see above).

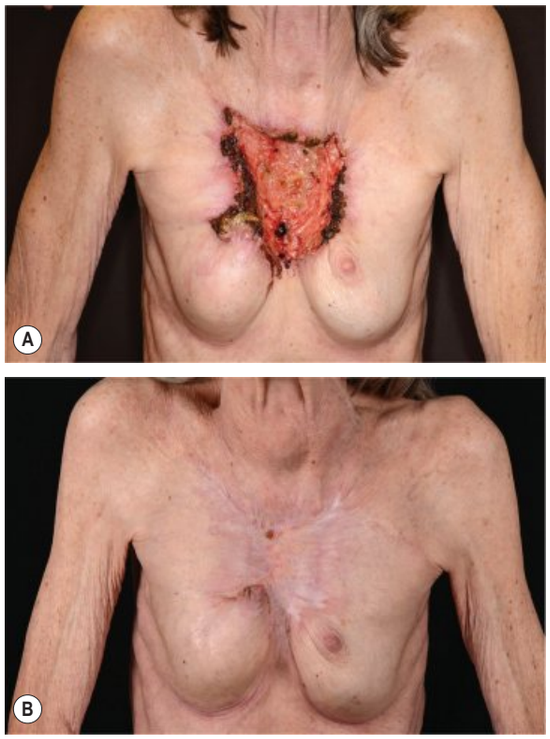

Fig. 108.23 Locally advanced basal cell carcinoma treated with vismodegib. **A** Large ulcerated tumor of the central chest. **B** Nearly complete regression following administration of vismodegib (150 mg daily) for 10 weeks.

SIDE EFFECTS OF VISMODEGIB AND SONIDEGIB	
Common	
• Dysguesia* (>40% of patients)	• Nausea, reduced appetite, and weight loss
• Muscle spasms	• Diarrhea
• Alopecia	• Fatigue
Less common	
• cSCCs, including phenotypic switch of BCC to cSCC	• Keratoacanthomas
• Cough	• Amenorrhea
• Congestive heart failure	• Hyponatremia
• Pneumonia	• Arthralgia
• Thromboembolism	• Pruritus
*Due to altered cell turnover of adult tongue epithelium.	

Table 108.10 Side effects of vismodegib and sonidegib. Both medications can lead to birth defects or fetal death. BCC, basal cell carcinoma; cSCC, cutaneous squamous cell carcinoma.

Prevention

Primary prevention programs focused on lowering UV exposure appear to be having a beneficial effect in reducing the incidence of skin cancer. Consistent use of sunscreens has been shown to decrease the incidence of SCC, but to have no effect or only a weak effect on the incidence of BCC in both immunocompetent individuals and immunocompromised organ transplant recipients[104]. Lastly, educational programs for medical professionals and the public are also important interventions.

Acknowledgment

The editors wish to thank Dr. Darrell S. Rigel for his valuable contributions to this chapter in the previous editions.

Additional figures and tables on Uncommon cutaneous neoplasms that can mimic differentiated or undifferentiated invasive squamous cell carcinoma (SCC), and Histopathologic patterns observed in nodular basal cell carcinomas, available in our eBook (see inside front cover for access code).

eFig. 108.4 Basal cell nevus syndrome. Frontal bossing and hypertelorism, with multiple scars from previous excisions of BCCs.

eFig. 108.5 The multistep development of squamous cell carcinoma. UV irradiation of normal skin induces mutations in keratinocytes and facilitates clonal expansion of keratinocytes with a mutated *TP53* gene. Additional mutations (including a second *TP53* mutation) that affect genes controlling proliferation, cell migration and cell death provide for selective growth advantage and cause genomic instability. The final result is metastatic tumor cells, capable of growing in regional lymph nodes and internal organs.

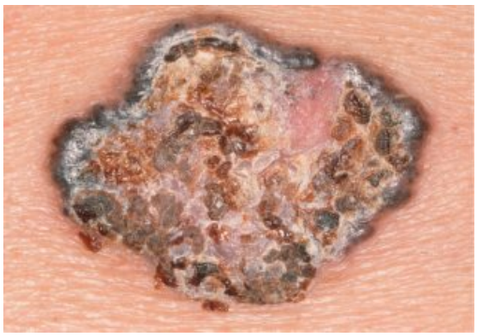
eFig. 108.20 Lymphoepithelioma – histopathologic features. A dermal tumor without a connection to the epidermis, comprised of mononuclear cells with vesicular nuclei and prominent nucleoli (inset left) that are admixed with large numbers of small lymphocytes, focally masking the tumor complexes. A staining for pan-cytokeratin (inset right) highlights the neoplastic epithelial cells. *Courtesy Lorenzo Cerrroni, MD*.

eFig. 108.21 The histopathologic spectrum of actinic keratosis (AK), SCC *in situ*, and invasive SCC. A An AK consists of a lower epidermal proliferation of cytologically abnormal keratinocytes; the adnexal epithelium is notably spared. **B** In SCC *in situ*, the atypical keratinocytes occupy the entire epidermis and intraepidermal portion of adnexal structures, without invasion into the dermis. **C** Invasive SCC is distinguished by the extension of the malignant keratinocytes into the dermis. If an invasive SCC is clinically suspected, the biopsy specimen should be deep enough to determine the extent of dermal invasion.



eFig. 108.22 The Hedgehog signaling pathway. A Unbound Patched silences Smoothened (SMO) signaling. **B** As Hedgehog binds to its receptor Patched, the repression of SMO is removed and signals are transduced via GLI to the nucleus. **C** Inactivating mutations in *PTCH* lead to dysfunctional Patched and this simulates Hedgehog binding and results in constitutive activation of GLI and downstream target genes. **D** An activating mutation in *SMO* results in constitutive signaling to GLI and downstream target genes. Such mutations are detected in sporadic BCCs in which *PTCH1* is intact. **E** Vismodegib and sonidegib are inhibitors of SMO that have been used to treat patients with BCNS as well as metastatic or locally advanced BCCs (see Fig. 108.23). At least 50% of advanced BCCs develop resistance to vismodegib, commonly via acquiring mutations in *SMO*.

UNCOMMON CUTANEOUS NEOPLASMS THAT CAN MIMIC DIFFERENTIATED OR UNDIFFERENTIATED INVASIVE SQUAMOUS CELL CARCINOMA (SCC)	
Neoplasm	**Clues to the diagnosis/comments**
Adnexal carcinomas	
• Microcystic adnexal carcinoma	Evidence of ductal differentiation Perineural infiltration in deeper areas Luminal CEA positivity in the ducts
• Syringomatous carcinoma	Evidence of ductal differentiation Perineural infiltration in deeper areas Luminal CEA positivity in the ducts
Atypical fibroxanthoma	Often a diagnosis of exclusion Some authors consider it to be an undifferentiated variant of SCC CD10 (+), CK (–), Melan-A (–), SOX10 (–), S100 (–) Sometimes SMA (+)
Carcinosarcoma	May be an undifferentiated SCC Stromal cells are pan-CKs (+), e.g. AE1/AE3, MNF116
Desmoplastic melanoma	Melanoma *in situ* may be present at dermal–epidermal junction Patchy lymphoid aggregates S100 (+), SOX-10 (+), p75 (+)
Epithelioid angiosarcoma	Hemorrhage and focal vascular lumina ERG (+), CD31 (+) podoplanin (+); may be CK (+)
Leimyosarcoma, undifferentiated	Evidence of smooth muscle differentiation in more differentiated areas SMA (+), desmin (+)
Lymphoepithelial-like carcinoma	May be an undifferentiated SCC CK (+) in the cellular aggregates within the lymphoid nodules

eTable 108.1 Uncommon cutaneous neoplasms that can mimic differentiated or undifferentiated invasive squamous cell carcinoma (SCC). See Table 122.4 for evaluation of cutaneous metastases. CEA, carcinoembryonic antigen; CK, cytokeratin; SMA, smooth muscle actin.

HISTOPATHOLOGIC PATTERNS OBSERVED IN NODULAR BASAL CELL CARCINOMAS			
I. Epithelial patterns		**II. Cytologic characteristics**	
Adamantinoid	Labyrinthine	***Nuclear features***	***Cytoplasmic features***
Adenoid	Macronodular	Bowenoid	Basosquamous

SOLAR LENTIGO

Synonyms: ■ Lentigo senilis ■ Liver spot ■ Senile freckle

Key features

- Tan to brown to black macules in sites of exposure to UVR
- Histologically, the rete ridges often have club-shaped or bud-like extensions, in addition to increased basal layer pigmentation
- Solar lentigines and macular seborrheic keratoses exist along a continuum

Epidemiology

Solar lentigines are present in 90% of White individuals over the age of 60 years, and their incidence increases with advancing age. They also occur, but less often, in younger individuals and in Asians as a consequence of acute or chronic sun exposure. Inherited patterned lentiginosis favors African-Americans with lighter skin phototypes, including those with mixed Native American heritage.

Pathogenesis

Solar lentigines result from epidermal hyperplasia, with variable proliferation of melanocytes and accumulation of melanin within keratinocytes, in response to chronic exposure to UVR. Similar to seborrheic keratoses, activating somatic mutations in *FGFR3* and *PIK3CA* have been detected in solar lentigines (Table 109.1)[1]. As with ephelides, variants in the melanocortin-1 receptor gene are also linked to the development of solar lentigines.

Clinical Features

Solar lentigines are well-circumscribed, round, oval or irregularly shaped macules that vary in color from tan to dark brown or black. More lightly pigmented lesions are usually homogeneous, whereas darker ones tend to have a mottled appearance. Solar lentigines almost always present as multiple lesions. They usually vary in diameter from 3 mm to 2 cm and can become confluent. Solar lentigines occur in sun-exposed sites, predominantly the dorsal aspects of the hands and forearms, face, upper trunk, and shins (Fig. 109.2A).

By tangential lighting, a reticulated pigment pattern may be appreciated, and Wood's lamp illumination enhances both visible and inapparent lesions. The dermoscopic features of a solar lentigo may include the following: a diffuse light brown structureless area, sharply demarcated and/or moth-eaten borders, fingerprinting, and a reticular pattern with thin lines that are occasionally short and interrupted[2]. A particular variant that has been termed hypermelanotic or "ink spot" solar lentigo is characterized by a striking jet-black color and a stellate outline. By dermoscopy, a black branching pattern is seen.

While solar lentigines may fade slightly after cessation of exposure to UVR, they usually persist indefinitely. Solar lentigines have been shown to be an independent risk factor for the development of cutaneous melanoma. Histologic overlap suggests that both lichenoid keratoses and reticulated seborrheic keratoses can evolve from solar lentigines.

Associated Diseases and Special Forms

A PUVA (psoralen + UVA) lentigo is a well-defined hyperpigmented macule that commonly develops in individuals undergoing long-term PUVA photochemotherapy (see Ch. 134). These lentigines can arise in any site exposed to UVA light and often persist for years after discontinuation of PUVA therapy. In contrast to solar lentigines, PUVA lentigines usually exhibit a darker brown color and more of a stellate appearance, clinical features that may suggest cutaneous melanoma. Histologically, PUVA lentigines display lentiginous hyperplasia of large melanocytes that often exhibit mild cytologic atypia and often contain *BRAF* mutations[3]. Numerous solar lentigines are also seen in patients with xeroderma pigmentosum, and they are often an initial cutaneous finding (see Ch. 87).

Pathology

The rete ridges often have club-shaped or bud-like extensions (Fig. 109.2B), as well as branching or fusing of rete ridges, forming a reticulated pattern. The epidermis between the rete ridges may appear thinned. There is increased basal layer pigmentation, especially in the basaloid cells of the rete ridges, and the lesional keratinocytes are larger than those of adjacent, non-involved epidermis. In some (but not all) cases, the melanocytes are slightly increased in number. Melanocytes in DOPA-stained sections of solar lentigines exhibit increased melanogenesis, and these cells have more numerous as well as longer and thicker dendritic processes than the melanocytes

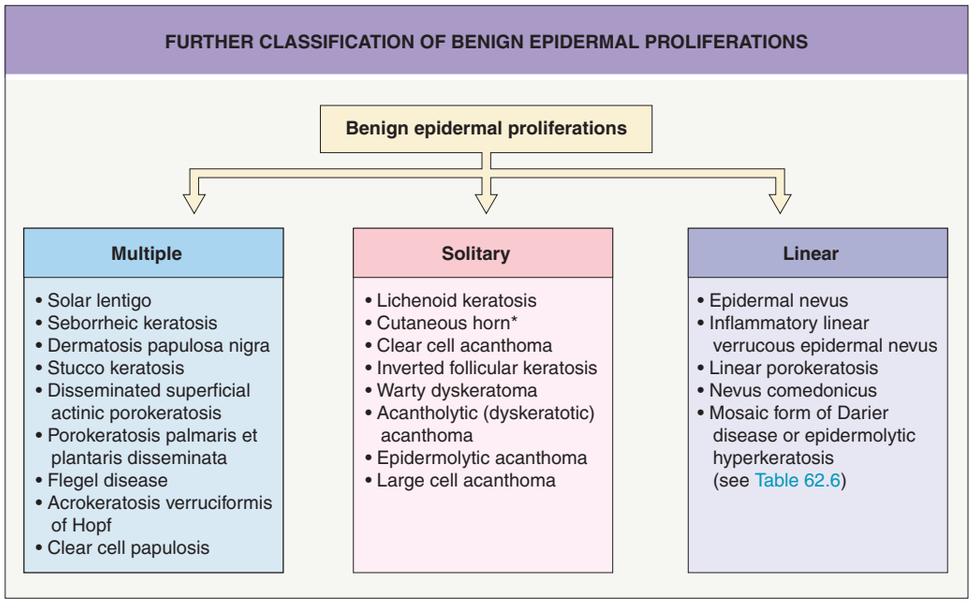

Fig. 109.1 Further classification of benign epidermal proliferations. Although the term solitary lichenoid keratosis is sometimes used, patients may develop multiple lesions, especially those with skin phototypes I or II and significant actinic damage. *When arising from a verruca or seborrheic keratosis.

SOMATIC ACTIVATING MUTATIONS IN BENIGN EPIDERMAL TUMORS

Tumor	Gene(s)
Solar lentigines	*FGFR3**, *PIK3CA*†
PUVA lentigines	*BRAF*
Seborrheic keratoses	*FGFR3*, *PIK3CA* > *KRAS*, *HRAS*, *EGFR*, *AKT1*
Lichenoid keratosis‡	*FGFR3*, *PIK3CA*, *HRAS* > *KRAS*
Dermatosis papulosa nigra	*FGFR3*
Stucco keratoses	*PIK3CA*
Epidermolytic acanthoma	*KRT10*
Acantholytic (dyskeratotic) acanthoma	*ATP2A2*, *ATP2C1*
Epidermal nevi with hyperkeratosis, acanthosis and papillomatosis (but no epidermolytic hyperkeratosis) histologically; also referred to as non-epidermolyic verrucous epidermal nevi (NEVEN) or keratinocytic epidermal nevi (see Table 62.6)	*FGFR3*, *FGFR2*, *PIK3CA*, *HRAS* > *KRAS* > *NRAS*; primarily in syndromic forms: *AKT1*, *PTEN* > *BRAF*
Acneiform nevus (Munro acne nevus)	*FGFR2*
Nevus comedonicus	*NEK9*
See Table 62.6 for genes underlying nevus sebaceus and epidermal nevi with epidermolytic hyperkeratosis, acantholytic dyskeratosis, or associated overgrowth syndromes	

*Germline mutations in this gene lead to skeletal dysplasia syndromes associated with acanthosis nigricans.
†Germline mutations in this gene are often lethal, but occasionally can lead to a Cowden syndrome-like phenotype.
‡Related to benign lentigo, SK, or actinic keratosis; the latter can have *RAS* mutations.

Table 109.1 Somatic activating mutations in benign epidermal tumors. Phosphatidylinositol-4,5-bisphosphate 3-kinase functions downstream of FGFR3. FGFR3, fibroblast growth factor receptor 3; NEK9, NIMA-related kinase 9; PIK3CA, phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit alpha.

Fig. 109.2 Solar lentigines. A Multiple, round to irregularly shaped, brown macules on the dorsal aspect of the hands in an older woman. **B** The rete ridges have club-shaped extensions and the epidermis between the rete ridges appears thinned. There is increased basal layer pigmentation, but the number of melanocytes is normal or only slightly increased. *B, Courtesy Lorenzo Cerroni, MD.*

of normal skin. The superficial dermis often contains melanophages and occasionally a mild perivascular infiltrate of lymphocytes. Solar elastosis is also prominent. Electron microscopic studies reveal abundant melanosome complexes in keratinocytes which appear to be larger than in normal surrounding skin.

Differential Diagnosis

The clinical differential diagnosis of a solar lentigo includes an ephelid, macular seborrheic keratosis, pigmented actinic keratosis, lentigo maligna, simple lentigo, junctional melanocytic nevus, and large cell acanthoma. Table 112.1 outlines the similarities and differences between solar lentigines and ephelides. There is essentially a continuum extending from solar lentigo to macular seborrheic keratosis. The presence of a keratotic surface and horn cysts points to a seborrheic keratosis. Pigmented actinic keratoses are more likely to have a scaly rough surface. Lentigo maligna often exhibits greater variation in pigmentation and irregularity of borders compared with solar lentigo, and by dermoscopy, rhomboidal structures and irregular pigmented

dots around hair follicles can be seen, in particular on the face. Simple lentigines are often smaller and more heavily pigmented than solar lentigines, and they arise during childhood with less relationship to UVR exposure (see Ch. 112).

Treatment

Although a solar lentigo is a benign lesion of cosmetic concern only, it is an indication of cumulative UVR exposure which dictates monitoring of the patient for cutaneous carcinomas. Bleaching agents (e.g. hydroquinone) are not effective. Both cryotherapy and laser surgery (e.g. frequency doubled Q-switched Nd:YAG) can lead to significant improvement[4], but caution must be used to prevent post-treatment dyspigmentation. Preventive measures include sunscreens, physical barriers, and limitation of sun exposure.

SEBORRHEIC KERATOSIS

Key features

- Common benign lesions that typically begin to appear during the fourth decade of life
- Develop anywhere except mucous membranes, palms, and soles
- Tan to black, macular, papular or verrucous lesions; often have a waxy "stuck-on" appearance
- May become irritated or inflamed
- Large variation in clinical appearance and can simulate melanocytic neoplasms

Introduction

Seborrheic keratoses (SKs) are common benign skin lesions that are almost ubiquitous among older individuals. They develop in hair-bearing skin, invariably sparing the mucosal surfaces and the palms and the soles. Thus, SKs can appear on the head and neck, extremities, and trunk, especially the upper back and submammary region (in women).

Many clinical and histologic variants of SK have been described, and although they are usually easily recognized clinically, some lesions may prove difficult to diagnose by inspection alone, so biopsy for histopathologic examination may be required. This is especially true when there is a history of recent change or if there is inflammation. Larger dark lesions are sometimes biopsied when there is concern about the possibility of melanoma, but with the advent of dermoscopy, nowadays this occurs less frequently.

History

The date of the initial description of SKs is uncertain. In 1927, Freudenthal delineated their clinical and histologic features.

Epidemiology

Autosomal dominant inheritance with incomplete penetrance has been postulated to explain an apparent familial predisposition. Despite their frequent occurrence, there are few large-scale statistical analyses regarding prevalence or sex and racial predilection. In part, this is because epidemiologic studies often view SKs as coincidental findings. They have been reported to be more common in White populations and to affect men and women equally[5]. Their appearance prior to the fourth decade is uncommon, with lesions continuing to develop throughout one's lifetime.

Pathogenesis

SKs are considered a sign of aging and overexpression of amyloid precursor protein within SKs has been reported. While SKs can occur in sun-protected sites (e.g. inframammary fold), sun exposure has also been implicated in their development. Supporting evidence comes from the more frequent occurrence and earlier age of onset of SKs in individuals residing in tropical climates. An Australian study found a higher prevalence of SKs within sun-exposed areas in contrast to non-sun-exposed areas in the same subjects. A higher frequency and an earlier age of onset were also observed in their Australian study group population compared to a UK study group[6].

Alterations in the distribution of epidermal growth factor receptors have been observed in SKs, and based upon androgen receptor polymorphisms, a clonal origin was detected in over half of lesions evaluated, suggesting a neoplasm rather than hyperplasia[7]. Importantly, similar to solar lentigines, somatic activating mutations in two genes – *FGFR3*, which encodes fibroblast growth factor receptor 3[8], and *PIK3CA*, whose protein product is the alpha subunit of phosphoinositide-3-kinase[9] – have been detected within SKs (see Table 109.1). The enhanced activity of these two proteins leads to increased AKT activity[10]. Less frequently, mutations in *KRAS*, *HRAS*, *EGFR*, and *AKT1* oncogenes as well as within the promoters for *TERT* and *DPH3* have been identified.

In irritated SKs, apoptosis within areas of squamous differentiation has been implicated as a cause of the irritation[11]. Although SKs are often clinically verrucous, human papillomavirus (HPV) has been detected infrequently, except in lesions in the genital region. It is likely that these latter lesions actually represent condyloma acuminatum, as the two entities may appear similar both clinically and histopathologically[12].

Clinical Features

Although occasionally solitary, SKs more commonly present as multiple, pigmented, sharply marginated lesions. On the back, raindrop-like and streaming patterns can be seen (Fig. 109.3). SKs may be macules, papules, or plaques, depending on their stage of development. Even within the same lesion there may be a marked variation in color. They are usually light brown in color but may appear white to waxy yellow

Fig. 109.3 Seborrheic keratoses. A Multiple seborrheic keratoses of the posterior trunk that vary in size and color. **B** Sharply demarcated, pigmented papule and plaques with a papillomatous surface and pseudohorn cysts. Note the "stuck-on" appearance.

to brown–black. SKs typically evolve from a macule and may progress to become papular or verrucous. Keratotic plugging, a "stuck-on" appearance, and/or overlying scale are helpful features in distinguishing SKs from melanocytic neoplasms, noting that occasionally keratotic plugging can be seen in compound and intradermal melanocytic nevi. Dermoscopic features are reviewed in Ch. 0.

Individual lesions may be of any size but usually measure about 1 cm in diameter. They can become quite large, i.e. >5 cm in diameter. SKs may become inflamed or irritated due to friction or trauma, but rarely from secondary bacterial infection. Although usually asymptomatic, irritated or inflamed lesions can become tender, pruritic, erythematous, crusted, and rarely, pustular. Sometimes inflammation reflects an underlying diathesis, e.g. psoriasis.

Spontaneous regression, although observed, is not a common feature of SKs, even following inflammation. With trauma, the lesion may crumble, explaining reports of SKs "falling off". Conditions associated with an abrupt appearance or increase in number of lesions, followed by regression when the condition resolves, include pregnancy, coexisting inflammatory dermatoses (in particular erythroderma)[13], and malignancy (next section)[14].

Seborrheic Keratosis and Malignancy

Instances of malignant neoplasms arising within and adjacent to SKs were reported as early as 1932[15]. Invasive and *in situ* squamous cell carcinoma (SCC), cutaneous melanoma, basal cell carcinoma (BCC), and keratoacanthoma have all been observed in association with SKs. This most likely represents a coincidental neoplasm developing within adjacent skin, i.e. a collision lesion, although it is possible that the various cell types present in an SK could develop into their respective neoplasms. In theory, the basaloid cells could give rise to BCC, the spinous cells to SCC, and melanocytes to melanoma[15]. While several histopathologic studies have found BCC to be the most frequently associated neoplasm[15], the neoplasms most commonly misdiagnosed clinically as SKs were SCC *in situ* (e.g. 60 [1.4%] of 4310 specimens[16]) and invasive SCC. In one investigation, 4.6% of SCCs were clinically diagnosed as SKs, and in some of these, features of SK were seen in association with the SCC. The "collision" theory, when two distinct neoplasms develop separately at the same site, has been proposed as a possible explanation for this occurrence, especially given the prevalence of keratinocyte carcinomas and SKs in the population at large[17]. Others believe that BCCs and SKs are both derived from the infundibular portion of the hair follicle, cells of which could evolve into either neoplasm, and in some cases, both concurrently.

The sign of Leser–Trélat is a rare cutaneous marker of internal malignancy, most commonly adenocarcinomas of the gastrointestinal tract and less often other solid organ malignancies and lymphoma. It is considered to be a paraneoplastic cutaneous syndrome characterized by an abrupt and striking increase in the number and/or size of SKs occurring before, during, or after an internal malignancy has been detected[18,19]. Associated pruritus has been documented in over 40% of cases and the majority of the lesions are located on the back, followed by the extremities, face, and abdomen[20,21]. Malignant acanthosis nigricans, another paraneoplastic syndrome, may appear at the same time or shortly after the sign of Leser–Trélat in ~20% of patients[20].

Since its initial description in 1900, the validity of the sign of Leser–Trélat as a reliable marker of internal malignancy has been challenged, given the frequency of both neoplasia and SKs in the elderly population, in whom the condition is usually observed[21]. Its description is also loosely defined, which is problematic as there are no standards for quantifying the number of lesions required for the diagnosis. In addition, determining the magnitude of a patient-reported increase in number can be difficult. The few studies investigating SKs and their link with internal malignancy have largely been inconclusive. One retrospective review examined 1752 consecutive patients with the diagnosis of SK, and of these, 62 individuals were diagnosed with an internal malignancy within 1 year before or after the diagnosis of SK. Of those 62 patients, six patients presented with findings consistent with the sign of Leser–Trélat. However, an age- and sex-matched control group demonstrated similar findings[22].

The pathogenesis of the sign of Leser–Trélat is uncertain, but it is thought to be related to secretion of a growth factor by the neoplasm which leads to epithelial hyperplasia[20], as in malignant acanthosis nigricans. To qualify as a paraneoplastic process, the cutaneous findings need to coincide with the presence of the malignancy, resolve when the primary tumor is excised or successfully treated, and reappear with its recurrence or metastasis, i.e. fulfill Curth's postulates (see Ch. 53).

Pathology

There are at least six histologic types of SK: acanthotic, hyperkeratotic, reticulated, irritated, clonal, and melanoacanthoma. Different histopathologic features are often present in the same lesion, resulting in diverse appearances. There are varying degrees of hyperkeratosis, acanthosis, and papillomatosis. Pseudohorn cysts, the product of cross-sectioned epidermal invaginations, are highly characteristic, though not invariably present. Generally, the base of an SK lies on a flat horizontal plane flanked by normal epidermis. The characteristic acanthosis is the result of an accumulation of benign squamous and basaloid keratinocytes, typically projecting outward and upward in an irregular fashion. The sharp demarcation at the base of most lesions has been called the "string" sign. The marked papillomatosis and hyperkeratosis are often likened to "church spires" with shadows of retained cornified material at their peaks.

The squamous cells of many SKs are representative of those found in the normal-appearing epidermis, but some SKs may contain basaloid cells that have a smaller size, uniform appearance, and large oval-shaped nuclei. When slight intercellular edema is present, intercellular bridges are easily visualized. Cytologic atypia is usually not a feature of most SKs. Mild keratinocyte atypia and mitotic figures, when present, are usually associated with irritation and inflammation. The papillary dermis in most instances is unremarkable.

The *acanthotic* SK is the most common histologic type. It usually presents as a smooth-surfaced, dome-shaped papule. Slight hyperkeratosis and papillomatosis are often present, while the greatly thickened epidermis typically contains a preponderance of basaloid cells (Fig. 109.4A). Papillae may be narrow in some lesions, while others may be composed of interwoven aggregates of epithelial cells surrounding islands of connective tissue in a retiform pattern. Invaginated pseudohorn cysts are most prevalent in this variant. Melanin is often increased in the acanthotic type of SK; it is primarily concentrated within keratinocytes, having been transferred from neighboring melanocytes. Deeply pigmented lesions contain abundant melanin in basaloid cells.

The *hyperkeratotic* type of SK, also known as a digitated, serrated or papillomatous type, is almost the morphologic reverse of the acanthotic type. Acanthosis is present but there is more prominent hyperkeratosis and papillomatosis (Fig. 109.4B). A preponderance of squamous cells relative to basaloid cells is seen. Abundant pigmentation is unusual, and keratinizing pseudocysts are observed less frequently than in acanthotic SKs. The hyperkeratotic type is the variant often described as having epidermal projections resembling "church spires", a finding also seen in acrokeratosis verruciformis.

The *reticulated* or *adenoid* type of SK is characterized histologically by delicate strands of epithelium that extend from the epidermis in an interlacing pattern (Fig. 109.4C). They are composed of a double row or more of basaloid cells that may be hyperpigmented. Pseudohorn cysts, although less common than in the acanthotic variant, may be observed. Often, a solar lentigo is seen at the lateral margins of the lesion, supporting the notion that reticulated SK evolves from a solar lentigo.

A lymphoid infiltrate is often present in the dermis of *inflamed* or *irritated* SKs (Fig. 109.4D). It may be perivascular, diffuse, or lichenoid. Spongiosis is often present and there may be necrosis of keratinocytes. Squamous eddies are common findings as well and these consist of whorls of eosinophilic keratinocytes. Irritated SKs often lack the sharply demarcated horizontal base seen with most SKs.

Clonal SKs are considered by some to represent a variant of irritated SK. The clonal, or nested, type of SK is characterized by having well-defined nests of loosely packed cells within the epithelium (Fig. 109.4E). The nests are composed predominantly of variably sized keratinocytes that are often paler than adjacent cells and have a uniform appearance. Nests may also contain melanocytes.

There is a rare variant of SK with numerous basal clear cells that histologically can mimic melanoma *in situ*[23,24]. However, these clear cells demonstrate negative immunostaining for Melan-A/MART-1, MITF, SOX10, and S100 protein.

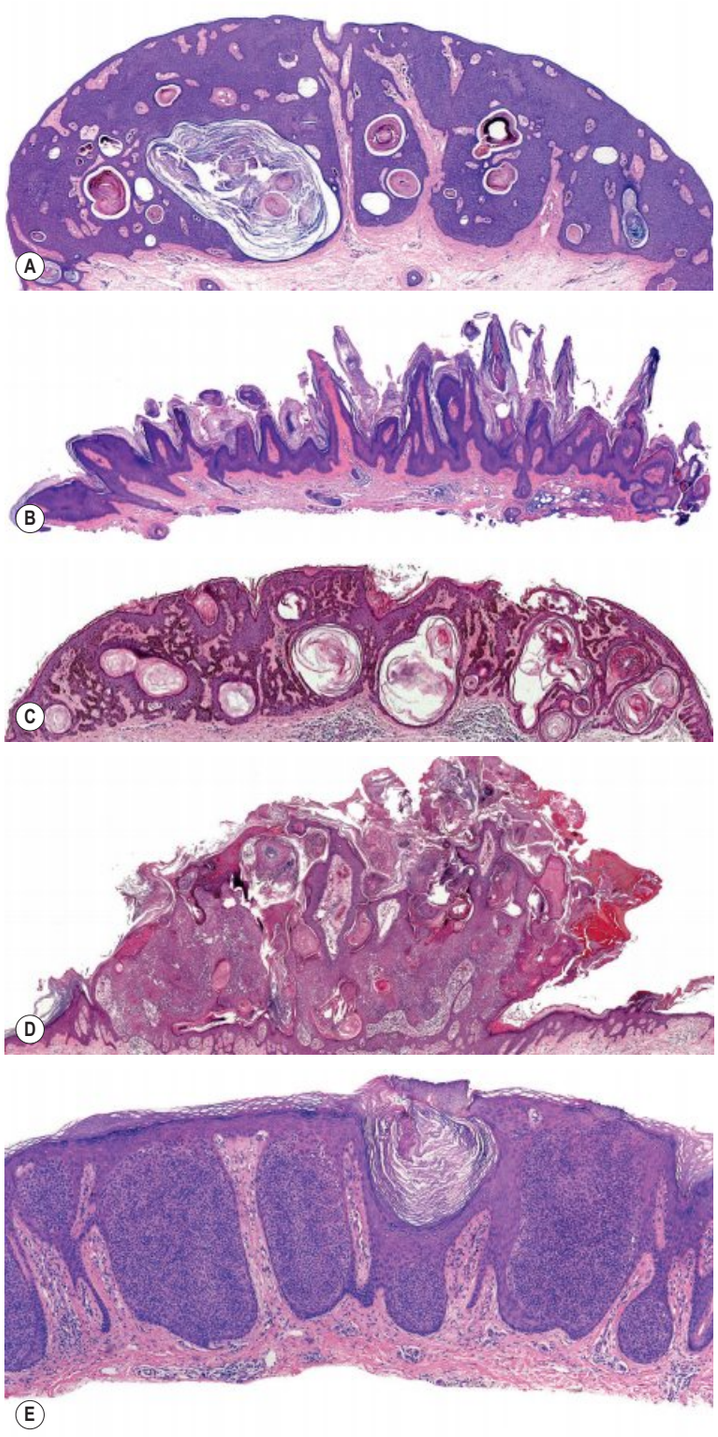

Fig. 109.4 Seborrheic keratoses (SKs) – spectrum of histologic subtypes. **A** Acanthotic type with lobular hyperplasia with prominent horn cysts. **B** Papillomatous or hyperkeratotic type with church spires of papillomatosis and hyperkeratosis. **C** Reticulated or adenoid type with delicate, lace-like strands of interconnecting epithelium and interspersed pseudohorn cysts. **D** Irritated seborrheic keratosis. Exophytic lesion with papillomatosis, hyperkeratosis, hemorrhagic crust, and dermal inflammation. Mild keratinocyte atypia and mitotic figures, when present in SKs, are usually associated with irritation and inflammation. **E** Clonal type with Borst–Jadassohn phenomenon characterized by well-demarcated nests of keratinocytes within the epidermis. *C, D, Courtesy Lorenzo Cerroni, MD.*

Differential Diagnosis

Most SKs are easily identified clinically, although there are entities that may have a similar appearance. Conditions thought to be variants of SKs include dermatosis papulosa nigra, stucco keratoses, and inverted follicular keratoses. They are discussed in this chapter under their respective headings. The clinical differential diagnosis of SK includes solar lentigo, verruca vulgaris, condyloma acuminatum, Bowen disease, SCC, melanocytic nevus, melanoma, acrochordon, and tumor of the follicular infundibulum.

Clinical differentiation between macular SKs, solar lentigines, and melanocytic neoplasms such as melanoma may at times be impossible. Solar lentigines are neither keratotic nor elevated, but some are considered to represent an incipient reticulated type of SK. Over time, solar lentigines can develop into SKs as the buds of pigmented basaloid cells become thicker and there is greater acanthosis. Dermoscopy can prove useful in distinguishing these entities (see Ch. 0).

A review of 20 cases of verrucous melanoma demonstrated how difficult it may be to distinguish between benign and malignant tumors. Of interest, 50% of these verrucous melanomas were thought to represent SKs clinically and a histopathologic diagnosis of a benign nevus was assigned to 10%. A broad spectrum of histopathologic findings, including hyperkeratosis, pseudoepitheliomatous hyperplasia, asymmetry, and an exophytic papillomatous growth pattern, were present in these cases[25].

Acanthotic and irritated types of SK should be distinguished from eccrine poroma. On occasion, SKs may demonstrate "poroid" differentiation. Histologically, poromas are comprised of homogeneous, small basophilic cells with a delicate fibrovascular stroma and narrow ductal lumina with eosinophilic, PAS-positive, diastase-resistant cuticles (see Ch. 111).

Differentiation between an irritated SK, an SCC *in situ* (Bowen disease), and SCC may require histopathologic examination. An irritated SK may be misdiagnosed as an SCC if atypia is present. Although squamous eddies may be abundant in both tumors, there should be no evidence of involvement of the dermis in irritated SKs. Bowen disease demonstrates a preponderance of atypical keratinocytes with vacuolated cytoplasm, close crowding of nuclei, abundant mitoses, and parakeratosis. The adnexal epithelium is also involved.

The Borst–Jadassohn pattern of clonal SK is also seen in some examples of Bowen disease. In general, Bowen disease with a clonal or nested pattern has greater atypia of the individual keratinocytes.

Melanoacanthoma was originally described by Bloch and named "non-nevoid melano-epithelioma, type 1". It is now regarded as a heavily pigmented SK by most authorities. In this variant, melanocytes are distributed throughout the lesion. While the keratinocytes contain melanin, the bulk of the pigment is present within melanocytes, many of which also have long dendrites[26]. Although the melanocytes are prominent, there is no significant increase in their number. The heavy pigmentation of melanoacanthoma has been explained by a possible blockage in the transfer of melanin to keratinocytes.

Intraoral melanoacanthoma or melanoacanthosis was first described in 1979. These lesions bear a striking clinical resemblance to the melanoacanthoma type of SK. Histologically, they are distinct from the cutaneous variant by having only minimal epithelial hyperplasia. Their histologic features are most like those of a heavily pigmented lentigo simplex, with a proliferation of dendritic melanocytes within the basal layer of the epithelium[27].

Verrucae and condylomata acuminata are hyperplasias caused by HPV. Both can clinically mimic SKs but differ in that they most frequently occur in younger individuals. Verrucae often present as rough papules with pinpoint red or black dots that represent tiny intracorneal hemorrhages. Verrucae favor acral locations, while condylomata acuminata occur primarily in the anogenital region. As noted previously, HPV has been reported in anogenital lesions with histologic features of SK[28]. Koilocytic changes of perinuclear vacuolization with nuclear pyknosis in the superficial epidermis may not be present in some verrucae, but are helpful if present. An SK generally tends to be oriented in a more horizontal than vertical fashion, often has pseudohorn cysts, and lacks koilocytes.

Tumor of the follicular infundibulum is distinguished from an SK by a superficial distinct plate-like epithelial proliferation. The latter consists of multiple slender epidermal connections composed of basaloid or pale cells, without as much hyperkeratosis as an SK. The reticulated type of SK has a similar pattern but lacks the distinct plate-like growth. Skin-colored SKs, especially in flexural sites, can easily be mistaken for an acrochordon, which has a pedunculated shape and is usually smoother and smaller in size.

Other conditions with papillated epidermal hyperplasia histologically are readily distinguished on a clinical basis. Some of these include

acanthosis nigricans, epidermal nevus, and confluent and reticulated papillomatosis. Epidermal nevi tend to follow the lines of Blaschko, appearing in a linear arrangement on the extremities and a whorled pattern on the trunk. Although histologic sections of epidermal nevi typically exhibit acanthosis and hyperkeratosis, they usually lack the pseudocysts seen in many SKs. Epidermal nevi are also usually apparent at birth or shortly thereafter, unlike SKs, which are seen in adults.

Acrokeratosis verruciformis of Hopf has a "church spire" configuration similar to that described for hyperkeratotic SK[29], but it is an autosomal dominant disorder and lesions are usually limited to the distal extremities (see Ch. 59). Acanthoma fissuratum may clinically resemble a large SK, but histopathologic analysis reveals irregular epidermal hyperplasia due to friction.

Treatment

Treatment of asymptomatic SKs is largely performed for cosmetic reasons. Symptomatic lesions are usually removed by destruction, curettage, or shave excision. The most common method of destruction is cryotherapy. Other methods include electrodesiccation and laser vaporization (e.g. erbium:YAG). More recently, a topical solution of 40% hydrogen peroxide was FDA-approved for SK removal[30]. Inhibitors of AKT activity have been shown to induce apoptosis in cultured intact seborrheic keratoses and may possibly represent a future topical therapy[10].

LICHENOID KERATOSIS

Synonyms: ■ Lichen planus-like keratoses (LPLK) ■ Solitary lichenoid keratosis (SLK) ■ Benign lichenoid keratosis (BLK)

Key features

- A pink to red–brown scaly papule that arises in sun-exposed sites, most commonly the forearms and upper chest
- Histologically, it appears almost identical to lichen planus, but is distinguished by clinical correlation
- Represents an inflammatory stage of a solar lentigo, SK, or actinic keratosis

History

In 1966, two independent groups reported solitary asymptomatic lesions with the histologic features of lichen planus. These two groups referred to these lesions as solitary lichen planus and solitary lichen planus-like keratosis.

Epidemiology

In one series, 85% of lichenoid keratoses (LKs) developed between the ages of 35 and 65 years[31]. Women are diagnosed with the condition twice as frequently as men, and the vast majority of lesions are seen in White individuals. Occasionally, patients with a fair complexion and significant photodamage develop multiple LKs.

Pathogenesis

LKs have been thought to represent inflammation of a solar lentigo, SK, or actinic keratosis. *FGFR3*, *PIK3CA*, and *RAS* mutations have been detected in ~50% of LKs, providing support for this relationship (see Table 109.1)[32]. Because some of the lesions are related to "precancerous" actinic keratoses, the term lichenoid keratosis is preferred over the term benign lichenoid keratosis. Lesions are best referred to as a lichenoid actinic keratosis when there is significant keratinocyte cytologic atypia or other classic features of an actinic keratosis, and as an irritated SK when a lichenoid infiltrate is associated with other features of an SK.

Increased numbers of Langerhans cells have been observed in the epidermis of LKs. This has led to the suggestion that the lichenoid infiltrate of lymphocytes is secondary to a stimulus from an unidentified epidermal antigen. This mechanism is similar to that proposed for lichen planus.

Clinical Features

LKs occur primarily as solitary pink to red–brown, often scaly, papules ranging from 0.3 to 1.5 cm in diameter (Fig. 109.5A). An astute clinician can oftentimes suspect the diagnosis before the biopsy is performed. LK most closely resembles Bowen disease or BCC, and for this reason, these lesions are frequently biopsied. They are usually asymptomatic, although occasionally patients complain of slight pruritus or stinging[33]. The most common sites are the forearms and upper chest, with less frequent occurrence on the shins (in women) and other chronically sun-exposed sites. Dermoscopic findings include light brown pseudonetworks due to residual solar lentigo and overlapping pinkish areas related to lichenoid inflammation. Annular granular structures and gray pseudonetworks are present in the early regressing stage, while blue–gray fine dots can be seen in the late regressing stage. Blue–gray dots or globules, representing melanophages, are also considered typical of an LK.

Pathology

LK has a lichenoid infiltrate composed primarily of lymphocytes with scattered histiocytes (Fig. 109.5C). Eosinophils and plasma cells are sometimes present. All other elements of an interface dermatitis are observed, including basal vacuolar alteration, melanin incontinence, and colloid bodies. When melanin incontinence is prominent, the term pigmented lichenoid keratosis is sometimes used. Parakeratosis may be seen, unlike in typical lichen planus. Sometimes there is frank separation of the epidermis from the infiltrate in the dermis, giving rise to a subepidermal cleft or blister cavity. Basal cell proliferation is absent, and keratinocyte atypia is either mild or absent. Changes of a solar lentigo or macular SK are often present at the periphery of the specimen.

Occasionally, the histopathologic findings in an LK may mimic mycosis fungoides due to the presence of Pautrier-like microabscesses, alignment of lymphocytes along the basal layer, and epidermotropism of the infiltrate. When the entire lesion is excised, in contrast to mycosis fungoides the infiltrate in lichenoid keratosis ends abruptly at the lateral edges of the lesion (Fig. 109.5C) (this feature cannot be observed in incisional biopsies). There is also an atrophic variant, and sometimes the lesion may mimic lupus erythematosus (LE) histopathologically[34].

LKs may undergo regression, and thus, histologically, they may be confused with other regressing tumors, especially melanoma. The regressed LK usually displays a loosely fibrotic papillary dermis with scattered lymphocytes and melanophages. Regressed melanoma typically has a dense band of melanophages with lymphocytes and dilated blood vessels; usually there is also a thin epidermis overlying

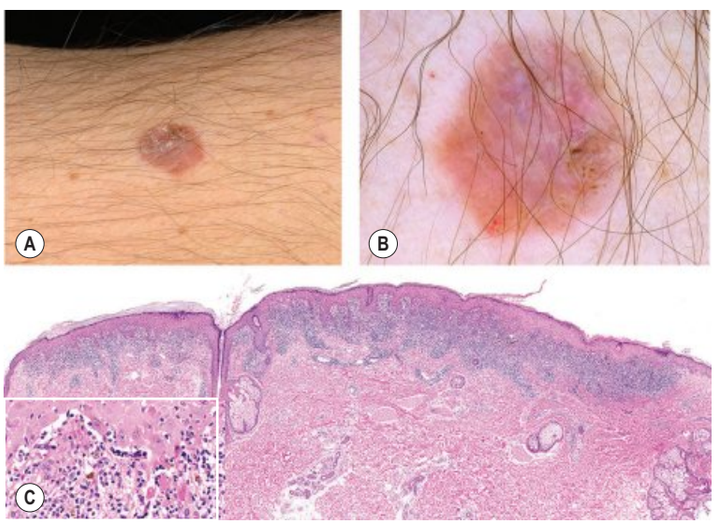

Fig. 109.5 Lichenoid keratosis. A Pink and light brown flat papule with focal scale-crust. **B** Dermoscopy demonstrates irregular granular pigmentation and whitish areas corresponding to focal hypergranulosis and hyperkeratosis. **C** Well-circumscribed lichenoid infiltrate; several necrotic keratinocytes and a few melanophages are present (inset). *Courtesy Lorenzo Cerroni, MD.*

effaced rete ridges. In states of partial regression, histopathologic clues to the proper diagnosis remain, but the end stages of both tumors may not be distinguishable. Careful search for elements of superficial BCC is also advisable.

Differential Diagnosis

Frequently cited clinical impressions include Bowen disease, actinic keratosis, BCC, irritated SK, melanoma (including amelanotic), and melanocytic nevus. Development of inflammation or color change within a pigmented lesion may lead the clinician to suspect an atypical melanocytic nevus or melanoma[31]. Even when a melanocytic neoplasm is not in the clinical differential diagnosis, the pathologist must take care to ensure that the lichenoid infiltrate is not obscuring melanoma *in situ* or even melanoma involving the superficial dermis, as the latter may become heavily inflamed. Multiple LKs may be misdiagnosed as a lichenoid drug eruption and can be a cause of pruritus in elderly patients[35].

Histologically, LK resembles other conditions with a band-like inflammatory (lichenoid) reaction pattern, including lichen planus, "lichenoid" LE, lichenoid fixed drug reactions, and mycosis fungoides. Clinical correlation is very useful in excluding these conditions, e.g. LK occurs as a single lesion in the majority of patients. While lichen planus may be virtually identical to LK histologically, there is usually more wedge-shaped hypergranulosis and less parakeratosis in lichen planus.

Treatment

Once the diagnosis of LK is made, no further therapy is necessary. Any remaining lesion may be destroyed by any method.

DERMATOSIS PAPULOSA NIGRA

Key features

- Most common in individuals of African descent with darkly pigmented skin
- Multiple hyperpigmented papules on the face
- Considered to be a variant of SK
- Cryotherapy can result in hypopigmentation; optimal treatment is scissor snip, curettage, or light electrodesiccation, when desired

Introduction

Dermatosis papulosa nigra (DPN) presents as multiple, hyperpigmented, filiform to sessile, smooth-surfaced papules measuring from 1 to 5 mm. The lesions typically develop on the face of darkly pigmented individuals.

History

DPN was first described by Castellani in 1925 based on his observations during visits to Central America and Jamaica.

Epidemiology

DPN has a strong familial predisposition and, in selected populations, reported incidences have ranged from 10% to 75%. This variability in incidence may be a reflection of sampling, as African-Americans with lighter skin phototypes are affected less commonly. In addition to those with African heritage, the condition has also been reported in Filipinos, Vietnamese, Europeans, and Mexicans. Women are twice as likely to be affected as men and it rarely occurs in children. DPN is not related to any systemic disease or syndrome.

Pathogenesis

The cause of DPN is unknown. It tends to have an earlier age of onset than that of SKs, but otherwise is similar and probably represents a variant of SK. Some authors have viewed it as a variant of multiple acrochordons. However, an *FGFR3* mutation was detected in two samples of DPN, supporting its relationship to SKs (see Table 109.1)[36].

Fig. 109.6 Dermatosis papulosa nigra. Multiple hyperpigmented papules with typical location on the cheeks.

Clinical Features

Pigmented papules are distributed symmetrically on the malar eminences and forehead (Fig. 109.6). Less often, lesions are on the neck, chest and back. The papules usually appear during adolescence and gradually increase in size and number over time, peaking in the sixth decade.

Pathology

DPN is characterized by acanthosis, papillomatosis, and hyperkeratosis in a pattern quite similar to the acanthotic type of SK. Pseudohorn cysts, however, are not a common feature.

Differential Diagnosis

The differential diagnosis of DPN includes primarily multiple SKs and acrochordons. Occasionally, verrucae, melanocytic nevi, adnexal tumors (e.g. trichoepitheliomas, fibrofolliculomas, tricholemmomas, basaloid follicular hamartomas, syringomas), and angiofibromas might be considered clinically (see Fig. 111.5).

Treatment

Treatment of DPN is generally performed for cosmetic purposes, although individual lesions may be troublesome. Care should be exercised to avoid treatments that may result in dyspigmentation, so initially it may be best to treat just a small number of lesions. Snip excision with scissors, curettage, and light electrodesiccation are the most common treatment modalities. Hypopigmentation after cryotherapy can be particularly problematic, since melanocytes are more sensitive to freeze damage than are keratinocytes.

STUCCO KERATOSIS

Synonym: ■ Keratosis alba

Key features

- Gray–white papules
- Typically on the lower extremities of older adults, especially the ankles
- Lesions are "stuck on", and when scraped off, there is minimal bleeding
- Probably a variant of SK

Introduction

Stucco keratoses are discrete, gray–white papules that are hard and opaque, with the latter reflecting focal accumulations of cornified material. They are usually distributed symmetrically below the knee, especially on the ankle and dorsal aspect of the foot.

History

In 1958, Kocsard was the first to describe stucco keratoses and eight years later he coined the term *stucco keratosis* to reflect its "stuck-on" appearance. Although early accounts of stucco keratoses described elastotic changes in the upper dermis, this has been shown to represent solar elastosis.

Epidemiology

There is no familial predilection for stucco keratoses. They can become more apparent during cold winter months, most likely due to lower humidity and more xerotic skin. They occur primarily in middle-aged to elderly individuals and are usually first observed after 40 years of age. Men are four times more likely to be affected than women. Although precise epidemiologic data are lacking, most descriptions have been in White individuals. There are no known associated diseases or syndromes.

Pathogenesis

Histochemical studies suggest an acquired focal abnormality of keratinization, and a *PIK3CA* mutation was detected in three of five samples of stucco keratoses[37]. There was a single case report of several HPV types within multiple keratoses detected by PCR, but the significance of this finding is unclear as HPV DNA is purported to be detectable in at least 20% of normal skin specimens[38]. Ultrastructural examination has revealed no viral particles[39].

Sun exposure has been proposed to be a factor in the formation of stucco keratoses, as most affected individuals have evidence of solar damage. However, this may be a reflection of the age and phototype of the patients. Heat and petroleum products such as tar have also been implicated, but none of these theories explain the distribution pattern.

Clinical Features

Usually tens, but sometimes hundreds, of gray–white papules are present on the lower extremities of older adults (Fig. 109.7). They favor the ankles and dorsal feet but may extend to the thighs. Occasionally, stucco keratoses appear on the forearms. The lesions are usually small, measuring from 1 to 4 mm; rarely larger plaques are seen. The lesions may be scraped or flicked off the skin surface with a fingernail and there is usually minimal, if any, bleeding. A collarette of dry scale may remain. On occasion, brown, pink, and deep yellow shades have been described.

Fig. 109.7 Stucco keratoses. Multiple gray–white keratotic papules, primarily on the ankle and dorsal foot.

Pathology

Stucco keratoses display prominent orthokeratotic hyperkeratosis and papillomatosis, often imparting a peaked "church spire" pattern. Acanthosis is usually present, but to a lesser degree than in some SKs. The granular layer may be thickened. Horn cysts are usually absent and cytologic atypia is not a feature.

Differential Diagnosis

Stucco keratoses may resemble SKs, acrokeratosis verruciformis of Hopf, verruca plana, or epidermodysplasia verruciformis. SKs tend to be larger and pigmented with a surface that appears "waxy", in contrast to stucco keratoses, which are smaller and have a dry, rough surface. The differential diagnosis also includes the disorder multiple minute digitate hyperkeratosis. In addition to flattened or dome-shaped keratotic papules, patients have numerous nonfollicular, hyperkeratotic, filiform projections measuring 1–2 mm in diameter. Histologically, stucco keratoses resemble hyperkeratotic SKs and acrokeratosis verruciformis; all three may demonstrate papillomatosis and digitation, giving an appearance similar to "church spires". As discussed below, the lesions of acrokeratosis verruciformis favor the dorsal aspects of the hands (as well as the feet).

Treatment

As with SKs, treatment is generally for cosmetic reasons, although symptomatic lesions may require removal. Curettage, or local destruction with cryosurgery or electrodesiccation, are the usual forms of treatment. In older patients, initial treatment of a few lesions allows assessment of healing time. Topical application of urea, lactic acid, or retinoids may reduce the hard scale, but the actual lesions persist.

POROKERATOSIS

Key features

- At least eight clinical variants of porokeratosis are recognized
- The prototype, *porokeratosis of Mibelli*, is a plaque that appears during infancy or childhood, usually on an extremity
- *Disseminated superficial actinic porokeratosis* (DSAP) is the most common type, with multiple thin papules appearing in chronically sun-exposed skin of the extremities
- *Disseminated superficial porokeratosis* has a widespread distribution pattern but lesions do not exclusively involve chronically sun-exposed sites
- *Solar facial porokeratosis* is a variant with thin papules on the face of young women, especially Asians
- *Linear porokeratosis* develops during infancy or childhood and follows the lines of Blaschko
- *Punctate porokeratosis* appears during or after adolescence as 1–2 mm papules of the palms and soles
- *Porokeratosis palmaris et plantaris disseminata* (PPPD) is a variation of punctate porokeratosis, with lesions also present on other areas of the body
- *Porokeratosis ptychotropica* is a rare variant that favors the intergluteal cleft and buttocks
- Some forms are inherited in an autosomal dominant fashion (e.g. DSAP)
- A thread-like raised hyperkeratotic border is characteristic and its histologic correlate is the cornoid lamella, a thin column of parakeratosis
- Development of SCC is possible but in most variants rare

Introduction

Porokeratosis consists of a disease spectrum in which lesions can vary significantly in size and distribution but characteristically share a thin keratotic rim. The latter is a clinical reflection of the cornoid lamella, the

diagnostic column of parakeratosis seen histologically. An explanation for the gradual centrifugal expansion of lesions is the migration of a clone of "mutated" keratinocytes. The disorder was erroneously named porokeratosis because the cornoid lamella was initially described as being present over a sweat pore, which of course is a fixed structure that cannot expand peripherally. Clinically, at least eight types of porokeratosis have been recognized (Table 109.2). Previous reports of more than one type of porokeratosis developing in the same patient[40] and in multiple members of an affected family[41] can be explained by more recent genetic studies.

History

In 1893, Mibelli first described what is now considered classic porokeratosis: one to several discrete plaques that may occur anywhere on the skin or mucous membranes, usually appearing during infancy or childhood. That same year, Respighi reported a superficial and disseminated form of the disease while Chernosky defined disseminated superficial actinic porokeratosis (DSAP) nearly 70 years later. In the 1970s, porokeratosis palmaris et plantaris disseminata (PPPD) and punctate porokeratosis were described. Porokeratosis ptychotropica is a more recently recognized form.

CLINICAL VARIANTS OF POROKERATOSIS

Variant	Clinical features
Porokeratosis of Mibelli	Plaque that arises during infancy or childhood, usually on a distal extremity; often several cm in diameter; a distinct keratotic rim may not be apparent (Fig. 109.9A)
Disseminated superficial actinic porokeratosis (DSAP)	Pink to brown papules and plaques with peripheral scale; arise in sun-exposed sites, especially the extensor forearms and shins; usually measure from a few mm to 1 cm in diameter; familial form has autosomal dominant inheritance pattern (Fig. 109.9B–D)
Solar facial porokeratosis	Thin papules on the face of young women, especially Asians, and may be pigmented (Fig. 109.9E,F)
Disseminated superficial porokeratosis (DSP)	Widespread distribution similar to DSAP but lesions do not exclusively involve sun-exposed sites
Linear porokeratosis	Streaks along the lines of Blaschko; arise during infancy or childhood; risk of development of squamous cell carcinoma (Fig. 109.9G)
Punctate porokeratosis	Palmoplantar papules that measure 1–2 mm in diameter; arise during adolescence or adulthood (Fig. 109.9H)
Porokeratosis palmaris et plantaris et disseminata (PPPD)	Palmoplantar papules in addition to involvement of the trunk, extremities, and even mucous membranes; onset during childhood or adolescence
Porokeratosis ptychotropica	Red to brown papules or plaques in the intergluteal cleft and on the buttocks; there may be coalescence of lesions centrally with scattered papules peripherally; a distinct keratotic rim may not be apparent (Fig. 109.9I)
Localized genital porokeratosis	Most commonly found on the scrotum followed by the penis; genital involvement may also be seen in other variants
Eruptive disseminated porokeratosis	Abrupt onset of numerous, widespread, inflamed keratoses; may be pruritic and can spontaneously regress; possibly a sign of an associated malignancy in up to ~30% of patients
Porokeratoma	Favors extremities but can occur on buttocks or in the intergluteal cleft

Table 109.2 Clinical variants of porokeratosis. Lesions that resemble porokeratosis are also seen in CDAGS syndrome: *c*raniosynostosis and clavicular hypoplasia, *d*elayed closure of the fontanelle, *a*nal anomalies, *g*enitourinary malformations, and *s*kin eruption[55]. Additional variants include follicular (cornoid lamellae within follicular ostia) and reticulated. Color can vary from pink to brown and several variants may develop a verrucous appearance.

Epidemiology

Porokeratosis can be inherited as an autosomal dominant disorder, including DSAP and PPPD, but many cases appear to be sporadic. Porokeratosis of Mibelli affects boys more than girls, but DSAP is more commonly diagnosed in women. Although PPPD is inherited in an autosomal dominant manner, it is twice as common in males than in females, perhaps reflecting an environmental factor. Given its relationship to sun exposure, DSAP is more frequently observed in patients with skin phototypes I and II and is rare in individuals with phototypes V and VI.

Pathogenesis

Heterozygous germline mutations in genes that encode enzymes in the mevalonate pathway – mevalonate kinase (MVK), phosphomevalonate kinase (PMVK), mevalonate diphosphate decarboxylase (MVD), and farnesyl diphosphate synthase (FDPS) – have been detected in different forms of porokeratosis, both familial and sporadic (Fig. 109.8)[42,43]. Cholesterol, an isoprenoid, is the end product of this metabolic pathway, and isoprenoids play an essential role in cellular proliferation and differentiation as well as cytoskeleton organization. Whether it is a deficiency of end products such as cholesterol, an accumulation of toxic intermediate metabolites, or both that leads to lesions of porokeratosis is not known. To date, germline mutations in one additional gene that encodes a vesicular nucleotide transporter, *SLC17A9*, have been reported in familial DSAP[44].

As anticipated given its distribution along the lines of Blaschko, a postzygotic somatic mutation in *MVD* or *PMVK*, i.e. a "second hit", was identified within lesions of linear porokeratosis in individuals who possessed respective germline heterozygous mutations (see Fig. 62.2)[45]. An explanation for the early appearance of linear porokeratosis is the occurrence of a single second hit during embryogenesis. In contrast, differing acquired second hits in patients with DSAP, who possess germline heterozygous mutations in *MVK* or *MVD*, represent UV-signature point mutations or somatic homologous recombinations[46]. The latter leads to biallelic deficiency.

Within lesions of DSAP, the concentration of epidermal cells with a second hit was found to be higher within their central portions than in the annular rings[46]. How these findings relate to the formation of the peripheral cornoid lamella remains speculative.

Clinical Features

Classic *porokeratosis of Mibelli* is a rare condition, appearing during infancy or childhood as an asymptomatic, small, brown to skin-colored keratotic papule that gradually enlarges over a period of years to form a plaque that may measure several centimeters in diameter. There is a raised, sharply demarcated, keratotic, thready border with a longitudinal furrow (Fig. 109.9A). The center of the lesion may be hyperpigmented, hypopigmented, atrophic, and/or anhidrotic. Lesions may occur anywhere on the body, including mucous membranes, but the extremities are most frequently involved. Multiple lesions may be present, but they are almost always regionally localized and unilateral.

Disseminated superficial actinic porokeratosis (DSAP) is much more common than the Mibelli type. Small asymptomatic or mildly pruritic keratotic papules, usually ranging from 3 to 10 mm in diameter, appear during the third to fourth decades of life. They are typically skin-colored to tan–brown to pink–red in color. As the lesions progress, they expand radially, and the older, central area becomes atrophic while the well-demarcated border develops a thin, elevated, furrowed keratotic rim (Fig. 109.9B–D). The lesions occur exclusively in sun-exposed areas, most commonly the shins and extensor forearms. In more extensive disease, there is involvement of the upper outer arms, upper trunk, and thighs. Facial sparing is characteristic, with the exception of the solar facial variant (Fig. 109.9E,F; see Table 109.2).

Some patients report that lesions of DSAP become more prominent and erythematous during the summer[47], and there are reports of patients with psoriasis receiving UVB or PUVA treatments developing DSAP. In individuals with skin phototypes I and II, DSAP may resemble and coexist with actinic keratoses, but, unlike actinic keratoses, DSAP almost always involves the legs and rarely the face, whereas patients

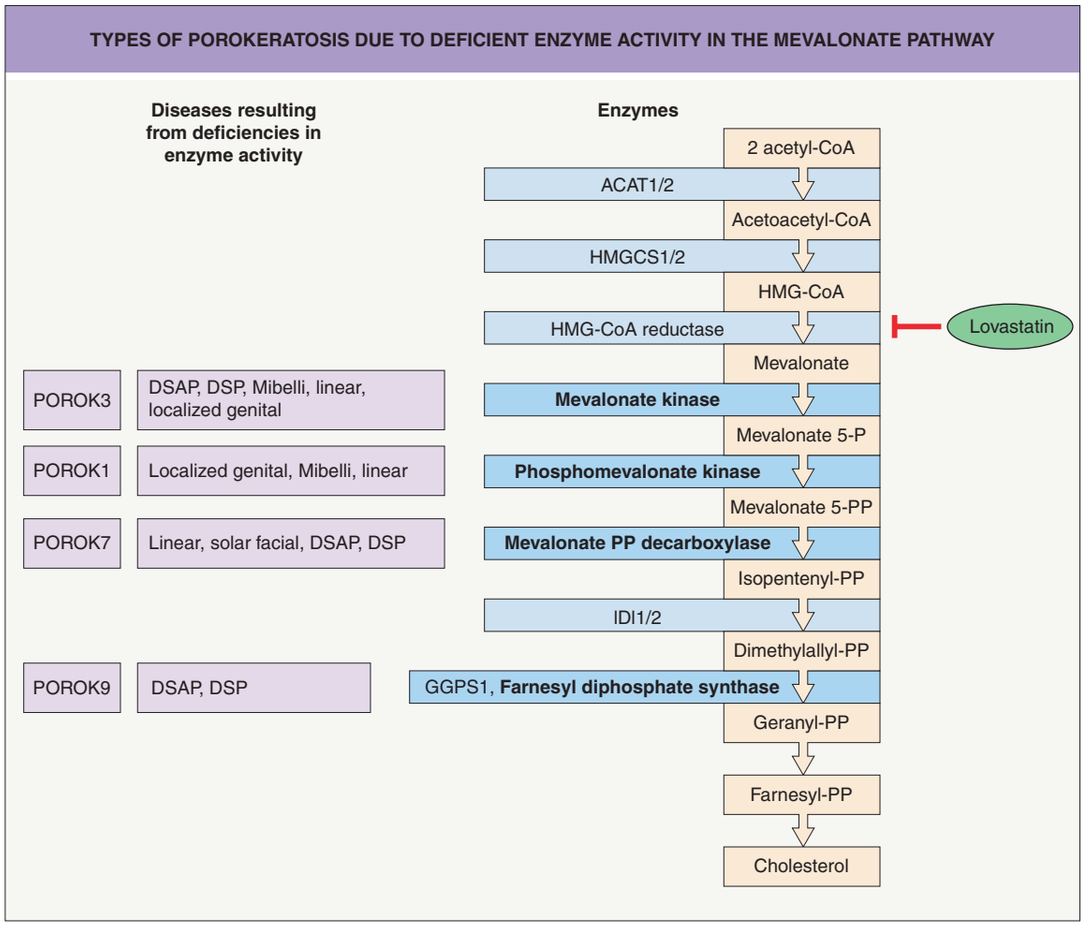

Fig. 109.8 Types of porokeratosis due to deficient enzyme activity in the mevalonate pathway. To date, enzymes in **bold** are dysfunctional in four forms of porokeratosis. POROK corresponds to the OMIM classification of porokeratoses; to date underlying genetic mutations for the following forms have not been detected: POROK2: porokeratosis palmaris et plantaris disseminata (PPPD); POROK4, POROK5: disseminated superficial actinic porokeratosis (DSAP); POROK6: linear, PPPD. Mutations in *SLC17A9* are associated with POROK8. ACAT, acetyl-coenzyme A acetyltransferase; DSP, disseminated superficial porokeratosis; GGPS, geranyl diphosphate synthase; HMGCS, HMG-CoA synthase; IDI, isopentyl-diphosphate isomerase; PP, diphosphate.

with actinic keratoses on the legs almost always have them on the face as well[48]. Rarely, DSAP has been reported in association with hepatitis C viral infection or systemic lupus erythematosus.

Disseminated superficial porokeratosis (DSP), like DSAP, has a more widespread pattern than the other types of porokeratosis. DSP usually involves the extremities bilaterally and symmetrically, sparing the palms, soles, and mucous membranes.

Linear porokeratosis arises during infancy or childhood, and it consists of one or more plaques that are similar in appearance to classic porokeratosis; however, the plaques follow the lines of Blaschko, most commonly on the extremities (Fig. 109.9G). The distribution pattern is a reflection of genetic mosaicism (see above). When an individual has both DSAP and linear porokeratosis, the latter represents type 2 mosaicism (see Fig. 62.2). Thicker plaques of linear porokeratosis have been associated with *PMVK* mutations and thinner plaques with *MVD* mutations[45].

PPPD is uncommon and individual lesions resemble those of porokeratosis of Mibelli except they are smaller and have a less pronounced keratotic border. They may be asymptomatic or pruritic, and generally arise during childhood or adolescence. As the name suggests, the palms and soles are initially affected, but any surface, including mucous membranes, may be involved.

Punctate porokeratosis is the most difficult type to diagnose clinically because of the small size of the lesions. It appears during adolescence or adulthood as small "seed-like" keratotic papules with a peripheral raised rim on the palms and/or soles[49] (Fig. 109.9H). Clinically, it may resemble punctate keratoderma, Darier disease, Cowden syndrome, or arsenical keratoses, but the presence of a cornoid lamella histologically narrows the differential diagnosis. There are two other palmoplantar disorders that also have parakeratotic columns – spiny keratoderma, where lesions resemble the spines of an old-fashioned music box, and porokeratotic eccrine ostial and dermal duct nevus (PEODDN; also referred to as porokeratotic adnexal ostial nevus) – but clinically these entities are easily discernible.

Porokeratosis ptychotropica is an unusual variant in which pruritic, red to brown papules and plaques develop in the intergluteal cleft and on the buttocks (Fig. 109.9I)[50]. There may be coalescence of lesions centrally. Histologically, multiple cornoid lamellae are seen rather than a single peripheral cornoid lamella.

Development of SCC within lesions of porokeratosis has been reported in all variants except punctate and ptychotropica. Lesions in older patients, those of longstanding duration, and linear variants all have higher rates of malignant degeneration. DSAP has the lowest risk of malignant change[51]. SCC generally appears as a papule or plaque arising in contiguity with the individual lesion of porokeratosis, leading to asymmetry.

In the setting of immunosuppression, multiple lesions of porokeratosis can appear and they may attain a large size (see Fig. 109.9B,C)[52]. Uncommon clinical variants of porokeratosis include a reticular form[53] and a follicular variant[54]. In CDAGS (*c*raniosynostosis and clavicular hypoplasia, *d*elayed closure of the fontanelle, *a*nal anomalies, *g*enitourinary malformations, and *s*kin eruption) syndrome, a very rare autosomal recessive disorder, patients develop erythematous plaques on the face and extremities that histologically resemble porokeratosis (see Table 109.2)[55].

Pathology

Identification of the cornoid lamella is the *sine qua non* for the histologic diagnosis of porokeratosis, although it may be seen in other conditions such as verruca vulgaris and actinic keratosis. It is characterized by a thin column of tightly packed parakeratotic cells extending from an invagination of the epidermis through the stratum corneum, often protruding above the surface of the adjacent skin (Fig. 109.10). Under the cornoid lamella, the granular layer is either absent or markedly attenuated, but it is of normal thickness in other areas of the lesion. Dyskeratosis and pyknotic keratinocytes with perinuclear edema are present in the spinous layer beneath the cornoid lamella. The superficial portion of the cornoid lamella trails toward the center of the lesion in

Fig. 109.9 Porokeratosis – clinical variants. A Porokeratosis of Mibelli on the hand of a child. **B** Large-sized actinic porokeratosis in a renal transplant recipient with significant solar damage; the narrow elevated rim is obvious. **C** Large-sized actinic porokeratosis with a prominent rim in a second immunocompromised patient. **D** Multiple lesions of disseminated superficial actinic porokeratosis (DSAP) with obvious peripheral keratotic rims; lesions can range in color from light brown to pink. **E** Multiple thin pigmented lesions in an Asian patient with the solar facial variant. **F** Dermoscopy of the solar facial variant with visualization of the narrow keratotic border. **G** Several streaks of linear porokeratosis on the lower extremity. **H** Multiple keratotic papules of the plantar surface due to punctate porokeratosis. **I** Porokeratosis ptychotropica with pink to brown papules localized to the intergluteal cleft and buttocks. *B, Courtesy Jean L. Bolognia, MD; E and H, Courtesy Kalman Watsky MD; F, Courtesy Nan Ring, MD; I, Courtesy César Cosme Álvarez Cuesta, MD.*

a pattern that has been likened to smoke coming out of a moving train as the "clone" of epidermal cells advances centrifugally. The cornoid lamella corresponds to the clinically observed raised keratotic border. The clinician should include this portion of the lesion in the biopsy to establish the diagnosis. Sometimes, cornoid lamellae are found in multiple locations throughout the lesion in addition to the periphery.

Compared to classic porokeratosis of Mibelli, the invagination from which the cornoid lamella extends is less pronounced in variants. Corresponding to the less prominent border seen in DSAP, the cornoid lamella in DSAP often does not protrude above the surface of the adjacent stratum corneum. The epidermis in the central portion of a porokeratotic lesion may be normal, hyperplastic, or atrophic, with effacement of rete ridges. The dermis contains lymphocytes that may be perivascular, localized beneath the cornoid lamella, or lichenoid in the central portion of the lesion.

Differential Diagnosis

Porokeratosis can resemble other annular lesions (see Table 19.1) as well as actinic keratoses, but dermoscopy can assist in detection of the furrowed keratotic rim as can application of ink to the skin surface. Linear porokeratosis may be confused with other linear lesions such as inflammatory linear epidermal nevus, incontinentia pigmenti (stage II), and linear lichen planus (see Ch. 62), but none of these have a cornoid lamella. Although cornoid lamellae can be found in actinic keratoses, in the latter, partial epidermal cytologic atypia is invariably present. Verruca vulgaris often has mounds of parakeratosis that are sometimes identical to cornoid lamellae, but koilocytosis is usually present along with other histologic features of warts. Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) is a separate entity (see Ch. 111).

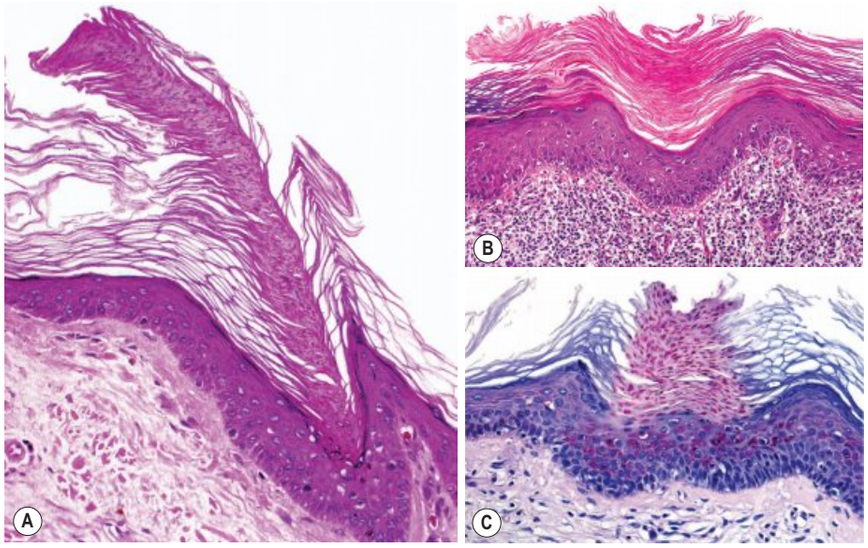

Fig. 109.10 Porokeratosis – histopathologic features. The cornoid lamella, a narrow column of parakeratotic cells, is the typical histologic feature of porokeratosis. It can vary in length and discernibility. **A** An obvious cornoid lamella. **B** More subtle cornoid lamella that becomes more obvious with a PAS stain (**C**).

Treatment

Cryotherapy[47], topical 5-fluorouracil (5-FU)[48], topical retinoids or calcipotriene (calcipotriol) in combination with 5-FU, topical imiquimod, topical tacrolimus[56], photodynamic or laser therapy, shave excision, curettage, and depending upon circumstances, linear excision[57] and dermabrasion[58] have all been used with variable degrees of success. Unless the abnormal clone of keratinocytes is destroyed, lesions tend to recur, and they are more difficult to eradicate than are actinic keratoses. Topical cholesterol 2%/lovastatin 2% cream or ointment is a newly described pathogenesis-directed therapy[59]. In widespread or refractory lesions, administration of oral acitretin may be beneficial, although the disease will recur following its discontinuation[60]. Photoprotection should be recommended, especially for patients with DSAP and linear porokeratosis.

FLEGEL DISEASE

Synonym: ■ Hyperkeratosis lenticularis perstans

Key features

- Very rare disorder; possible autosomal dominant inheritance pattern
- Multiple keratotic papules with a disc-like appearance in a symmetric distribution
- Predilection for the dorsal aspect of the feet and the distal extremities of adults

Introduction

In 1958, Flegel described this rare disorder in which asymptomatic, disc-shaped, keratotic papules appear most commonly on the distal extremities of adults. The name hyperkeratosis lenticularis perstans refers to the disc or lens shape (lenticularis) of the papules and their persistent nature (perstans).

Epidemiology

Flegel disease is possibly inherited in an autosomal dominant pattern, although it also develops sporadically. Lesions are usually not evident until mid to late adulthood, but they have been described in individuals as young as 13 years of age[61,62]. No racial predilection has been reported.

Pathogenesis

By electron microscopy, lamellar granules (Odland bodies) have been shown to be either absent or altered[63]. The lipid byproducts within lamellar granules influence stratum corneum desquamation, and, if they are absent or abnormal, hyperkeratosis may develop.

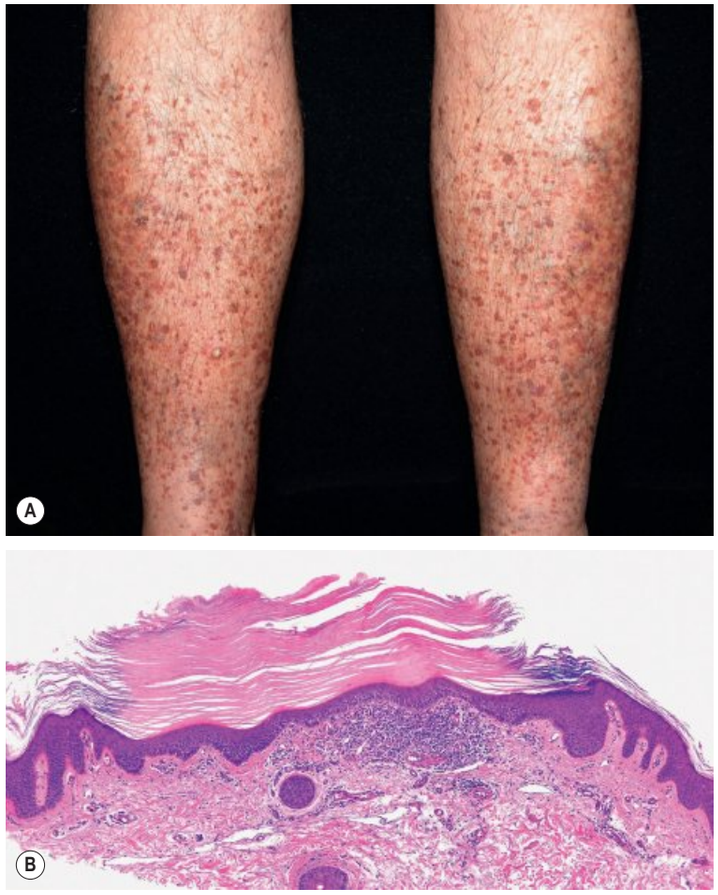

Fig. 109.11 Flegel disease. A Multiple symmetric hyperpigmented keratotic papules are present on the shins. **B** Thinned and flattened epidermis with overlying marked hyperkeratosis and an underlying patchy lichenoid infiltrate within the papillary dermis.

Clinical Features

In Flegel disease, numerous red–brown keratotic papules appear in a symmetric pattern (Fig. 109.11A); rarely, a unilateral distribution has been observed. Lesions most commonly develop on the dorsal aspect of the feet and distal legs and arms, including the palms and soles.

Involvement of the pinna and oral mucosa has also been described. Individual papules are small, typically measuring from 1 to 5 mm in diameter while lesions on the palms or soles often appear as fine pits. The papules have attached scale which may be more prominent at the peripheral margin. Removal of this scale can result in bleeding. Although lesions are usually asymptomatic, occasionally patients complain of pruritus. Flegel disease has reportedly been associated with endocrine disorders such as diabetes mellitus and hyperthyroidism[64].

Pathology

The papules consist of a discrete zone of ortho-hyperkeratosis, contrasting with the normal basket-weave cornified layer of the surrounding normal epidermis in most locations (Fig. 109.11B). There is often focal parakeratosis and hypogranulosis. The thin atrophic stratum spinosum is usually sharply indented or depressed at its lateral margins. A lichenoid infiltrate of lymphocytes is often present in the papillary dermis, along with dilated blood vessels. A slight degree of hyperchromatism or nuclear infoldings, resembling Sézary cells, has been described in some cases of Flegel disease[65].

Differential Diagnosis

Stucco keratoses present as whitish-gray papules on the dorsal feet and legs, but histologically there is papillomatosis not atrophy of the epidermis. Also, there is no inflammation unless lesions have become irritated. Perforating disorders have more prominent central keratotic plugs instead of disc-shaped hyperkeratosis, and there is a transepidermal elimination of connective tissue (see Ch. 96). With the exception of perforating granuloma annulare, perforating diseases rarely, if ever, occur on the palms or soles. DSAP typically occurs on the legs, but there is a keratotic rim due to the cornoid lamella. Although the dermal changes in Flegel disease may overlap with other lichenoid diseases (see Ch. 11), the clinical presentation allows differentiation. Without clinical correlation, cases with lymphocyte atypia could be misdiagnosed as cutaneous T cell lymphoma.

Treatment

Treatment of Flegel disease is problematic as lesions tend to resist all but destructive therapy. Application of topical 5-fluorouracil cream is moderately effective, although it may not be well tolerated because of irritation. Oral retinoids or PUVA in combination with oral retinoids or calcipotriene yielded unsuccessful or inconsistent results.

ACROKERATOSIS VERRUCIFORMIS

Key features

- Multiple small, skin-colored, warty papules primarily on the dorsal aspect of the hands and feet
- Rare autosomal dominant disorder of keratinization that is due to a mutation in *ATP2A2* and is allelic with Darier disease
- "Church spire" hyperkeratosis, papillomatosis, and acanthosis

Clinical Features and Pathogenesis

Acrokeratosis verruciformis of Hopf is a rare autosomal dominant disorder that has its onset during early childhood. Multiple small, skin-colored, warty papules appear on the dorsal aspect of the hands and feet and less commonly on the extensor surfaces of the forearms and legs (see Fig. 59.14). It can be seen in patients with Darier disease, and patients with acrokeratosis verruciformis may also have small, keratin-filled depressions on the palms and soles, as well as nail involvement. These observations are not surprising given that the two disorders are allelic, with both due to mutations in *ATP2A2* (see Fig. 59.1). However, to date, the same missense mutation – leading to a Pro602Leu substitution in ATP2A2 – has been detected in families with acrokeratosis verruciformis, but not in those with Darier disease[66].

Pathology

There is hyperkeratosis, papillomatosis, and acanthosis, often with hyperpigmentation. The hyperkeratosis may be quite prominent, and a "church spire" configuration, similar to that described for hyperkeratotic SK and stucco keratosis, is a frequent finding.

Differential Diagnosis

Histologic features similar to those of SK include hyperkeratosis, papillomatosis, and acanthosis as well as some degree of hyperpigmentation. Clinicopathologic correlation is necessary to distinguish between these disorders.

Treatment

Treatment is similar to that described for SKs and stucco keratoses.

CUTANEOUS HORN

Synonym: ■ Cornu cutaneum

Key features

- Clinical term for a white to yellow, hard, keratotic conical lesion; the base may be a papule, plaque, or nodule
- Most commonly in sun-exposed areas and arising from a hyperkeratotic actinic keratosis
- *In situ* or invasive SCC is present in up to 20% of lesions
- Other common causes include verruca and SK

Clinical Features

Cutaneous horn is a clinical term for a white to yellow, hard, keratotic conical lesion (Fig. 109.12A) whose base is a papule, plaque, or nodule that ranges from a few millimeters to several centimeters in diameter. The histologic correlate is an abnormal accumulation of keratin in an elongated, vertically oriented column overlying an abnormality of the underlying spinous layer. Cutaneous horns may arise anywhere on the body, but favor chronically sun-exposed sites. Men are affected more frequently than women. Individuals with a fair complexion and the elderly are particularly predisposed[67].

Pathology

A cutaneous horn consists of hyperkeratosis and parakeratosis associated with variable acanthosis (Fig. 109.12B), usually in association with the atypical keratinocytes of an actinic keratosis. Up to 20% of cutaneous horns arise in an *in situ* or invasive SCC[67]. Other lesions that may give rise to cutaneous horns include verrucae, SKs, and less commonly, other epithelial neoplasms, including those derived from follicular epithelium, especially tricholemmomas.

Treatment

Shave excision with local destruction is the most common treatment. The former must be done deeply enough to allow the pathologist to evaluate the dermis beneath the horn in order to determine if there is an invasive SCC. An elliptical excision can be performed, especially if the base is nodular or indurated. Treatment of AKs and SCCs is outlined in Chapter 108. Cryotherapy alone may fail because the base may not be adequately treated unless the horn is pared first.

CLEAR CELL ACANTHOMA

Synonym: ■ Degos acanthoma

Fig. 109.12 Cutaneous horn. A This cutaneous horn arose from an actinic keratosis. **B** Striking column of hyperkeratosis with hyperplasia of the underlying epidermis.

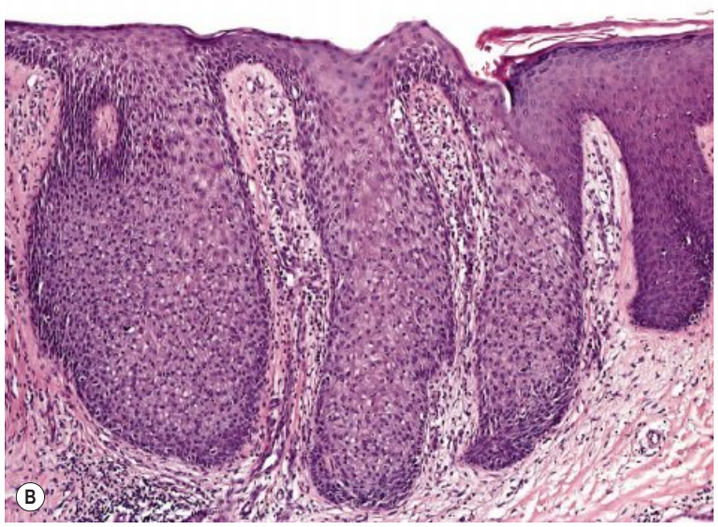

Fig. 109.13 Clear cell acanthoma. A Well-demarcated, dark red, shiny papule with a wafer-like collarette of scale. **B** Epidermal hyperplasia consisting of large pale keratinocytes. Note the sharp transition to normal skin. *B, Courtesy Lorenzo Cerroni, MD.*

Key features

- Uncommon, usually solitary, papule or plaque on the leg
- Lesions are blanchable, erythematous, and discrete; they may have attached "wafer-like" scale at their periphery
- Psoriasiform histology with well-demarcated zone containing clear to pale keratinocytes that stain positively with PAS

Introduction

First described by Degos in 1962, clear cell acanthoma is an uncommon red papule or plaque, usually on the leg. It may be suspected by astute clinicians, but usually a biopsy is required to establish the diagnosis.

Epidemiology

Clear cell acanthoma has no sex predilection and generally develops during middle-age, peaking in incidence by 50 to 60 years of age. It has not been described in children and neither an ethnic nor racial preference has been identified. Familial predisposition is rare, although there is one report of a French kinship with multiple affected family members having disseminated lesions[68].

Pathogenesis

The etiology of clear cell acanthoma is unknown. Although it was once thought to be induced by crude coal tar and UV light, there is no proof of a link with environmental trauma, drugs, toxic substances, or viruses. Given its abundant clear cytoplasm, it was originally thought to exhibit eccrine differentiation, but immunohistochemical and ultrastructural findings are more consistent with tricholemmal differentiation or features of the interfollicular epidermis[69,70]. It may be regarded as a variant of SK in which there are abundant glycogen-containing keratinocytes[71].

Others have proposed that clear cell acanthoma may actually be a localized, nonspecific, reactive inflammatory dermatosis. Several benign hyperproliferative dermatoses, including psoriasis, share a cytokeratin staining pattern similar to that seen in clear cell acanthoma. Furthermore, similarities in the histopathologic features between psoriasis and clear cell acanthoma suggest a common abnormality in the maturation of keratinocytes[72]. However, clear cell acanthomas do not develop following trauma and do not exhibit koebnerization, suggesting they are not simply a variant of localized psoriasis.

Clinical Features

Clear cell acanthoma presents as an asymptomatic, erythematous, rounded papule or plaque that appears "stuck on", similar to an SK (Fig. 109.13A)[73]. A "wafer-like" scale is often appreciated, especially at the periphery[74]. The majority of clear cell acanthomas are solitary and on the leg, but they may be found on the face, forearm, and trunk as well as in the inguinal region. Occasionally they are slightly eroded and a serous exudate may be present on the surface. There is often prominent vascularity as in a pyogenic granuloma, but the erythema can be blanched with application of pressure. By dermoscopy, the looped blood vessels within the dermal papillae create red dots in lines, referred to as a "string-of-pearls" (see Fig. 0.40C). Polarizing-specific white lines can also be seen.

Clear cell acanthomas usually develop slowly, often over a period of 2–10 years. They range in size from 0.3 to 2 cm in diameter, although rarely larger lesions have been reported, one of which had a diameter of 6 cm. Multiple lesions are also rare, with only about two dozen cases reported in the English literature, and these acanthomas may be either few in number or numerous and widespread[75]. Disseminated forms have been categorized as either discrete (<12 lesions) or eruptive (>30 lesions)[76]. One patient developed ~400 lesions[75] and another with eruptive acanthomas experienced spontaneous regression[77].

Clear cell acanthomas with cystic, pigmented, or polypoid features have been described, but these are uncommon. They have also been noted to develop in areas of pre-existing dermatoses, within epidermal nevi, after trauma, and following insect bites. SCC *in situ* has been rarely documented in association with clear cell acanthoma.

Pathology

Clear cell acanthoma displays a zone of sharply demarcated, thickened epidermis with regular psoriasiform hyperplasia composed of enlarged pale keratinocytes (Fig. 109.13B). The epidermis is eroded and neutrophils extend from the papillary dermis into the stratum spinosum, aggregating in the overlying thin crust. The granular layer is diminished and the rete ridges are elongated. PAS stains the pale cytoplasm of the keratinocytes red. The material that stains with PAS is diastase-sensitive, confirming it is glycogen. Electron microscopy also demonstrates abundant glycogen within the cytoplasm. The dermis contains dilated blood vessels and sparse perivascular lymphocytes.

Differential Diagnosis

Clear cell acanthoma may be clinically confused with a traumatized hemangioma, inflamed SK or verruca, BCC, SCC, pyogenic granuloma, poroma, amelanotic melanoma, or psoriasis; dermoscopy can assist in establishing the diagnosis. Histologically, other clear cell neoplasms may occasionally cause confusion, although the overall psoriasiform pattern of a clear cell acanthoma usually allows for distinction. Tricholemmomas usually appear on the face and consist of an inwardly growing lobule of pale keratinocytes lacking other features of psoriasis. The sebocytes of sebaceous neoplasms have a multiloculated cytoplasm containing lipid instead of glycogen, and they stain positively for epithelial membrane antigen or adipophilin.

Clear cell acanthoma-like lesions of the nipple/areola share histopathologic features with classic clear cell acanthomas but eosinophils are present and clinically the lesions resemble eczema of one or both nipples and areolae[78]. Resolution following application of corticosteroid cream has been reported.

Treatment

Shave excision or curettage combined with electrofulguration is a common and adequate form of treatment. Most lesions do not recur.

INVERTED FOLLICULAR KERATOSIS

Key features

- Asymptomatic, firm, white–tan to pink papule
- Typically solitary; most commonly on the face and neck of middle-aged and older adults
- Benign endophytic variant of irritated SK
- Histologically, squamous eddies and inflammation are common findings

History

Helwig was the first to delineate the features of inverted follicular keratosis (IFK) in 1955.

Epidemiology

IFK is seen most commonly in middle-aged to older White individuals. Men are affected twice as frequently as women.

Pathogenesis

In 1963, Duperrat and Mascaro proposed that the tumor was derived from the infundibulum of the hair follicle, although the cause is unclear.

Clinical Features

IFK is typically an asymptomatic, firm, white–tan to pink papule. It is found on the face in ~85% of cases, in particular on the cheek and upper lip. This is followed in frequency by other sites in the head and neck region. IFKs are usually <1 cm in diameter, but rarely they may reach up to 8 cm. They are typically stable and persistent lesions, but may regress.

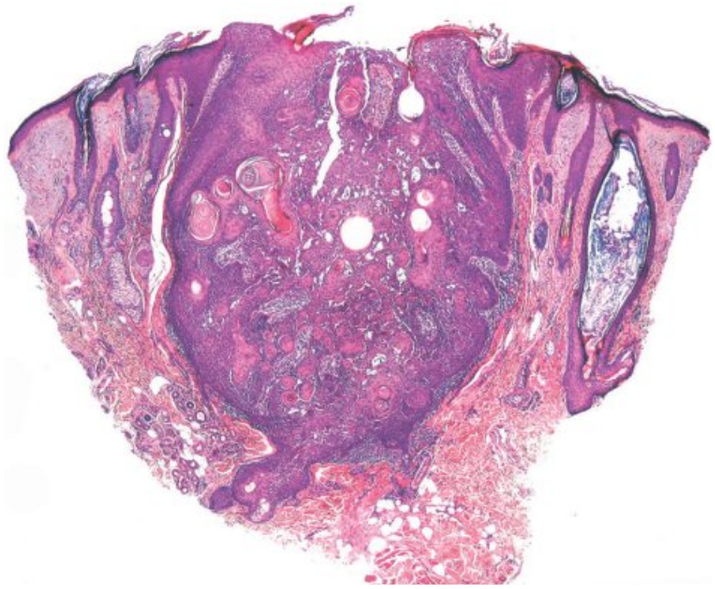

Fig. 109.14 Inverted follicular keratosis. An endophytic proliferation of keratinocytes with prominent squamous eddies is seen.

Pathology

IFK exhibits an endophytic, somewhat bulbous proliferation of eosinophilic keratinocytes with basaloid or squamous differentiation (Fig. 109.14). The keratinocyte proliferation seems to surround one or several follicular canals that open to the surface. There may be inflammation and squamous eddies are commonly seen.

Differential Diagnosis

The clinical differential diagnosis of IFK includes verruca, SK, tricholemmoma and other follicular adnexal tumors, BCC, and SCC. Tricholemmoma has a predominance of clear cells, often with a palisade of basal cells and a thickened basement membrane. Rare mitotic figures may be appreciated in an IFK, but overt cellular atypia as in SCC is absent.

WARTY DYSKERATOMA

Key features

- Uncommon, usually solitary papule or nodule with a central keratotic plug
- Favor the head and neck region
- Acantholytic dyskeratosis at the base and sides of a cup-like epidermal invagination

Introduction

Usually found on the head or neck, warty dyskeratoma is an uncommon solitary papule or nodule with a comedo-like plug and acantholysis with dyskeratosis histologically.

History

Helwig coined the term "isolated Darier's disease" in 1954. Three years later, the lesion was given the name warty dyskeratoma to indicate its solitary verrucous nature.

Epidemiology

Warty dyskeratomas are uncommon and demonstrate no genetic predisposition. They are more prevalent in men, usually appearing between the fifth and seventh decades of life. They occur more commonly in White individuals.

Pathogenesis

The pathogenesis of the acantholytic dyskeratosis in warty dyskeratomas has not been elucidated, although abnormal adhesion of keratinocytes has been demonstrated. Now that the gene responsible for Darier disease has been cloned, abnormalities in the function of its protein product could potentially be investigated in related entities like warty dyskeratoma.

Clinical Features

Warty dyskeratoma presents as a solitary (rarely multiple), verrucous, often crusted, skin-colored to red–brown papule or nodule with a central pore containing a keratotic plug. They grow slowly and are located most commonly on the scalp, face, or postauricular area[79]. Lesions have been found beneath the nail plate and in the mouth, especially on the hard palate and alveolar ridge. Warty dyskeratomas typically range in size from several millimeters to 2 cm in diameter. The scalp is the most common site for multiple lesions.

Most warty dyskeratomas are asymptomatic, but patients may occasionally complain of pruritus or burning. Bleeding and discharge of foul-smelling cornified material may occur. They have been reported to coexist with other skin lesions, including verruciform xanthoma, actinic keratosis, SCC, BCC, and adnexal carcinomas. To date, malignant degeneration in a warty dyskeratoma has not been reported.

Pathology

It is well circumscribed and usually involves at least one dilated folliculosebaceous unit. There is a central cup-like invagination lined with epithelium displaying acantholysis as well as individual cell necrosis, corps ronds and grains, most closely resembling Darier disease (Fig. 109.15). The central crater is filled with cornified debris. Villous-like papillae, sometimes composed of only a single layer of basal cells, often project upward from the invaginated hyperplastic base.

Differential Diagnosis

Warty dyskeratomas may resemble other epithelial neoplasms and proliferations such as a verruca, epidermal inclusion cyst, SK, hypertrophic actinic keratosis, or SCC. Histologically, other conditions with suprabasilar acantholytic dyskeratosis must be excluded, such as Darier disease, Grover disease, Hailey–Hailey disease, familial dyskeratotic comedones, acantholytic acanthoma, acantholytic actinic keratosis, and acantholytic SCC. Most of these entities are quite different clinically.

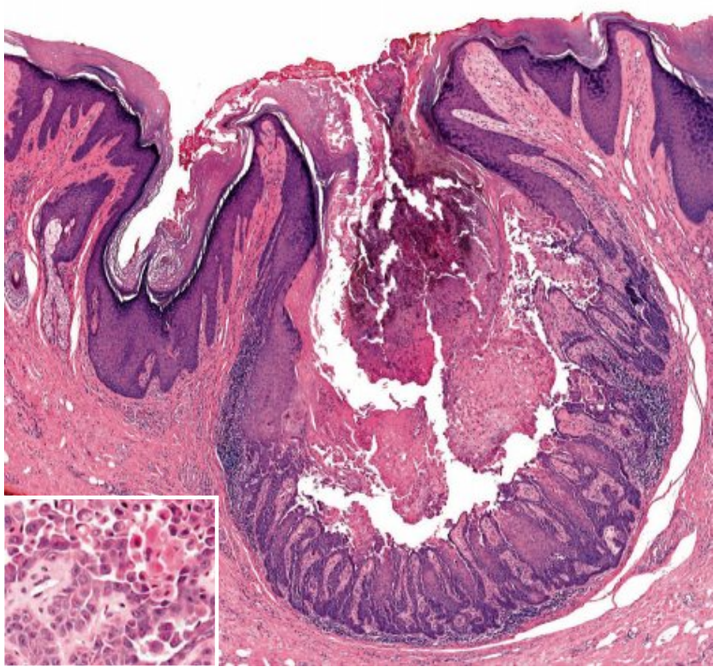

Fig. 109.15 Warty dyskeratoma. A cup-shaped invagination with a central keratotic plug. The lower portion of the wall has multiple villi. The epithelium demonstrates acantholysis and dyskeratosis (inset). *Courtesy Lorenzo Cerroni, MD.*

Treatment

Given its benign nature, treatment depends upon the clinical situation. Lesions are often biopsied to exclude the possibility of a malignancy.

ACANTHOLYTIC (DYSKERATOTIC) ACANTHOMA

Key features

- Often a solitary papule on the trunk of adults; may present as multiple lesions in the genital area
- Variant of a solitary keratosis with histopathologic findings of acantholysis, with or without dyskeratosis, in a hyperplastic epidermis with an overall flat architecture

An acantholytic (dyskeratotic) acanthoma is usually a solitary papule on the trunk of adults, and biopsy is often performed to exclude a BCC. Occasionally, there are multiple lesions in the genital area that can be confused with condylomata acuminata. Postzygotic mutations in *ATP2A2* or *ATP2C1* have been detected in these acanthomas; when germline, mutations in these genes lead to Darier disease and Hailey-Hailey disease, respectively. Histologically, there is acantholysis with or without dyskeratosis. Unlike warty dyskeratoma, there is neither a cup-shaped architecture nor an association with a hair follicle. In contrast to acantholytic actinic keratosis, there is no keratinocyte atypia.

EPIDERMOLYTIC ACANTHOMA

Key features

- Discrete keratotic papules in adults, with epidermolytic hyperkeratosis seen histologically
- Two varieties: an isolated form and a disseminated form

Epidemiology

Epidermolytic acanthomas may appear any time during adulthood. No particular race or sex is favored. To date, there are no reports of familial cases.

Pathogenesis

Because its clinical and histopathologic features may resemble those of verrucae, a viral origin was originally suspected, but HPV DNA has not been detected in the lesions[80]. Exogenous factors such as UVR, other viruses[81], and trauma[82] have all been suggested as causes of acquired epidermolytic hyperkeratosis. Recently, hotspot mutations in the Arg156 position of *KRT10*, known to cause epidermolytic ichthyosis, were detected in several epidermolytic acanthomas[83].

Clinical Features

The isolated form was initially described in 1970, while the disseminated form was described in 1973. Both forms present as pigmented keratotic papules that may resemble verrucae or SKs (Fig. 109.16A). Individual lesions are generally 1 cm or less in diameter. When isolated, they may appear on any body site. Discrete lesions, when in a cluster, are still categorized as the isolated variant. The disseminated form has a predilection for the trunk, especially the back; it has also been reported in the genital region where it can mimic condylomata acuminata[84]. Lesions are usually asymptomatic, but they may be pruritic.

Pathology

The histologic pattern of epidermolytic hyperkeratosis (Fig. 109.16B) consists of four components:

- clear spaces of varying size surrounding nuclei in the stratum spinosum and stratum granulosum

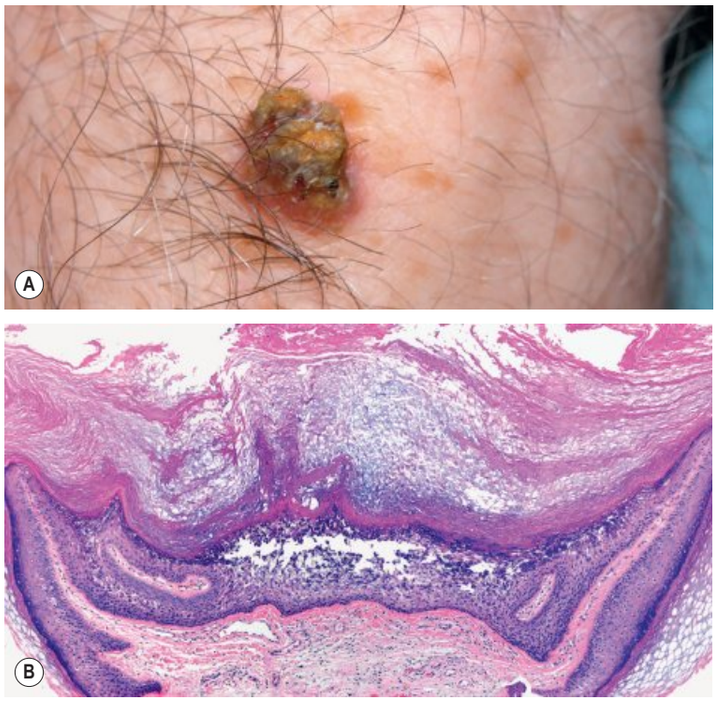

Fig. 109.16 Solitary epidermolytic acanthoma. A Keratotic papulonodule on the chest. **B** Marked hyperkeratosis and epidermolytic hyperkeratosis within the underlying epidermis.

- indistinct cellular boundaries consisting of reticulated, lightly staining material
- a markedly thickened granular zone containing an increased number of small and large, irregularly shaped, basophilic keratohyaline-like bodies
- compact hyperkeratosis.

The basal layer is normal. Epidermolytic acanthomas generally demonstrate more papillomatosis than is typically seen in other conditions with the histologic pattern of epidermolytic hyperkeratosis. There is often a slight superficial perivascular lymphocytic infiltrate in the dermis.

Differential Diagnosis

Clinically epidermolytic acanthomas resemble verrucae and SKs. Because they do not have a characteristic clinical appearance, the diagnosis is not usually made until after a biopsy is performed. Epidermolytic hyperkeratosis is a histologic finding common to several conditions, including epidermolytic ichthyosis (bullous congenital ichthyosiform erythroderma) as well as particular forms of epidermal nevi and palmoplantar keratoderma. It is seen incidentally in normal skin and in lesions such as follicular cysts, SKs, atypical nevi, actinic keratoses, and cutaneous horns.

Treatment

Treatment is not required as the lesions are benign. Destruction, shave excision, or linear excision is successful, although recurrence may follow superficial removal.

LARGE CELL ACANTHOMA

Key features

- Skin-colored, hyperpigmented, or hypopigmented papule or plaque
- Located on sun-exposed skin of older individuals
- Likely a variant of solar lentigo or SK

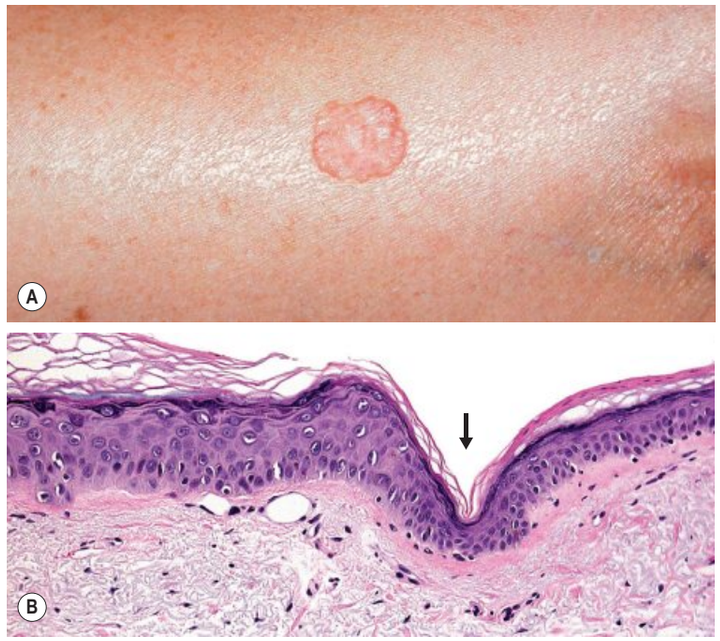

Fig. 109.17 Large cell acanthoma. A Well-demarcated, thin, pink–brown plaque. **B** Slight epidermal hyperplasia with uniformly enlarged keratinocytes; the latter have abundant cytoplasm and enlarged nuclei (left side). Arrow points to the border of the acanthoma. *Courtesy Lorenzo Cerroni, MD.*

Introduction

Large cell acanthoma is a benign keratinocytic lesion that is asymptomatic and often ignored[85]. Some dermatopathologists make the diagnosis frequently, while others do not believe that this is a specific entity.

History

Pinkus first described the lesion in 1967 during a lecture on benign epidermal neoplasms in which he coined the term[86].

Epidemiology

Large cell acanthomas most commonly arise in sun-damaged skin of middle-aged to elderly individuals, with ages at diagnosis ranging from 30 to 90 years and a mean age in the mid-60s. Women have a slightly higher incidence and most affected patients have skin phototypes I or II.

Pathogenesis

The pathogenesis of large cell acanthoma is unknown. Genetic studies have demonstrated low-grade aneuploidy, a finding typically associated with malignancy. Nevertheless, large cell acanthoma has generally been considered to be clinically benign. Some investigators have proposed that it is a variant of Bowen disease[87]. Still others classify it as a variant of solar lentigo in a stage evolving into a reticulated SK or lichen planus-like keratosis[88].

Clinical Features

It typically presents as a solitary, sharply demarcated, skin-colored, hyperpigmented, or hypopigmented papule or plaque (Fig. 109.17A). These acanthomas are most commonly located on the face or neck, including the eyelid, but can be extrafacial[87]. Rarely, multiple lesions are scattered on the extremities.

As it is asymptomatic and often ignored, the time to diagnosis is quite variable, ranging from 3 months to 15 years[85].

Pathology

Histologically, large cell acanthomas are well demarcated, with uniformly large keratinocytes with abundant cytoplasm and enlarged nuclei (Fig. 109.17B). Mild cytologic atypia may be present. There is

variable hyperkeratosis, papillomatosis, epidermal rete ridge elongation, and basal layer hyperpigmentation. Some lesions have minimal hyperkeratosis with flattened rete ridges and only small dermal papillae[87].

Differential Diagnosis

The differential diagnosis includes solar lentigo (histologically), SK, actinic keratosis, Bowen disease, and melanoma.

Treatment

Shave or simple excision as well as destruction are options.

EPIDERMAL NEVUS (SEE CH. 62)

Synonyms: ■ Keratinocytic nevus – nevus verrucosus, verrucous nevus, nevus unius lateris (multiple, unilateral), ichthyosis hystrix (extensive, bilateral)

Key features

- Onset typically within the first year of life
- Most commonly, hyperpigmented papillomatous papules and plaques appear in a linear array along the lines of Blaschko

Introduction

Within dermatology, the term nevus (plural, nevi) has three definitions: (1) a congenital lesion (birthmark) or lesion arising early in life; (2) a benign tumor of melanocytes; or (3) a hamartoma. The latter is a benign malformation with an excess or deficiency of structural elements normally found in the affected area, e.g. epidermis, connective tissue, adnexa. In most hamartomas, one element is predominant.

Epidemiology

The incidence of epidermal nevus is estimated to be 1 in 1000 infants. The vast majority of epidermal nevi develop sporadically, although familial cases have been reported. However, a familial pattern is more characteristic of the papular epidermal nevus with a "skyline" basal cell layer that presents with scattered rather than linear lesions[89,90]. There is no sex predilection.

Pathogenesis – see Ch. 62 and Table 62.6

Clinical Features

In a review of 131 patients with epidermal nevi, the age of onset ranged from birth to 14 years, with 80% evident within the first year of life[91], although the lesions may occasionally become apparent during adulthood[92]. Epidermal nevi most commonly present as a single linear lesion, but sometimes multiple unilateral or bilateral linear plaques are seen (see Ch. 62). Most lesions consist of well-circumscribed, hyperpigmented, papillomatous, keratotic, or velvety papules and plaques that are usually asymptomatic (Fig. 109.18A,B). The earliest lesions may be macular and confused with linear and whorled nevoid hypermelanosis. Rarely, epidermal nevi are hypopigmented. Once developed, the nevi may thicken and become more verrucous, especially over joints and in flexural areas such as the neck. Epidermal nevi follow the lines of Blaschko and may have an abrupt midline demarcation (Fig. 109.18C).

Epidermal nevus syndrome, a concept proposed by Solomon and Esterly in 1968, is diagnosed when epidermal nevi occur in combination with other developmental anomalies (see Ch. 62). These abnormalities most commonly involve the central nervous or musculoskeletal systems. Excluding cutaneous manifestations, a study of 119 patients with epidermal nevi found that 33% had abnormalities in one organ system, 6% in two, 5% in three, and 5% in five or more. Several overgrowth syndromes can present with epidermal nevi, including Proteus, CLOVES, and PTEN hamartoma-tumor syndromes (see Chs. 62 & 104).

Fig. 109.18 Epidermal nevi. A Obvious papillomatosis in a single thin linear plaque; this is the most common clinical presentation. **B** Larger sized verrucous hyperpigmented plaque. **C** Multiple verrucous hyperpigmented plaques that clearly follow the lines of Blaschko. Note the midline demarcation. **D** The most common histologic pattern is epidermal hyperplasia with papillomatosis and hyperkeratosis.
A, Courtesy Julie V. Schaffer, MD; B, Courtesy Kalman Watsky, MD; C, Courtesy Kathryn Schwarzenberger, MD.

Pathology

At least ten histologic patterns have been observed in epidermal nevi, and more than one may be present in the same lesion[93,94]. Virtually all are characterized by epidermal hyperplasia, hyperkeratosis, acanthosis, papillomatosis, and variable parakeratosis (Fig. 109.18D). Other findings such as epidermolytic hyperkeratosis and focal acantholytic dyskeratosis may be prominent features when there is mosaicism for mutations in *KRT1* or *KRT10* and *ATP2A2*, respectively. Inflammatory linear verrucous epidermal nevus (ILVEN) may have clinical and histologic features very similar to psoriasis (see the following section).

Neoplasms such as BCC, SCC, and keratoacanthoma may rarely develop in association with epidermal nevi. This malignant change occurs less commonly in epidermal nevi than in the closely related nevus sebaceus. Malignancy, when it does occur, typically develops after puberty[95]. Examples of BCC arising in epidermal and sebaceous nevi may actually be trichoblastomas, representing a manifestation of the hamartomatous nature of the neoplasm[96,97].

Differential Diagnosis

Nevus sebaceus, usually found on the head instead of the trunk or extremities, can be considered a subtype of epidermal nevus but with additional hamartomatous components of sebaceous and apocrine glands accompanying the papillomatous epidermis (see Ch. 111). Organoid nevi combine features of both epidermal nevus and nevus sebaceus, with variation often depending upon anatomic site (e.g. head and neck versus trunk). RAVEN (rounded and velvety epidermal nevus), also referred to as nevoid acanthosis nigricans, is a rare entity due to postzygotic mosaicism for FGFR3 or FGFR2 mutations in which lesions have a distinctive rounded outline. Lichen striatus is an acquired lesion, has less papillomatosis and acanthosis as well as more dyskeratosis and spongiosis, and does not persist indefinitely. There are other nevoid conditions that are distributed along the lines of Blaschko and therefore may simulate epidermal nevi, depending on the type and degree of epidermal proliferation. Examples include PEODDN, linear lichen planus, and X-linked dominant chondrodysplasia punctata. Small lesions must be distinguished from SKs, psoriasis, condylomata acuminata, and verrucae vulgares, especially if there is Koebner phenomena. The histologic differential diagnosis also includes hyperkeratosis of the nipple.

Treatment

Infants and children with epidermal nevi, particularly multiple or extensive lesions, require a thorough evaluation for systemic abnormalities in conjunction with a pediatrician (see Ch. 62). Full-thickness surgical excision is curative, but recurrence is common when only the epidermis is removed (e.g. by shave excision or curettage) because the hamartomatous process also involves at least the papillary dermis. However, surgical excision can be complicated by hypertrophic scars or keloid formation. Topical therapies such as corticosteroids, retinoic acid, tars, anthralin, 5-fluorouracil, and podophyllin have all been used, but they are of limited benefit. Chronic therapy with oral retinoids has been reported to be effective at decreasing the thickness of systematized epidermal nevi, although it does not result in resolution. Laser ablation may also be undertaken, but to be effective, it must induce scarring and fibrosis of at least the papillary dermis. Therefore, this treatment is often not cosmetically acceptable to patients and test sites are recommended. Most recently, topical sirolimus was reported to lead to improvement but results are modest.

INFLAMMATORY LINEAR VERRUCOUS EPIDERMAL NEVUS

Key features

- Linear, psoriasiform papules or plaques, usually on one extremity
- 75% of these nevi appear before the age of 5 years
- Usually persists for years despite attempts at treatment
- Histologically, psoriasiform hyperplasia with alternating parakeratosis and orthokeratosis

Introduction

Inflammatory linear verrucous epidermal nevus (ILVEN) is a relatively rare, linear, psoriasiform plaque that usually presents during childhood.

History

Altman and Mehregan are credited with the first description of ILVEN in 1971.

Pathogenesis

At least one patient with ILVEN was shown to have a postzygotic mutation in *GJA1*, which encodes connexin 43[98]. Germline mutations in this gene lead to erythrokeratodermia variabilis. In 2 of 15 patients with ILVEN, mosaicism for mutations in CARD14 was detected[99]. Germline mutations in this gene lead to CAPE (CARD14-associated papulosquamous eruption) which has features of both psoriasis and pityriasis rubra pilaris. Two additional patients, who subsequently developed psoriasis, were found to have a germline heterozygous CARD14 mutation plus a postzygotic hotspot mutation in KRT10 while the second had a postzygotic hotspot mutation in HRAS[99a].

Clinical Features

ILVEN has a psoriasiform appearance and may be associated with significant pruritus. Scaly, erythematous papules coalesce to form a linear plaque, usually on a limb (Fig. 109.19A), although occasionally the trunk may be involved. Lesions are almost always unilateral. In ~75% of patients, onset is before the age of 5 years and is often within the first six months of life[100]. Isolated instances of adult onset have been reported[101] and, rarely, there may be a familial predisposition[102]. In earlier studies, ILVEN was observed more commonly in females[102]. Most lesions tend to be persistent. A possible association of ILVEN with arthritis has been described[103].

Pathology

The psoriasiform histology of ILVEN correlates with its psoriasiform clinical appearance. Epidermal rete ridges are elongated, and broad zones of parakeratosis without an underlying granular layer alternate abruptly with depressed regions of orthokeratosis and hypergranulosis (Fig. 109.19B). There is often exocytosis of lymphocytes and neutrophils into the spongiotic papillomatous epidermis and occasionally Munro microabscesses are seen.

Differential Diagnosis

At least three other variants of epidermal nevi with inflammation have been described, including lichenoid epidermal nevus, psoriasis superimposed on an epidermal nevus, and epidermal nevi in X-linked dominant *c*ongenital *h*emidysplasia with *i*chthyosiform nevus and *l*imb *d*efects (CHILD) syndrome. Lichenoid epidermal nevus is typically a verrucous plaque with a lichenoid lymphocytic dermal infiltrate. It is debatable whether lichenoid epidermal nevus truly represents linear lichen planus. The age of onset, distribution, resistance to therapy, and lack of family history are all features of ILVEN. Patients with linear (nevoid) psoriasis or *CARD14* mutations can have or develop classic plaques of psoriasis elsewhere.

It has been suggested that ILVEN may be a forme fruste of CHILD syndrome because rarely, ipsilateral skeletal anomalies are seen in patients with ILVEN. Also, although large areas of ichthyosiform erythema characteristically involve one-half of the body with an affinity for skin folds (ptychotropism), patients with CHILD syndrome can have linear keratotic plaques along the lines of Blaschko that have an appearance similar to ILVEN. CHILD syndrome differs histologically from ILVEN in that it has features of verruciform xanthoma, especially when biopsy specimens are from body folds[104], as well as vacuoles within the cells of the lower stratum corneum ultrastructurally. However, electron microscopy is rarely performed nowadays, and in a series of 5 patients initially diagnosed as having ILVEN, 2 were found to have germline *NSDHL* mutations, i.e. CHILD syndrome[99a]. This might explain the previous reports of female predominance.

Fig. 109.19 Inflammatory linear verrucous epidermal nevus (ILVEN). A Linear erythematous scaly plaque with a psoriasiform appearance on the leg. **B** Epidermal hyperplasia and broad zones of parakeratosis alternating with ortho-hyperkeratosis.

Treatment

As with other epidermal nevi, ILVEN is difficult to treat. Treatments that are successful in psoriasis are only partially effective for ILVEN[103]. Surgical excision is effective but results in scarring. The pulsed dye laser has been used successfully in some cases. Its mechanism of action is thought to involve destruction of small blood vessels in the papillary dermis that supply the overlying epidermis[105]. Combination therapy with topical tretinoin and 5-fluorouracil creams has also been employed with beneficial results, but long-term success can only be achieved with maintenance therapy[106]. Topical synthetic derivatives of vitamin D_3, such as calcipotriene, may also be partially effective[107,108]. There are anecdotal reports of improvement with crisaborole ointment, TNF inhibitors, and other lasers (e.g. excimer, fractionated CO_2, ablative CO_2). In a patient with mosaicism for a *CARD14* mutation, ustekinumab led to significant improvement[99].

Arthritis in association with ILVEN, although rare, can lead to significant morbidity. Early recognition is critical. Treatment is the same as for psoriatic arthritis[103].

NEVUS COMEDONICUS

Synonyms: ■ Comedo nevus ■ Comedonal nevus

Key features

- Benign hamartoma, usually arising before the age of 10 years
- Multiple grouped comedones in a linear array, most commonly on the face, trunk, or neck
- Histologically, epidermal invaginations containing keratin plugs and underdeveloped hair shafts

Introduction

Nevus comedonicus is a rare hamartoma of the folliculosebaceous unit resulting in numerous dilated, keratin-filled comedones.

History

Kofmann, in 1895, was the first to delineate the features of nevus comedonicus. In 1914, White attempted to change the name to "nevus follicularis keratosis" as he thought the comedo-like lesions did not represent true comedones, as sebaceous glands were either rudimentary or absent in most cases.

Epidemiology

Approximately half of the cases of nevus comedonicus are evident at birth, with others appearing during childhood, usually before the age of 10 years. Onset in adulthood, albeit rare, is often associated with irritation or trauma. There is no racial or sex predilection. Although most cases arise sporadically, familial clustering has been reported[109].

Pathogenesis

Nevus comedonicus is thought to represent growth dysregulation affecting the mesodermal portion of the pilosebaceous unit. The epithelial-lined invaginations, incapable of forming mature terminal hairs and sebaceous glands, accumulate a soft cornified ostial product resulting in a comedo-like plug.

In 2016, mosaic activating mutations in the NIMA-related kinase 9 gene (*NEK9*) were identified in the affected skin of patients with classic nevus comedonicus (see Table 62.6)[110]. Two decades earlier, *FGFR2* mutations had been detected in lesional but not adjacent normal skin of an acneiform nevus referred to as the Munro acne nevus, also providing evidence for genetic mosaicism[111]. In contrast to a classic nevus comedonicus, the Munro acne nevus tends to have pre-existing linear hypopigmentation, peripubertal onset of the acne lesions, and histopathologic findings of an atrophic comedonal wall with prominent associated sebaceous lobules. Of note, patients with Apert syndrome, sporadic or inherited in an autosomal dominant manner and due to mutations in *FGFR2*, may have comedones and severe cystic acne (see Table 62.6).

Clinical Features

There is usually a single circumscribed area (Fig. 109.20A) or linear streak composed of clusters of dilated follicular ostia that contain firm, darkly pigmented, cornified material. Occasionally, multiple linear plaques may be seen with midline demarcation. The overall size is variable and can range from a few centimeters in diameter to extensive lesions affecting half of the body. The site most commonly affected is the face, followed by the trunk, neck, and upper extremity. These nevi may also arise in areas that are devoid of hair follicles such as the palms, soles, and glans penis. When present on the elbows and knees, lesions can be verrucous in appearance. Inflammatory papules and cysts are often admixed with the comedones. Hormonal influences of puberty often worsen the condition. Development of SCC or keratoacanthoma within the nevus is exceedingly rare.

Pathology

Nevus comedonicus consists of grouped undeveloped hair follicles, presenting as dilated invaginations filled with cornified debris devoid of

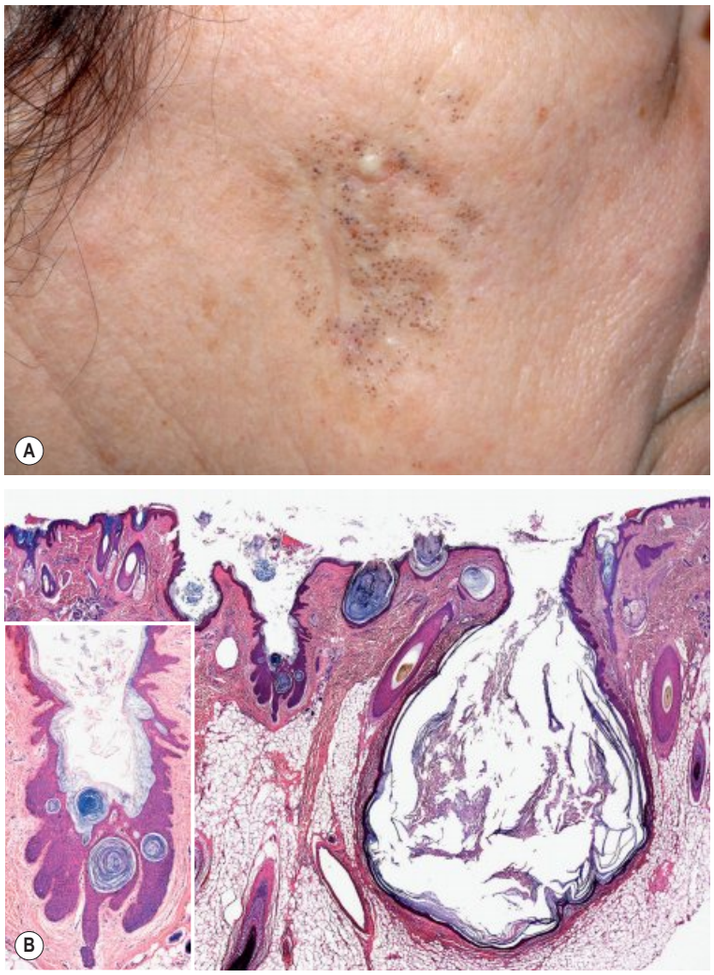

Fig. 109.20 Nevus comedonicus. A Numerous comedones as well as two cysts within a circumscribed area on the right cheek. **B** Dilated infundibula filled with orthokeratotic keratin. Occasionally, the wall of the comedo will display epithelial hyperplasia (inset). *A, Courtesy Lorenzo Cerroni, MD.*

hair shafts (Fig. 109.20B). Epidermolytic hyperkeratosis may sometimes be present in the follicular epithelium.

Differential Diagnosis

Many skin conditions present with comedones, and these must be differentiated from nevus comedonicus. Distinctive features of *acneiform nevus* are discussed under Pathogenesis. *Infantile acne* typically presents on the face between the ages of 3 and 24 months. The comedones, pustules, and papules in this disorder are not linear, and they are self-limited. Chloracne is associated with exposure to toxins that lead to the formation of comedones, generally located on both sides of the face and commonly behind the ears.

Familial dyskeratotic comedones is a rare autosomal dominant disorder in which comedones arise during childhood or adolescence and are widely scattered on the trunk and extremities without a linear configuration. Histologically, acantholytic dyskeratosis in the comedo wall is seen.

The *dilated pore nevus* resembles nevus comedonicus clinically but differs histologically by containing dilated follicular cysts. *Porokeratotic eccrine ostial and dermal duct nevi* also may be confused with nevus comedonicus, especially when the latter involves the palms or soles. These lesions are comprised of dilated eccrine ducts containing parakeratotic debris. The keratinocyte cytoplasm is typically vacuolated and the granular layer is absent.

Treatment

As with other epidermal nevi, treatment of nevus comedonicus is problematic. Localized lesions can be surgically excised, although it is often difficult to excise larger lesions. Manual comedo extraction, dermabrasion, and the use of keratolytic agents (e.g. salicylic acid, tretinoin, ammonium lactate[112]) may be helpful, but they are not curative. Isotretinoin is not usually recommended owing to the long-term treatment required, but it may be beneficial in preventing cyst formation. Antibiotics may be necessary to treat secondary infections.

Fig. 109.21 Nevoid hyperkeratosis of the nipple and areola. Diffuse seborrheic keratosis-like thickening and hyperpigmentation of the areola. *Courtesy Lorenzo Cerroni, MD.*

ACANTHOSIS NIGRICANS

Acanthosis nigricans is discussed in detail in Chapter 53. Histologically, it may be misinterpreted as an SK, epidermal nevus, or confluent and reticulated papillomatosis, unless appropriate clinical correlation is provided.

NEVOID HYPERKERATOSIS OF THE NIPPLE AND AREOLA

This unusual condition of unknown etiology affects women more frequently than men. It is usually bilateral, but can be unilateral (Fig. 109.21). Progressive diffuse thickening of the skin of both areolas, which appears hyperpigmented, often begins after puberty. Histologically, there is irregular basaloid acanthosis with elongation and anastomosis of rete ridges, orthokeratotic hyperkeratosis, and hyperpigmentation of the basal layer, mimicking a seborrheic keratosis. Nevoid hyperkeratosis may become more evident during pregnancy and it may also occur in men receiving hormonal therapy. Although no uniformly effective treatment exists, there are case reports of improvement with topical retinoids, cryotherapy, or radiofrequency ablation.

CONFLUENT AND RETICULATED PAPILLOMATOSIS

Synonym: ■ Confluent and reticulated papillomatosis of Gougerot and Carteaud

Key features

- Onset typically during puberty
- Multiple brown, verrucous, thin papules or plaques in a confluent and/or reticulated pattern, most commonly on the central chest and upper abdomen
- Oral minocycline is effective in ~50% of patients

History

Confluent and reticulated papillomatosis of Gougerot and Carteaud (CARP) was first described in 1927.

Epidemiology

The typical onset of CARP is during puberty[113]. Depending upon the series, young women are affected more frequently than young men and vice versa; racial predisposition also varies. Occurrence of CARP is mostly sporadic, although familial cases have been reported.

Pathogenesis

Some think CARP may be caused by an endocrine imbalance, especially insulin resistance, because of its association with conditions such as obesity, menstrual irregularities, and diabetes mellitus as well as pituitary and thyroid disorders. In addition, there is a clinical resemblance to acanthosis nigricans. However, many patients are otherwise healthy. Another hypothesis is that CARP is a disorder of keratinization. This theory arose because a number of patients have been successfully treated with topical and systemic retinoids[114]. An abnormal host response to *Malassezia furfur* has also been suggested, as this organism is sometimes prevalent within areas of involvement in its yeast (and less often hyphal) forms and because treatment with topical selenium sulfide has sometimes been successful[115]. The majority of cases, however, demonstrate no evidence of *M. furfur* proliferation.

Clinical Features

The initial lesions of CARP are 1–2 mm papules, first appearing in the intermammary area or less frequently the interscapular or epigastric regions. Lesions rapidly enlarge to 4–5 mm and become brown, keratotic, verrucous papules, patches, or thin plaques. The papules coalesce and become confluent centrally and reticulated peripherally (Fig. 109.22). There can be involvement of the neck, upper trunk, and other flexural areas. Oral lesions have not been reported. The eruption is asymptomatic or, rarely, mildly pruritic.

Fig. 109.22 Confluent and reticulated papillomatosis (CARP). Multiple thin hyperpigmented papules of the upper back that are confluent centrally and have a reticulated pattern peripherally. *Courtesy Ronald Savin, MD.*

Pathology

There is hyperkeratosis, acanthosis, and papillomatosis. Sparse superficial perivascular infiltrates of lymphocytes are also seen. A characteristic feature is the club-shaped, bulbous epidermal rete ridges that protrude slightly into the papillary dermis with pigment at their bases ("dirty feet").

Differential Diagnosis

CARP can clinically resemble acanthosis nigricans, tinea versicolor, and Darier disease. Acanthosis nigricans has thicker, more velvety plaques involving intertriginous areas; it also lacks the reticulated pattern of CARP. Acanthosis nigricans is most commonly associated with insulin resistance and improves with weight loss; some authors refer to this form of the disease as pseudoacanthosis nigricans. Tinea versicolor may be related to CARP because of its brownish scale and association with *M. furfur*, but it is neither reticulated nor papillomatous. Occasionally, retention hyperkeratosis, also referred to as terra firma-forme, may be confused with CARP, but the former can be easily removed with an alcohol swab.

Histologically, CARP may be misinterpreted as an SK, epidermal nevus, acanthosis nigricans, or other papillomatous epithelial proliferation, unless appropriate clinical information is provided.

Treatment

Treatment of CARP is often frustrating because it may not respond to therapeutic interventions or recurs after cessation of therapy. No single agent has been uniformly successful at providing long-term resolution. Temporary improvement has been reported with the use of various oral antibiotics (e.g. tetracyclines) and oral retinoids (e.g. isotretinoin, acitretin)[114,116] as well as topical salicylic acid, hydroquinone, tacrolimus[117], sirolimus, antifungals (e.g. selenium sulfide)[115], vitamin D_3 analogues, and 5-fluorouracil. Oral minocycline has been reported to be effective in ~50% of patients, with some reporting no recurrences, while others experienced disease-free intervals for up to 18 months[118]. Oral retinoids are no more successful than oral antibiotics at maintaining a disease-free state, and given their potential for causing hypertriglyceridemia and teratogenicity, they are generally considered to be second- or third-line agents.

TERRA FIRMA-FORME DERMATOSIS

Terra firma-forme dermatosis is a benign skin disease characterized by brown papules and plaques, often in a corrugated pattern. Histopathologic examination is not necessary as lesions can be removed via rubbing with 70% isopropyl alcohol pads.

CLEAR CELL PAPULOSIS

Key features

- Extremely rare condition, mainly described in Asian children
- Hypopigmented macules and papules arranged along the milk lines
- Histologically, large clear cells are scattered along the basal layer of the epidermis and within the malpighian layer

Epidemiology

Clear cell papulosis (CCP) is an extremely rare condition that preferentially affects Chinese and other Asian children[119].

Pathogenesis

The pathogenesis of CCP is unknown. The arrangement of lesions along the so-called milk lines and the appearance of clear cells in lesional skin suggest a histogenetic relationship with Toker cells. Some authors have considered this process as the benign counterpart of extramammary Paget disease[120].

Clinical Features

CCP is characterized by multiple, asymptomatic, white macules or papules that are 2–10 mm in diameter and favor the anterior chest, abdomen, and lumbar region (see Fig. 66.31). The lesions are often arranged along the milk lines. In rare cases, the face may be also involved.

Pathology

Lesions of CCP are mildly acanthotic and have a slightly disorganized arrangement of epidermal keratinocytes. Numerous clear cells are scattered primarily along the basal layer of the epidermis, but also within its upper layers. These clear cells are larger than adjacent keratinocytes and have cytoplasmic vacuolization due to abundant mucin within their cytoplasm; the latter may be highlighted by PAS, mucicarmine, Alcian blue, or colloidal iron stains. Immunohistochemically, clear cells of CCP express carcinoembryonic antigen, cytokeratins ($CK7^+$, $AE1/AE3^+$, $CAM5.2^+$), epithelial membrane antigen (EMA), and gross cystic disease fluid protein-15 (GCDFP-15), but are negative for expression of CD1a, S100 protein, and HMB45[119].

Differential Diagnosis

Clinically, CCP should be differentiated from hypopigmented lesions of tinea versicolor, pityriasis lichenoides chronica, guttate lichen sclerosus, achromic verrucae plana, and confetti lesions of tuberous sclerosis (see Table 66.5). Histologically, CCP needs to be distinguished from extramammary Paget disease and pagetoid dyskeratosis. Neoplastic cells of extramammary Paget disease are more atypical and pleomorphic than those of CCP. Pagetoid dyskeratosis is a disorder of keratinization characterized by clear and pale eosinophilic keratinocytes scattered within the epidermis; it is an incidental histopathologic finding without any clinical significance.

Treatment

CCP is a benign process and no treatment is necessary. Most patients experience at least a partial regression[121].

Acknowledgment

The authors would like to acknowledge Raymond Barnhill, MD, for his contribution to the solar lentigo section of this chapter.

110 Cysts

Mary Seabury Stone

Chapter Contents

Cysts with a Lining of Stratified Squamous Epithelium *1935*
Cysts Lined with Non-Stratified Squamous Epithelium *1942*
Cysts without an Epithelial Lining *1945*

Key features

- Cutaneous cysts present as circumscribed dermal or subcutaneous papules or nodules
- Cysts may be lined by either stratified squamous epithelium or non-stratified squamous epithelium; cystic structures without an epithelial lining are better classified as pseudocysts
- Histologic features of the cyst lining and the anatomic location determine the type of cyst
- Treatment of cysts, when indicated, is primarily surgical

INTRODUCTION

Cysts are common cutaneous lesions. Patients with cysts may present to clinicians because of medical or cosmetic concerns, or due to discomfort from mechanical irritation or inflammation of the cyst. The definitive diagnosis of a cyst requires histologic examination, as many other dermal and subcutaneous tumors can form cyst-like nodules. Cysts can be classified by anatomic location (as they may occur in virtually any organ of the body), by embryologic derivation, or by histologic features. As the histologic features determine the definitive diagnosis, that scheme will be used in this chapter, which is limited to cutaneous cysts.

True cysts have an epithelial lining that may be composed of stratified squamous epithelium or other forms of epithelia while "pseudocysts" have no epithelial lining at all. Cutaneous cysts can be divided into three main categories based on the presence or absence and composition of the cyst wall (Table 110.1; Fig. 110.1). Many non-dermatologists refer to epidermoid and pilar cysts as "sebaceous cysts", possibly believing erroneously that the hydrated white keratinized contents of many epithelial-lined cysts is of sebaceous origin. The only true sebaceous cyst is the steatocystoma. The term "sebaceous cyst" is best avoided.

CYSTS WITH A LINING OF STRATIFIED SQUAMOUS EPITHELIUM

Epidermoid Cyst

Synonyms: ■ Epidermal inclusion cyst ■ Infundibular cyst ■ Epidermal cyst

Epidermoid cysts are the most common cutaneous cysts. They can occur anywhere on the skin, but are most common on the face and upper trunk. These lesions are well-demarcated, skin-colored to yellowish dermal nodules, and they may have a clinically visible punctum representing the follicle from which the cyst is derived (Fig. 110.2). Epidermoid cysts range from a few millimeters to several centimeters in diameter. Tiny superficial epidermoid cysts are known as milia (see below). These cysts derive from the follicular infundibulum, hence

THE THREE MAIN CATEGORIES OF CUTANEOUS CYST

Category	Type	Most common location
Stratified squamous epithelium	Epidermoid (infundibular) cyst	Face; upper trunk
	Milium	Face
	Tricholemmal cyst	Scalp
	Proliferating tricholemmal cyst	Scalp (favors elderly women)
	Proliferating epidermoid (infundibular) cyst	Pelvic (anogenital)
	Vellus hair cyst	Trunk (chest)
	Steatocystoma	Trunk; axillae; groin
	Cutaneous keratocyst	No characteristic location
	Pigmented follicular cyst	Face (men)
	Dermoid cyst	Face along embryonic fusion planes, e.g. lateral eyebrow (infants)
	Verrucous cyst	Face; upper trunk; plantar surface (HPV-infected epidermoid cysts)
	Ear pit cyst Pilonidal cyst	Preauricular Upper gluteal cleft; sacrococcygeal area
Non-stratified squamous epithelium	Hidrocystoma	
	• Eccrine	Face (lower eyelid, cheek)
	• Apocrine	Face (eyelid margin)
	Bronchogenic cyst	Suprasternal notch (infants)
	Thyroglossal duct cyst	Midline anterior neck
	Branchial cleft cyst	Lateral neck; preauricular; mandibular (teenagers, young adults)
	Cutaneous ciliated cyst	Lower extremities (young women)
	Ciliated cyst of the vulva	Labia majora
	Median raphe cyst	Ventral glans and penile shaft
	Omphalomesenteric duct cyst	Umbilical; periumbilical
Absence of epithelium (pseudocysts)	Mucocele	Oral mucosa (lower labial)
	Digital mucous cyst (pseudocyst)	Dorsal aspect of distal phalanx of finger (occasionally toe)
	Ganglion	Wrist
	Pseudocyst of the auricle	Scaphoid fossa of the ear (adult men)
	Cutaneous metaplastic synovial cyst (pseudocyst)	Sites of surgical trauma

Table 110.1 The three main categories of cutaneous cyst.

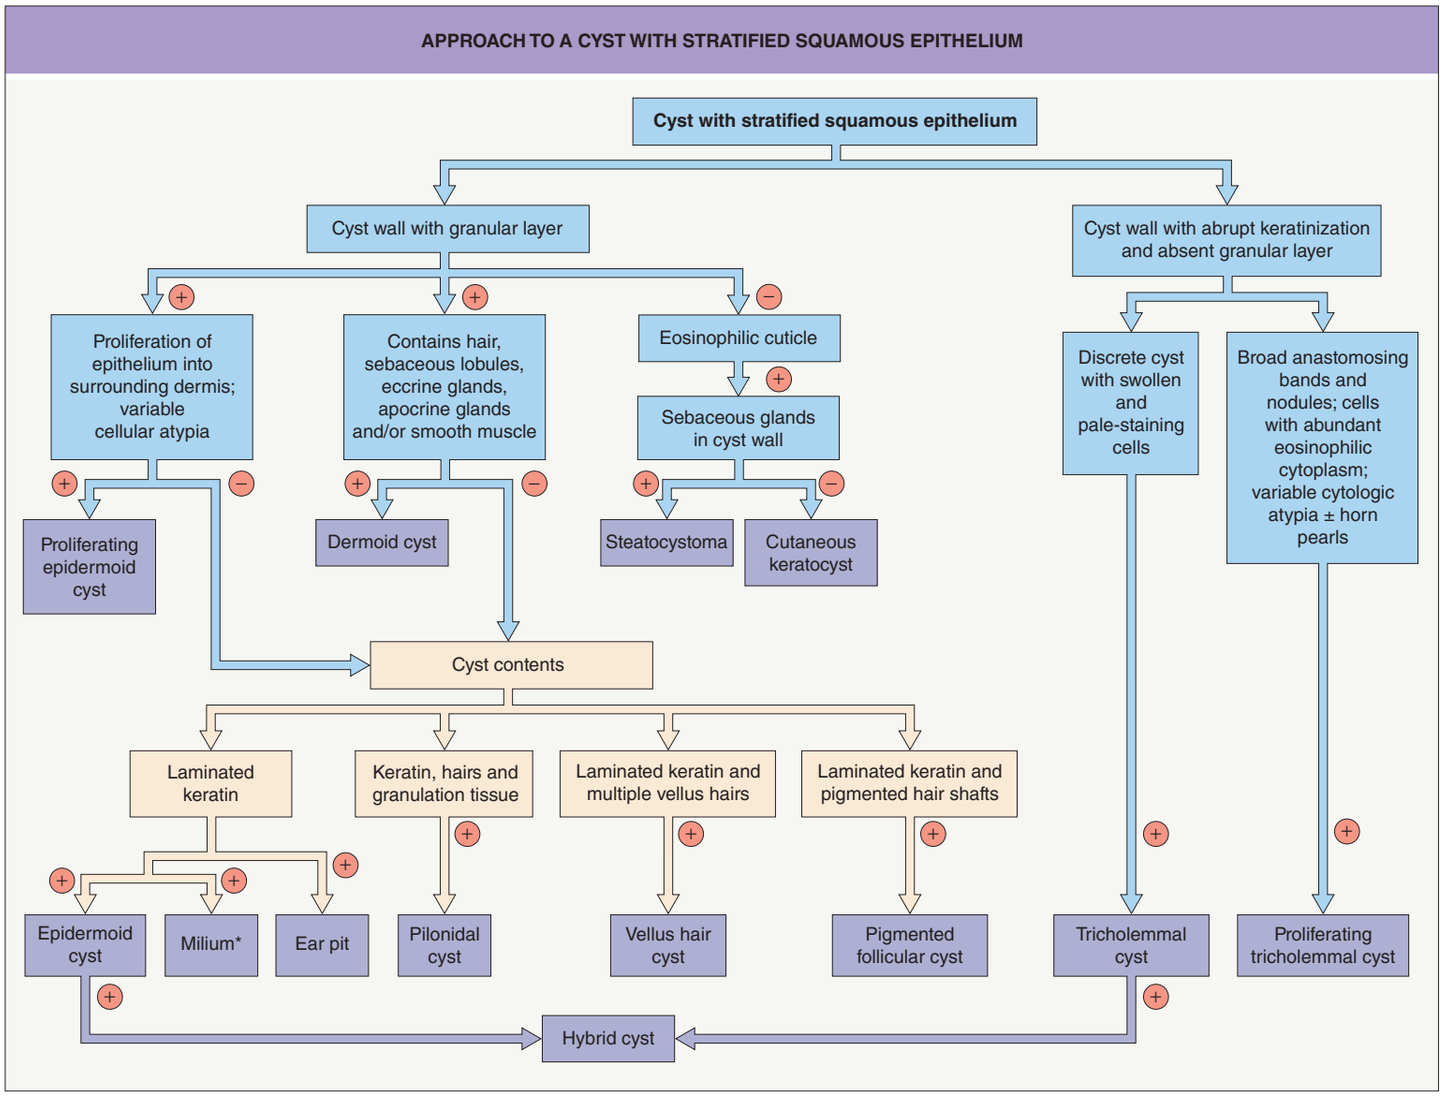

Fig. 110.1 Approach to a cyst with stratified squamous epithelium. *Diameter 1–2 mm.

Fig. 110.2 Epidermoid cyst. Typical clinical appearance of an epidermoid cyst with a yellowish hue. Two pores are present in this example.

the synonym infundibular cysts (Fig. 110.3). They may be primary, or they may arise from disrupted follicular structures or traumatically implanted epithelium (hence the synonym epidermal "inclusion" cyst).

As follicular disruption is important in the pathogenesis of many epidermoid cysts, multiple epidermoid cysts may occur in individuals with a history of significant acne vulgaris. Multiple cysts may also occur in the setting of Gardner syndrome (familial adenomatous polyposis) and in basal cell nevus syndrome[1,2]. Patients receiving cyclosporine to prevent solid organ transplant rejection or BRAF inhibitors, both non-selective (e.g. sorafenib) and selective (e.g. vemurafenib), can develop multiple epidermoid cysts or milia, often on the face[3]. Multiple scrotal cysts (Fig. 110.4) may lead to scrotal calcinosis via dystrophic calcification[4].

Non-inflamed epidermoid cysts are usually asymptomatic, but with pressure, cyst contents may be expressed that may have an objectionable odor. Rupture of the cyst wall can result in an intensely painful inflammatory reaction, and this is a common reason for presentation to a physician (Fig. 110.5). Development of a basal cell carcinoma (BCC) or squamous cell carcinoma (SCC) within an epidermoid cyst is a very rare event.

Pathology

Histologic examination shows a cystic cavity filled with laminated keratin lined by a stratified squamous epithelium that includes a granular layer (Fig. 110.6). A surrounding inflammatory response with both acute suppurative and chronic granulomatous inflammation as well as variable fibrosis may be seen as evidence of prior rupture. In individuals with Gardner syndrome, some cysts have, as a characteristic feature, columns of pilomatricoma-like shadow cells projecting into the cyst cavity[1].

Treatment

If treatment is desired, excision is curative. Removal may be accomplished by simple excision, or incision and expression of the cyst contents and wall through the surgical defect. If the entire cyst wall is not removed, the cyst may recur. Excision is best performed when the cyst is non-inflamed ("cold"). Inflamed epidermoid cysts may require incision and drainage, and occasionally, antibiotic therapy. Intralesional injections of triamcinolone may speed resolution of the inflammation.

Dilated Pore of Winer

Dilated pore of Winer presents as a single dilated comedo, primarily occurring on the face of adults.

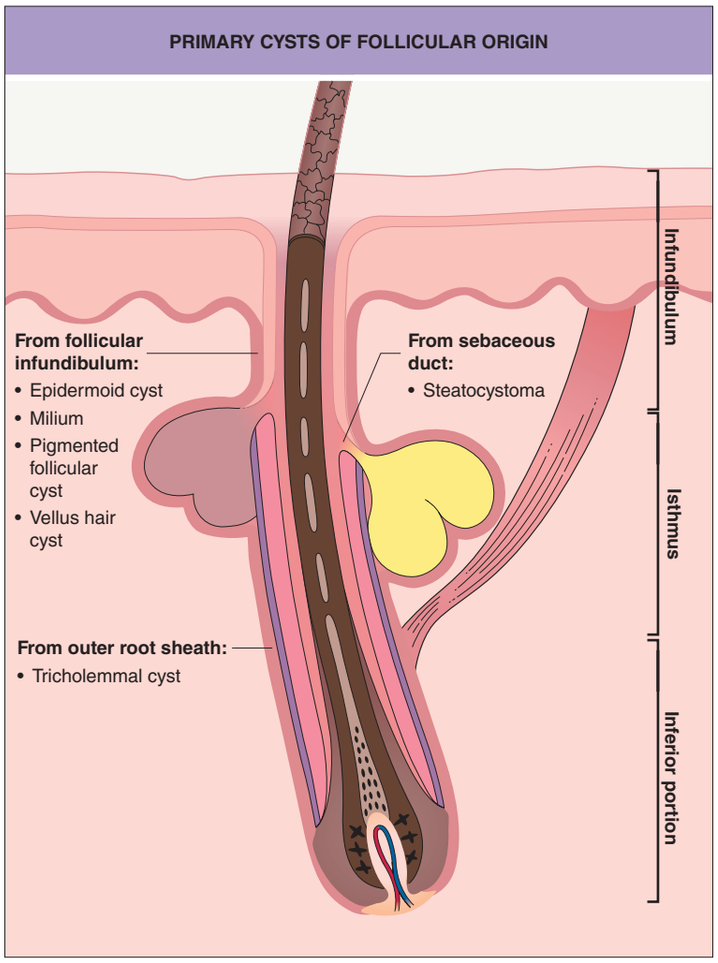

Fig. 110.3 Primary cysts of follicular origin. Anatomic origin of cysts derived from the pilosebaceous unit. *Adapted from Requena L, Sanchez Yus E. Follicular hybrid cysts. An expanded spectrum. Am J Dermatopathol 1991;13:228–33.*

Fig. 110.4 Multiple epidermoid cysts of the scrotum. *Courtesy Lorenzo Cerroni, MD.*

Pathology

A dilated follicular opening, filled with keratinous debris and lined by squamous epithelium with a granular layer, is seen. The lining is acanthotic with finger-like projections pushing into the surrounding dermis.

Fig. 110.5 Inflamed epidermoid cyst. Such painful inflammatory reactions to cyst rupture are a frequent cause for presentation to a physician.

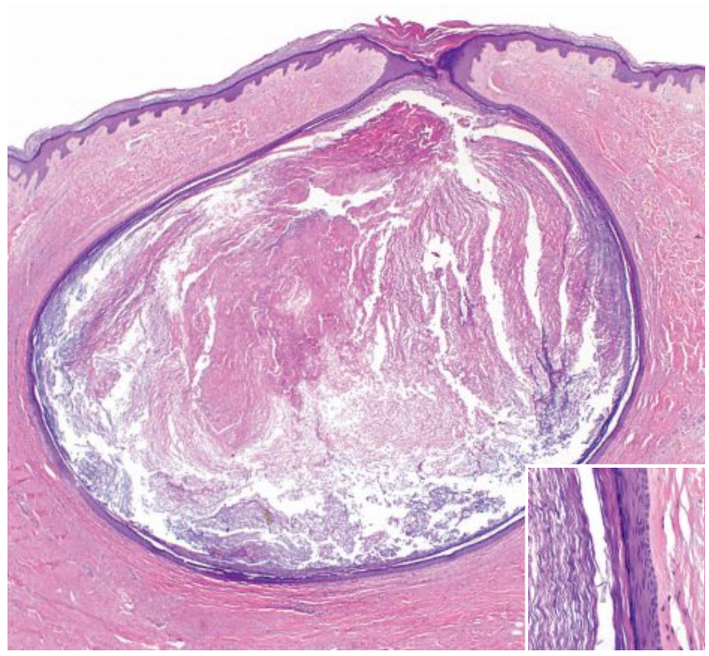

Fig. 110.6 Histopathology of an epidermoid cyst. Laminated keratin within an epithelial-lined cyst in the dermis. The cyst wall shows infundibular keratinization including a granular layer (inset).

Differential diagnosis

Although there is usually a more papular component, an obvious pore can be seen in a pilar sheath acanthoma, trichoepithelioma, and large-pore BCC.

Treatment

If treatment is desired, excision is curative.

Milium

Milia are small superficial cysts and are quite common, occurring in individuals of all ages. They may originate from the infundibulum of hair follicles or from eccrine ducts, and in the mouth from minor salivary gland ducts or from epithelium entrapped within embryologic fusion planes. Milia present as 1–2 mm, firm, white to yellow, subepidermal papules (Fig. 110.7).

Between 40% and 50% of infants will have milia, most commonly on the face. Most milia in newborns will resolve spontaneously during the first 4 weeks of life. Milia in newborns may also occur on the hard palate (Epstein pearls) or on the alveolar ridges (Bohn nodules). These also resolve spontaneously. Milia may occur as a primary phenomenon, especially on the face, or as secondary phenomena following blistering processes (e.g. porphyria cutanea tarda, epidermolysis bullosa acquisita) or superficial ulceration from trauma or cosmetic procedures. Milia

Fig. 110.7 Milia. Tiny (1–2 mm), white, dome-shaped papules on the face.

may also occur in areas of topical corticosteroid-induced atrophy[5], in follicular mycosis fungoides, and as a side effect of BRAF inhibitors (see above).

Milia en plaque is characterized by multiple milia within an erythematous edematous plaque, and the most common location is the postauricular area. Numerous milia in an infant may be a sign of oral–facial–digital syndrome type 1, an X-linked disorder that is lethal in males, in which milia are associated with facial and skull malformations, cleft lip and palate, a lobulated tongue, developmental delay, and polycystic kidneys; the associated alopecia follows the lines of Blaschko on the scalp. Milia are also seen in the setting of a number of other syndromes, including the BCC-associated syndromes basal cell nevus syndrome, Rombo syndrome, and Bazex–Dupré–Christol syndrome, as well as atrichia with papular lesions, Loeys–Dietz syndrome, basaloid follicular hamartoma syndrome, Basan syndrome, hypohidrotic ectodermal dysplasia, and a subset of Brooke–Spiegler syndrome (Rasmussen syndrome).

Pathology

Histologic features are those of a small epidermoid cyst with a stratified squamous epithelial lining that includes a granular layer. The cyst contents consist of laminated keratin.

Treatment

Milia may be removed by incising the epidermis over the milium with a needle, scalpel, or lancet and expressing the milium. The latter can be aided by the use of a comedo extractor. Laser ablation and electrodesiccation are also reported options. For multiple facial milia, topical retinoid therapy may be helpful in reducing the number of new milia and aiding in the ease of removal.

Tricholemmal Cyst

Synonyms: ■ Trichilemmal cyst ■ Pilar cyst ■ Wen ■ Isthmus–catagen cyst

Tricholemmal cysts are clinically indistinguishable from epidermoid cysts, but they are fourfold to fivefold less common. Ninety percent of tricholemmal cysts are located on the scalp (Fig. 110.8A). They may be solitary, but frequently are multiple, and they may be inherited as an autosomal dominant trait due to a germline variant of *PLCD1*, which encodes phospholipase C delta 1a. Interestingly, the somatic mutations in the cysts were found to be on the same chromosome as the germline variant[5a].

Pathology

The walls of tricholemmal cysts show keratinization analogous to that of the outer root sheath of the hair follicle at the isthmus *and* the sac surrounding catagen and telogen hairs (hence the synonym isthmus–catagen cyst). Tricholemmal cysts are lined by stratified squamous epithelial cells that become swollen and pale close to the cystic cavity and show abrupt keratinization without an intervening granular layer (Fig. 110.9). The cyst contents consist of homogeneous, eosinophilic, compact material that often contains foci of calcification. A suppurative and/or granulomatous response may surround the cyst if prior wall rupture has occurred. Occasionally, if the outermost epithelial portion of the cyst wall separates from the remainder of the cyst, the histologic features can resemble a hidrocystoma.

Fig. 110.8 Tricholemmal cyst versus proliferating tricholemmal cyst. A A tricholemmal cyst is a well circumscribed, mobile, mid dermal nodule with a smooth surface. **B** A proliferating tricholemmal cyst presenting as a large skin-colored to light-pink nodule on the scalp. Both types of cyst favor the scalp. *B, Courtesy Luis Requena, MD.*

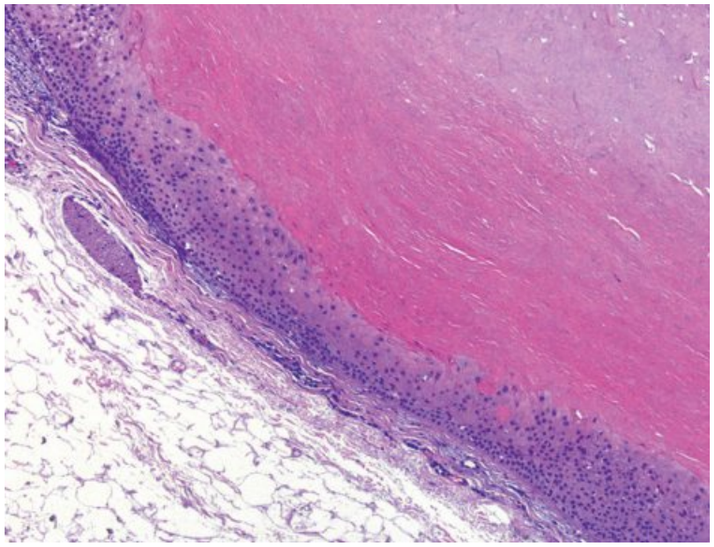

Fig. 110.9 Histopathology of a tricholemmal cyst. The cyst wall shows swollen keratinocytes with abrupt keratinization without formation of a granular layer. Compact, eosinophilic keratin fills the cyst. *Courtesy Luis Requena, MD.*

Differential diagnosis

In addition to epidermoid cysts, ruptured pilar cysts of the scalp can overlap with alopecic and aseptic nodules of the scalp.

Treatment

Treatment is by excision. Tricholemmal cysts typically "deliver" themselves through an incision without rupture more easily than do epidermoid cysts, and, therefore, the distinction between a tricholemmal cyst and an epidermoid cyst can often be correctly made at the time of excision.

Verrucous Cyst

HPV infection of the lining of an epidermoid, or rarely a tricholemmal, cyst can lead to a verrucous cyst. Verrucous cysts occur most commonly

on the face, upper trunk, and plantar surface and may harbor a number of different HPV types, including those associated with epidermodysplasia verruciformis. In verrucous plantar cysts, HPV 60 has been the most commonly reported HPV type. Verrucous cysts have also been observed in association with proliferating epidermoid cysts and have been hypothesized to be a possible precursor[6].

Pathology

In addition to features of an epidermoid or tricholemmal cyst, these cysts have a lining with verrucous features including acanthosis, papillomatosis, focal hypergranulosis with coarse keratohyalin granules, and occasionally koilocytes.

Treatment

Excision is curative.

Proliferating Tricholemmal Cyst

Synonyms: ■ Proliferating trichilemmal cyst ■ Proliferating tricholemmal tumor ■ Proliferating pilar tumor ■ Proliferating follicular cystic neoplasm

A proliferating tricholemmal cyst classically occurs as a slow-growing nodule on the scalp (see Fig. 110.8B). Ninety percent occur on the scalp and ~85% occur in women, with a median age of 63 years[7]. Proliferating tricholemmal cysts vary in size from a few millimeters to up to 25 cm in diameter. These tumors generally behave in a benign fashion, although on occasion, aggressive local growth with recurrences and metastases has been observed[7,8]. Extremely rarely, spindle cell carcinomas may develop within a proliferating tricholemmal cyst[9]. Distant metastases are rare.

Pathology

The histologic features of a proliferating tricholemmal cyst consist of broad anastomosing bands and nodules of squamous epithelium (Fig. 110.10). The epithelium consists of a proliferation of cells with abundant eosinophilic cytoplasm; the cells undergo abrupt keratinization and form dense homogeneous keratin that fills cystic spaces. There may be areas of epidermoid keratinization with formation of horn pearls as well as areas of foreign body giant cell reaction. One-quarter of cases show an epidermal connection[5]. Cytologic atypia can vary markedly. Most tumors show well-circumscribed, pushing borders surrounded by compressed collagen. The lack of infiltrative growth into the surrounding stroma and abrupt tricholemmal keratinization helps to differentiate these cysts from SCC. Areas of marked atypia and infiltrative borders are features associated with a potential for aggressive behavior[10].

Treatment

Treatment is by complete surgical excision.

Proliferating Epidermoid Cyst

Synonyms: ■ Proliferating epithelial cyst ■ Proliferating infundibular cyst

Proliferating epidermoid cysts were first described in detail in 1995[7]. Unlike proliferating tricholemmal cysts, proliferating epidermoid cysts are observed more commonly in men and only 20% occur on the scalp. The most common location is the anogenital region. They range in size from 0.5 to 15 cm. In a series of 30 patients for whom follow-up was available, 20% of the cysts recurred, some multiple times, and one patient died of intractable local disease[7]. None of the patients developed metastatic disease.

Pathology

Histologically, almost half of cases show an epidermal connection, usually with a narrow opening or connection to a dilated follicle. Most tumors show areas of typical epidermoid cyst wall. In addition, areas of squamous proliferation with squamous eddy formation are seen, with formation of a granular layer and production of loose laminated keratin. The epithelium tends to proliferate peripherally into the surrounding dermis, rather than centrally as seen in proliferating tricholemmal cysts. Degrees of cellularity and atypia are variable, and frank carcinomatous change with an infiltrative growth pattern may be seen.

Fig. 110.10 Histopathology of a proliferating tricholemmal cyst. Well-circumscribed nodules of squamous epithelium in the dermis. Within their central portions, abrupt keratinization is seen. *Courtesy Lorenzo Cerroni, MD.*

Treatment

Treatment is by complete surgical excision.

Vellus Hair Cysts

Vellus hair cysts, described by Esterly, Fretzin, and Pinkus in 1977[11], most commonly present as numerous, small, dome-shaped papules, ranging from skin-colored to darkly pigmented (Fig. 110.11). These cysts are most commonly located on the trunk, and they may be inherited in an autosomal dominant pattern. Multiple lesions are known as "eruptive" vellus hair cysts; occasionally, solitary cysts are seen. Although some lesions may resolve via transepidermal elimination of cyst products, most lesions persist indefinitely. Vellus hair cysts may become inflamed, but in general, they are asymptomatic except for cosmetic concerns.

Eruptive vellus hair cysts may be seen in conjunction with steatocystoma multiplex, and both types of cysts have been reported in the setting of pachyonychia congenita, most commonly PC-17 (see Ch. 58).

Pathology

Histologically, one sees a small cystic structure lined by stratified squamous epithelium with epidermoid (infundibular) keratinization. The cysts contain loose laminated keratin and numerous vellus hair shafts (Fig. 110.12). A follicle may be found entering the lower portion of the cyst.

Visualization of the vellus hair shafts via microscopic examination of expressed cyst contents allows for a bedside diagnosis.

Treatment

Vellus hair cysts may be treated by a number of modalities, including incision and drainage, needle evacuation, puncture followed by forceps-assisted extraction, topical retinoic or lactic acid, and laser ablation.

Fig. 110.11 Eruptive vellus hair cysts. Admixture of pigmented, skin-colored, and yellow–white papules of varying sizes on the trunk.

Fig. 110.12 Histopathology of a vellus hair cyst. A cyst shows epidermoid keratinization of its wall as well as laminated keratin and several vellus hair shafts within its cavity (inset).

Steatocystoma

Steatocystomas occur as single (steatocystoma simplex) or multiple (steatocystoma multiplex) lesions. They tend to be a few millimeters to a centimeter in diameter and appear as cysts within the dermis that drain oily fluid if punctured (Fig. 110.13A–C). Steatocystomas are most numerous on the chest and in the axillae and groin. There are unusual facial and acral variants as well as a rare congenital linear form. Steatocystomas persist indefinitely, and they are usually asymptomatic except for cosmetic concerns.

Steatocystoma multiplex can be inherited as an autosomal dominant condition, and is due to mutations in *KRT17*. It may occur in association with eruptive vellus hair cysts and pachyonychia congenita, most frequently PC-17 (see Fig. 58.11)[12,13].

Pathology

Biopsy specimens show a dermal cyst lined by a thin stratified squamous epithelium without a granular layer. The epithelium is surmounted by a thin, irregular, corrugated eosinophilic cuticle (Fig. 110.13D). Small sebaceous lobules are found in or immediately adjacent to the cyst wall. Cysts with the typical corrugated eosinophilic lining of steatocystoma, but with no adjacent sebaceous glands, have been termed cutaneous keratocyst or sebaceous duct cyst. The latter can be seen in patients with the basal cell nevus syndrome.

Treatment

Lesions can be excised or incised with removal of the cyst wall.

Follicular Hybrid Cyst

Synonym: ■ Hybrid cyst

Follicular hybrid cysts are not distinctive clinically, but rather represent a histologic variant of cysts with a stratified squamous lining in which there is transition in the cyst wall between epidermoid keratinization and tricholemmal or matrical keratinization[14,15]. They were originally described by Brownstein[15]. Hybrid cysts with features of both an epidermoid cyst and a keratocyst have been associated with the basal cell nevus syndrome[16].

Pigmented Follicular Cyst

Pigmented follicular cysts, described by Mehregan and Medenica[17], are usually solitary and occur primarily on the face of men. They are often deeply pigmented and may be confused clinically with a melanocytic nevus.

Histologically, these cysts have a pore-like connection to the epidermis, are lined by stratified squamous epithelium that includes a granular layer, and contain pigmented hair shafts. The clinical presentation, epidermal connection, and pigmented terminal hair shafts rather than vellus hair shafts distinguish the pigmented follicular cyst from vellus hair cysts.

Dermoid Cyst

Cutaneous dermoid cysts typically present in an infant along an embryonic fusion plane as a discrete, subcutaneous nodule (see Ch. 64). Dermoid cysts are usually 1–4 cm in diameter. The most common location is around the eyes.

Pathology

Histologically, dermoid cysts are lined by stratified squamous epithelium that includes a granular layer. They contain other normal cutaneous structures such as hair, sebaceous lobules, eccrine glands, apocrine glands, and/or smooth muscle.

Treatment

Treatment is by excision. However, as the differential diagnosis includes neural heterotopias, imaging studies may be appropriate prior to excision in order to exclude a connection to the CNS (see Ch. 64).

Ear Pit

Synonyms: ■ Preauricular cyst ■ Congenital auricular fistula ■ Preauricular fistula

Ear pits are congenital defects, and they may present as a true cystic nodule or an invagination in the preauricular area (Fig. 110.14). During development, the ear is formed by the fusion of six tubercles: three each from the first two branchial arches. Preauricular cysts reflect defective embryologic fusion with epithelial entrapment. These defects are relatively common, occurring in ~0.5%–1% of the normal population, and they may be transmitted in an autosomal dominant fashion[18]. Ear pits are usually unilateral and right-sided. Infection with tenderness and purulent drainage may prompt presentation to a physician.

Although ear pits are usually not associated with other significant abnormalities, they can occur in conjunction with deafness or with deafness plus renal anomalies in the branchio-otic syndrome and branchio-oto-renal syndrome, respectively. Ear pits are also seen in a number of other congenital syndromes, including Treacher Collins, Goldenhar, and cat-eye syndromes.

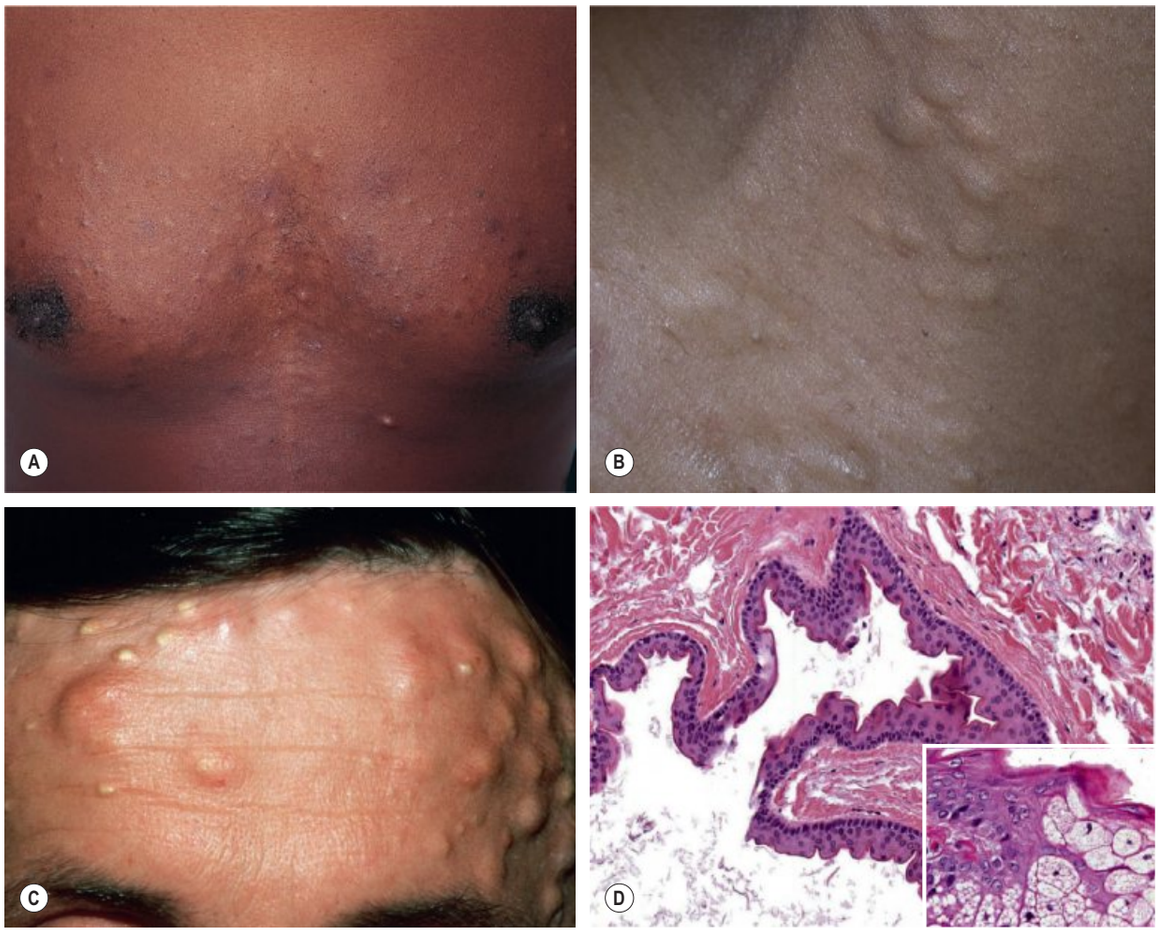

Fig. 110.13 Steatocystoma multiplex. A, B Numerous cystic papules on the trunk and multiple cystic nodules on the neck. **C** Larger cystic nodules on the forehead. **D** Histopathology of steatocystoma. The cyst wall is characterized by an undulated, thin stratified epithelium lacking a stratum granulosum and lined by an eosinophilic cuticle. A search may be required to identify small sebaceous lobules in or immediately adjacent to the cyst wall (inset). *C, Courtesy Luis Requena, MD; D, Courtesy Lorenzo Cerroni, MD.*

Fig. 110.14 Ear pit. *Courtesy Julie V. Schaffer, MD.*

Pathology

Histologically, preauricular pits or cysts are lined by stratified squamous epithelium with a granular layer.

Treatment

If removal is desired, simple excision is curative. Although most ear pits are incidental findings, in a newborn, a physical examination to exclude one of the associated syndromes and an evaluation for hearing loss is indicated. Infected lesions may require antibiotic therapy.

Pilonidal Cyst

Synonyms: ■ Pilonidal sinus ■ Pilonidal disease ■ Barber's interdigital pilonidal sinus (when located in the interdigital spaces)

Pilonidal cysts typically present as an inflamed, painful, cystic swelling in the upper gluteal cleft or sacrococcygeal area, but they have been described in other locations. They most commonly occur in White individuals and in males who are hirsute[19]. Pilonidal cysts usually present clinically during the second decade of life.

The etiology of pilonidal cysts and sinuses has been a controversial issue. Some authors have argued that they are congenital, essentially representing a dermoid cyst, whereas most authors now believe that the vast majority of lesions are acquired, representing a foreign body response to entrapped hair. A pilonidal cyst can be seen as part of the "follicular inclusion tetrad" which consists of acne conglobata, hidradenitis suppurativa, dissecting cellulitis (perifolliculitis capitis abscedens et suffodiens), and pilonidal cyst (see Ch. 38). Persistent exogenous hairs in the interdigital space of barbers or dog groomers may incite an encompassing epidermal proliferation, giving rise to a pilonidal cyst.

Pathology

Histologic features are those of an epidermal-lined cyst or sinus tract. Cyst cavities contain hair and keratin debris and are surrounded by fibrosis, granulation tissue, and mixed inflammation.

Treatment

Treatment is surgical.

CYSTS LINED WITH NON-STRATIFIED SQUAMOUS EPITHELIUM

Hidrocystoma

Synonyms: ■ Cystadenoma ■ Sudoriferous cyst ■ Moll gland cyst

Hidrocystomas typically present as translucent, skin-colored to bluish cysts on the face, although they may occur in other sites. Hidrocystomas are traditionally divided into apocrine and eccrine hidrocystomas based upon histologic features, and as solitary (Smith type) or multiple (Robinson type). Hidrocystomas may be associated with specific syndromes of ectodermal dysplasia, including Schöpf–Schulz–Passarge syndrome.

Apocrine hidrocystomas are usually solitary (Fig. 110.15), whereas eccrine hidrocystomas may be solitary or multiple and are occasionally quite numerous (Fig. 110.16). Eccrine hidrocystomas can enlarge with heat exposure or during the summer and regress with cooler temperatures. In general, eccrine hidrocystomas are thought to develop from cystic dilation of eccrine ducts due to retention of eccrine secretions, while apocrine hidrocystomas are thought to represent adenomas of apocrine gland coils[20]. Apocrine hidrocystomas are sometimes referred to as cystadenomas, although it has been recommended that this term be reserved for lesions with true papillomatous projections histologically[21]. Lesions along the lower eyelid margin are also known as Moll gland cysts.

Pathology

Histologically, *apocrine* hidrocystomas are unilocular to multilocular dermal cysts lined by two layers of epithelial cells that show luminal bulbous protrusions ("snouting") and decapitation secretion (Fig. 110.17). Similarly lined papillary projections may extend into the cyst lumen. Histologic features of *eccrine* hidrocystomas are those of a uniloculate cyst containing clear fluid, lined by two layers of cuboidal to flattened epithelium (Fig. 110.18). Hidrocystomas that appear by light microscopy to be eccrine include a subset of lesions that stain positively for milk fat globulin 1, as in lesions of apocrine origin[20].

Treatment

Hidrocystomas may be removed by simple excision, including via Gradle scissors, or by electrodesiccation. Multiple eccrine hidrocystomas may also be treated with daily application of topical 1% atropine in aqueous solution, although lesions reappear within days of discontinuing therapy[22]. Flattening after botulinum toxin A injections has been reported[23].

Bronchogenic Cyst

Cutaneous bronchogenic cysts are most commonly found in the suprasternal notch, and rarely they appear on the anterior neck or chin (see

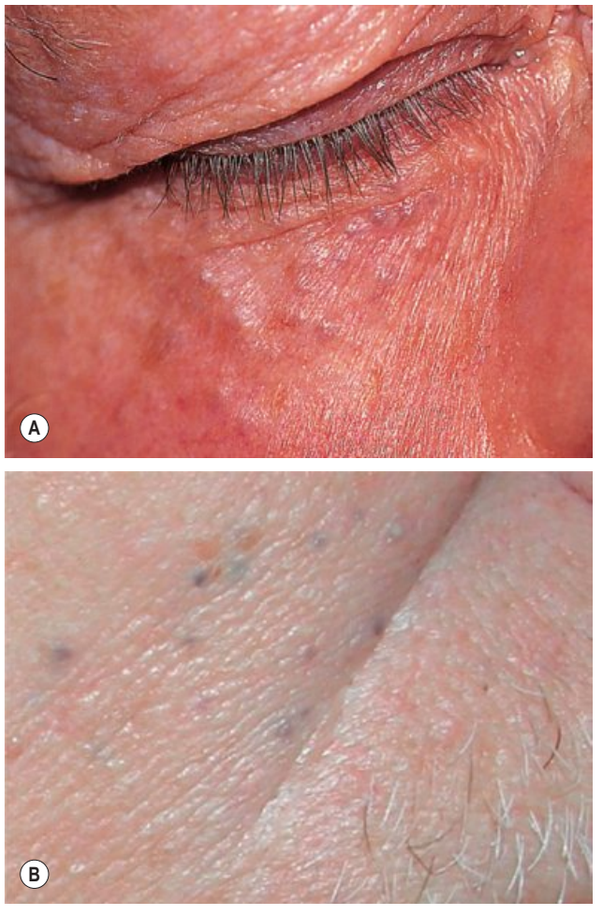

Fig. 110.16 Eccrine hidrocystomas. Numerous, tiny, translucent or bluish papules on the lower eyelid (**A**) or the cheek (**B**).

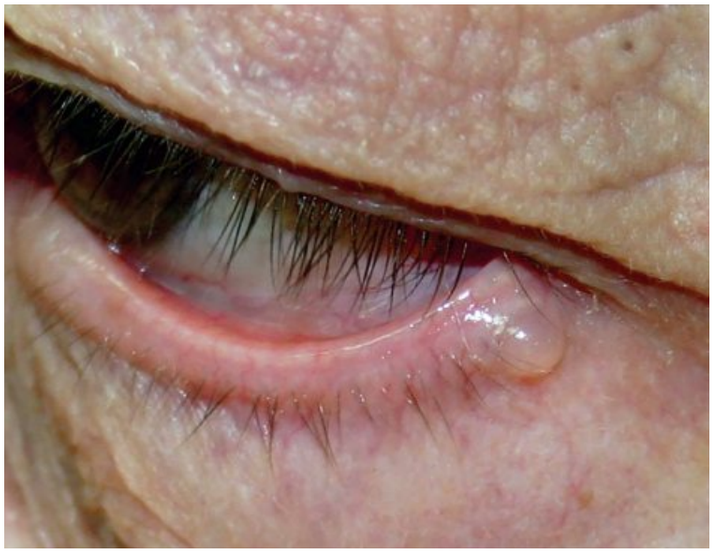

Fig. 110.15 Apocrine hidrocystoma. A single, clear fluid-filled cyst on the lateral lower eyelid margin.

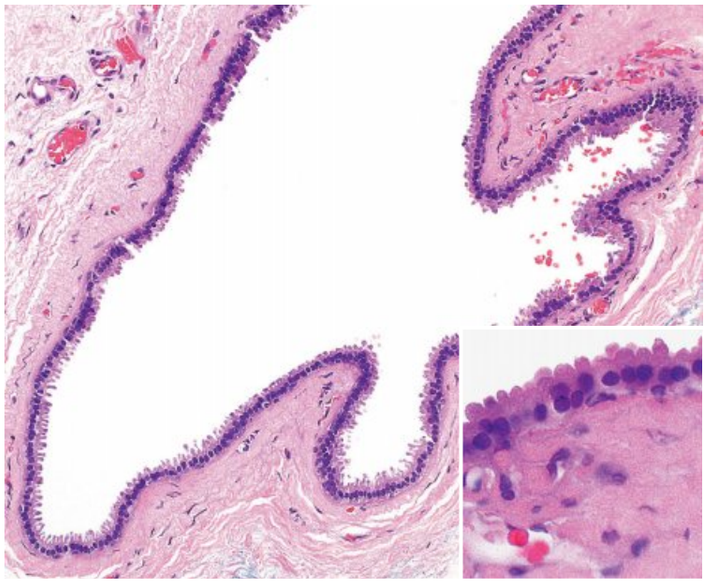

Fig. 110.17 Histopathology of an apocrine hidrocystoma. A unilocular cyst whose wall shows typical apocrine decapitation secretion (inset).

Fig. 64.2). A fistulous tract may connect to the epidermis. Rarely, they present as a pedunculated growth[24]. Bronchogenic cysts are solitary, and they are typically noted at birth. Malignant transformation is very rare. They represent respiratory epithelium sequestered during embryologic development of the tracheobronchial tree.

Pathology

Bronchogenic cysts are lined by pseudostratified, ciliated, columnar epithelium with interspersed goblet cells. The cyst wall often contains smooth muscle and mucous glands and rarely cartilage.

Treatment

Treatment is by excision.

Thyroglossal Duct Cyst

Thyroglossal duct cysts present as deep midline cystic nodules on the anterior neck in children or young adults (see Fig. 64.2). During development, the thyroid gland descends from the floor of the pharynx to the anterior neck. The tract it forms is known as the thyroglossal duct. Thyroglossal duct cysts arise from remnants of the thyroglossal duct. A tract connecting these cysts to the hyoid bone is frequently present, resulting in characteristic movement of the cyst with swallowing. Rarely, thyroid carcinoma may originate in a thyroglossal duct cyst[25].

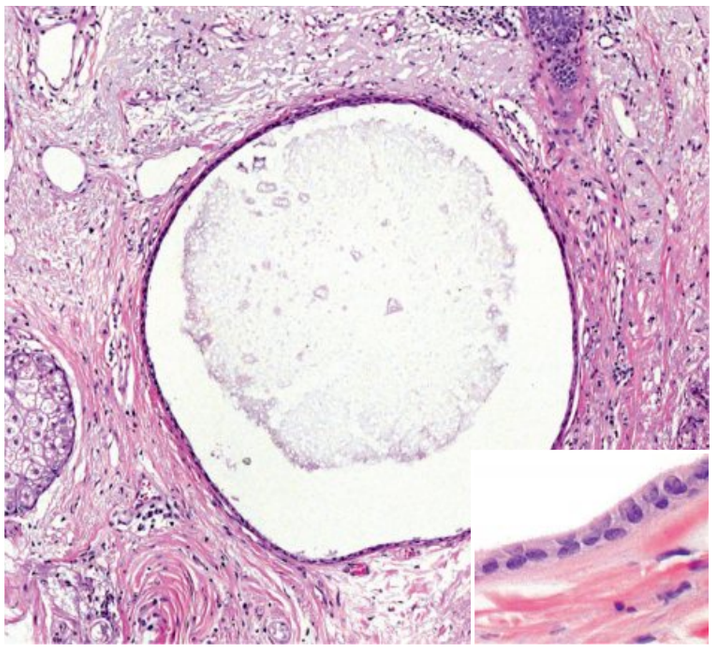

Fig. 110.18 Histopathology of an eccrine hidrocystoma. Two layers of flattened epithelium form the cell wall (inset).

Pathology

Histologically, thyroglossal duct cysts may be lined with cuboidal, columnar, or stratified squamous epithelium, and it may contain some ciliated columnar cells. The characteristic histologic feature is the presence of thyroid follicles, characterized by low cuboidal cells surrounding homogeneous pink material, in the cyst wall (Fig. 110.19).

Treatment

Treatment is surgical, with excision of the cyst and any residual tract.

Branchial Cleft Cyst

Synonyms: ■ Lymphoepithelial cyst ■ Lateral cervical cyst

Branchial cleft cysts occur in the preauricular area, mandibular region, or along the anterior border of the sternocleidomastoid muscle (see Fig. 64.2). The origin of these cysts is controversial. There are two major theories regarding their origin:

- they arise from branchial cleft remnants
- they represent cystic alteration of embryologic epithelium or tonsillar epithelium within cervical lymph nodes[26].

Branchial cleft cysts most commonly manifest during the second or third decade of life. Infection of these cysts is a frequent cause of presentation to a physician.

Pathology

Histologically, these cysts are lined by stratified squamous epithelium or by pseudostratified ciliated columnar epithelium, and they are surrounded by lymphoid tissue.

Treatment

Treatment is by excision of the cyst and its associated tract after delineation of the extent of the lesion by CT or MRI[27].

Cutaneous Ciliated Cyst and Ciliated Cyst of the Vulva

Synonyms: ■ Cutaneous müllerian cyst ■ Cutaneous ciliated cystadenoma ■ Paramesonephric mucinous cyst of the vulva

Cutaneous ciliated cysts are uncommon cysts that typically occur on the lower extremities of young women, although a few cases have been reported in men. They are usually a few centimeters in diameter and,

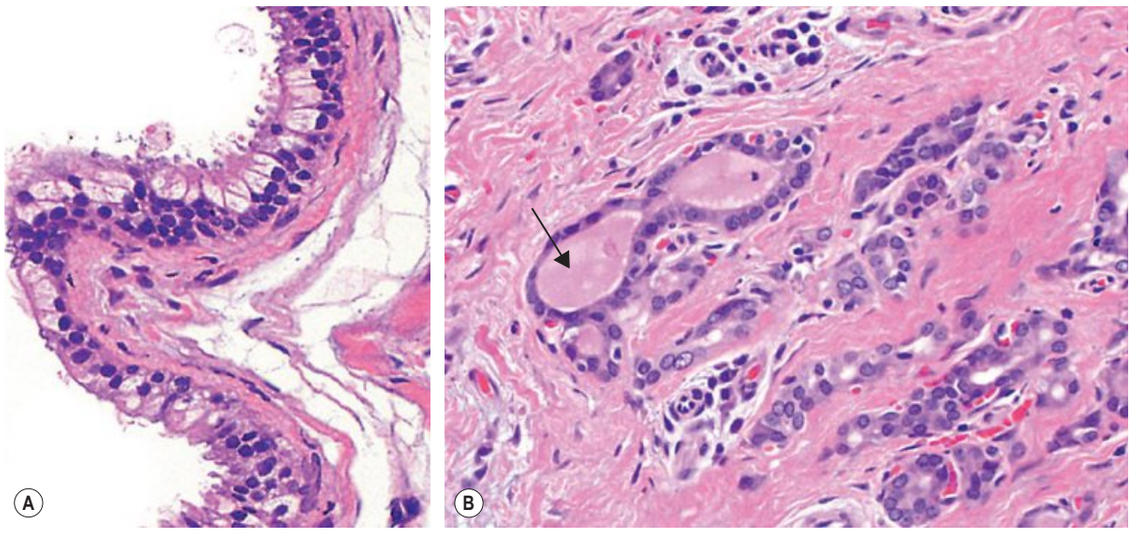

Fig. 110.19 Histopathology of a thyroglossal duct cyst. A The cyst is lined by ciliated columnar epithelium; some of the cells contain clear cytoplasm. **B** Thyroid follicles are present in the tissue surrounding the cyst; note the homogeneous colloid within the lumina (arrow).

on rupture, drain clear to amber fluid. The histogenesis of these cysts is controversial. Most authors have suggested a müllerian duct origin, hence the term cutaneous müllerian cyst. However, the few occurrences in men and the rare reports of ciliated cysts on the scalp have led to the alternative hypothesis that some cases represent ciliated metaplasia of eccrine glands[28].

Ciliated cysts of the vulva are müllerian heterotopias, and they are located most commonly on the labia majora. They usually measure between 1 and 3 cm in diameter.

Pathology

Cutaneous ciliated cysts may be unilocular or multiloculated. The cyst wall is composed of simple cuboidal to columnar ciliated epithelium that may have papillary projections into the cyst lumen (Fig. 110.20).

Differential diagnosis

Bartholin gland cysts and abscesses occur on either side of the vaginal opening and are more common than ciliated cysts of the vulva.

Treatment

Excision is curative.

Median Raphe Cyst

Median raphe cysts are solitary and usually only a few millimeters in diameter, although they may extend over several centimeters linearly. They occur in young men on the ventral aspect of the penis, most commonly on or near the glans. These cysts are thought to develop from aberrant urethral epithelium, but do not connect to the urethra[29].

Pathology

Histologically, median raphe cysts are lined by stratified columnar epithelium (one to four cell layers thick) without a connection to the overlying epithelium. Occasionally, mucin-containing cells are seen in the lining. Very rarely, a ciliated lining has been observed[30]. Positive immunohistochemical staining of the cyst wall epithelium for cytokeratin 7 and GATA3 supports the urothelial origin of these cysts[30a].

Treatment

Excision is curative.

Omphalomesenteric Duct Cyst

Synonyms: ■ Vitelline cyst ■ Omphalomesenteric duct remnant

Omphalomesenteric duct cysts represent a developmental defect in the closure of the omphalomesenteric duct. The omphalomesenteric duct is the fetal connection between the midgut and the yolk sac. It is usually obliterated and loses its intestinal attachment by 6 weeks of gestation[31]. Remnants of this duct may occur anywhere along its course between the intestines and the umbilicus. The spectrum of defects resulting from this faulty closure includes Meckel diverticulum, umbilical–enteric fistulae, umbilical sinuses, and omphalomesenteric duct cysts (internal or external); the latter can present as an umbilical polyp (Fig. 110.21A).

Pathology

These lesions are characterized histologically by ectopic gastrointestinal mucosa (Fig. 110.21B) and must be distinguished from umbilical metastases of gastrointestinal adenocarcinomas.

Differential diagnosis

In postmenarcheal female patients, the possibility of cutaneous endometriosis should be considered.

Treatment

Management of omphalomesenteric duct cysts includes appropriate radiologic studies to exclude communication to the gastrointestinal tract prior to surgical excision.

Urachal Cyst

The urachus is a tube connecting the fetal bladder to the umbilicus and it normally closes during development, resulting in a fibrous tract. A persistent urachus presents during infancy with urine leakage from the umbilicus. A urachal cyst results from an incomplete urachal duct remnant. Urachal cysts are rare, and they usually present as a painful umbilical mass due to secondary infection. The diagnosis can be established by ultrasound in the majority of patients[32].

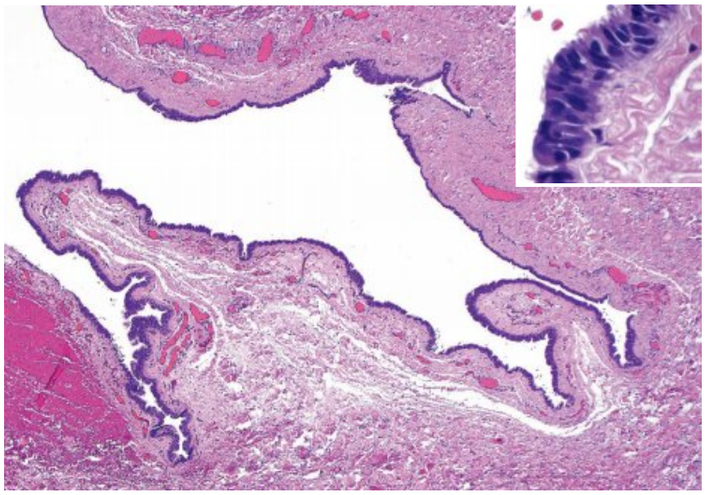

Fig. 110.20 Histopathology of a ciliated cyst of the vulva. The cyst wall is composed of columnar ciliated epithelium (inset).

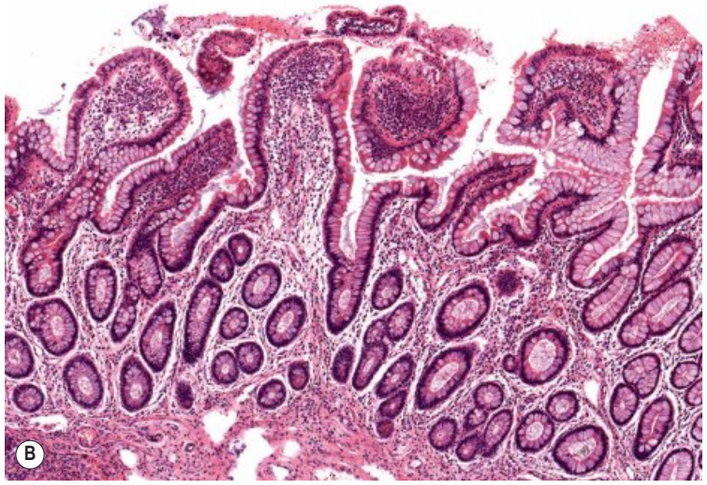

Fig. 110.21 Omphalomesenteric duct cyst. A An umbilical pink papule in an infant. The clinical differential diagnosis includes an umbilical (pyogenic) granuloma and urachal cyst/remnant. **B** Histologically, ectopic gastrointestinal epithelium is seen; note the villi and goblet cells. *B, Courtesy Luis Requena, MD.*

Pathology

These cysts are characterized by a urothelial lining of cuboidal or columnar cells.

Treatment

Excision is recommended to prevent secondary infections as well as late development of adenocarcinoma[32].

CYSTS WITHOUT AN EPITHELIAL LINING

Mucocele

Synonyms: ■ Mucous cyst of oral mucosa ■ Ranula (when located on the floor of the mouth)

Mucoceles most frequently develop on the lower labial mucosa, but they also occur on the floor of the mouth, buccal mucosa, and tongue. They appear as dome-shaped, mucosa-colored to bluish, translucent papules or nodules that range in size from a few millimeters to over a centimeter (Fig. 110.22; see Fig. 72.22). Mucoceles arise as a result of disruption of the ducts of minor salivary glands. This disruption leads to an accumulation of mucinous material, a reactive inflammatory response, and the development of surrounding granulation and fibrous tissue. Multiple mucoceles can develop in patients with GVHD.

A variant of mucocele, superficial mucocele, presents as a clear tense vesicle that is a few millimeters in diameter. Superficial mucoceles are most commonly found on the retromolar pad, posterior buccal mucosa, and soft palate. These lesions are short-lived, asymptomatic, and recurrent. They may be confused clinically with an immunobullous or viral process.

Pathology

Biopsy specimens of mucoceles show one or several spaces within the connective tissue filled with mucinous material, but without an epithelial lining. The spaces are surrounded by chronic inflammation and mucin-containing macrophages, as well as granulation and fibrous tissue. A salivary duct may be seen at the periphery of these findings. Adjacent minor salivary glands may show chronic inflammation and fibrosis. The mucinous material is sialomucin, and the latter contains both neutral and acid mucopolysaccharides, which stain with PAS (diastase-resistant) and with Alcian blue or colloidal iron, respectively.

Histologically, a superficial mucocele shows a subepithelial vesicle filled with mucin and a surrounding sparse to moderate mixed inflammatory infiltrate. Salivary gland ducts are seen opening into the vesicle or immediately adjacent to the vesicle.

Treatment

Mucoceles may resolve spontaneously. If they do not, treatment options include excision, marsupialization, electrodesiccation, intralesional corticosteroid injection, or cryosurgery.

Fig. 110.22 Mucocele. A bluish to mucosa-colored translucent papule on the lower mucosal lip.

Digital Mucous Cyst (Pseudocyst)

Synonyms: ■ Digital myxoid cyst ■ Cutaneous myxoid cyst

Digital mucous cysts (pseudocysts) most commonly occur on the dorsal surface of the distal phalanx of the finger (Fig. 110.23). Toe lesions are less commonly observed. A characteristic longitudinal depression in the nail plate may be seen distal to the cyst. These cysts are skin-colored to bluish and drain clear gelatinous material when punctured. The etiology of digital mucous cysts is controversial, with some authors stating that they are degenerative in origin while others believe they extend from the distal interphalangeal joint space. A pedicle connecting the cyst to the adjacent joint space can usually be demonstrated[33].

Pathology

Histologically, a digital mucous cyst resembles focal mucinosis, often with clefts in the dermis; an epithelial lining is absent (Fig. 110.24). The clefts and the surrounding loose connective tissue contain abundant acid mucopolysaccharides, which can be highlighted by Alcian blue or colloidal iron stains.

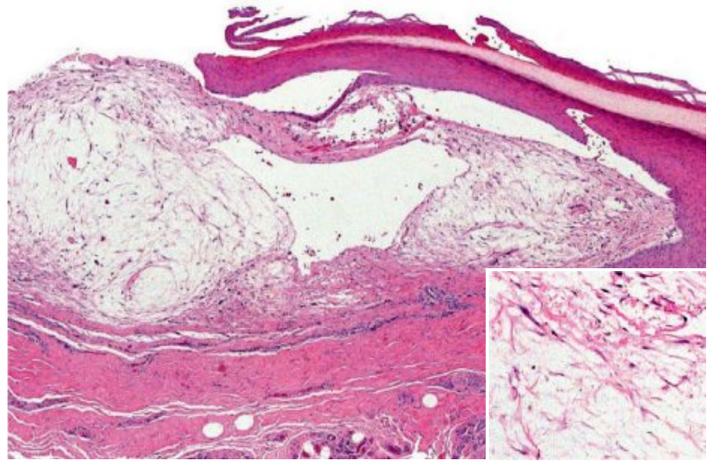

Fig. 110.24 Histopathology of a digital mucous cyst. A subepidermal cystic cavity is surrounded by mucin-rich dermis (inset). Note the prominent stratum lucidum of acral skin. *Courtesy Lorenzo Cerroni, MD.*

Fig. 110.25 Ganglion (cyst) – clinical presentation and histologic features. **A** A skin-colored, compressible, subcutaneous nodule is present on the wrist (arrow), the most common location. **B** A cystic space of acral skin is surrounded by fibrous tissue. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Lorenzo Cerroni, MD.*

Treatment

Resolution may be seen after intralesional injection of corticosteroids, injection of sclerosing agents, or repeated puncture and drainage[34]. Surgical excision may lead to even higher success rates.

Ganglion

Synonyms: ■ Ganglion cyst ■ Synovial cyst

Ganglia are soft cystic masses up to 4 cm in diameter that most commonly occur on the dorsal aspect of the wrist; they may also be found on the volar wrist or fingers, the dorsal aspect of the feet, or the knees (Fig. 110.25A). Ganglia rarely develop on the lateral elbow or anterior shoulder. They occur more commonly in women and may cause discomfort with activity, impairment of mobility, or cosmetic concerns. In the rare disorder cystic ganglionosis, multiple lesions appear during childhood or adolescence.

Ganglia are frequently attached to a tendon sheath or the joint capsule, but usually do not communicate with the joint space[35,36]. The mucin present within a ganglion is thought to be produced by local fibroblasts.

Pathology

Myxoid change is seen within the connective tissue that ultimately forms cystic spaces. These spaces coalesce into a dominant cystic space lined by variably thick fibrous tissue (Fig. 110.25B), sometimes with a synovial lining.

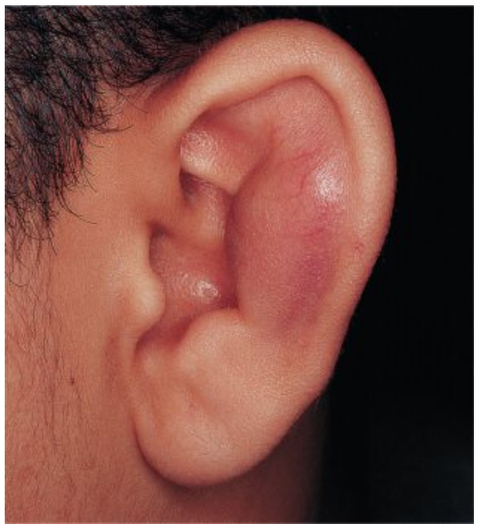

Fig. 110.26 Pseudocyst of the auricle. Erythematous firm nodule on the ear.

Treatment

Early lesions may respond to several weeks of compression therapy[35]. Other options include aspiration plus intralesional corticosteroid injection or excision. Recurrences are common, even with excisional therapy.

Pseudocyst of the Auricle

Synonyms: ■ Endochondral pseudocyst ■ Cystic chondromalacia ■ Intracartilaginous cyst

Pseudocyst of the auricle usually arises in the scaphoid fossa of the ear in middle-aged men. Lesions are usually unilateral. They present as a painless swelling (Fig. 110.26), and they tend to arise over the course of a few weeks. The etiology of pseudocyst of the auricle is unknown, but chronic trauma as well as a developmental defect have been suggested.

Pathology

Biopsy specimens show a cavity within the auricular cartilage (without an epithelial lining) that contains clear fluid. Fibrous tissue and granulation tissue may be found in the cavity as well. The cartilage lining the cavity may show degenerative changes. No inflammation is seen within the cartilage, a feature that distinguishes a pseudocyst from relapsing polychondritis, which may be in the clinical differential diagnosis.

Treatment

Treatment options include aspiration, with or without intralesional injection of corticosteroids, as well as incision and drainage with destruction of the cavity. Each of these modalities should be followed by pressure dressings[36].

Cutaneous Metaplastic Synovial Cyst (Pseudocyst)

Cutaneous metaplastic synovial cysts (pseudocysts) typically present as a solitary tender subcutaneous nodule, although multiple lesions have been reported[37,38]. They occur primarily in areas of prior trauma, particularly prior surgical trauma. Frequently, the preoperative diagnosis is that of a suture granuloma.

Pathology

A cystic cavity is seen within the dermis that is not lined by epithelium. The cavity may communicate with the overlying epidermis via fistulas. Variably cellular villous structures mimicking hyperplastic synovium protrude into the cavity. These villi are covered with a fibrinous exudate. The base of the villi tends to merge with surrounding scar tissue.

Treatment

Excision is curative.

111 Adnexal Neoplasms

Timothy H. McCalmont and Laura B. Pincus

Chapter Contents

Neoplasms and Proliferations with Follicular Differentiation . . . *1948*
Neoplasms and Proliferations with Sebaceous Differentiation . . *1960*
Neoplasms and Proliferations with Apocrine (or Eccrine) Differentiation *1962*
Neoplasms and Proliferations with Eccrine Differentiation *1969*

Key features

- Terminology and classification of adnexal tumors has varied considerably according to different authorities
- Adnexal neoplasms can differentiate toward the folliculosebaceous-apocrine unit or the eccrine apparatus
- As a reflection of joint ontogeny, tumors often exhibit combinations of follicular, sebaceous, and apocrine differentiation
- Many adnexal tumors historically classified as eccrine are probably apocrine

The nosology of adnexal neoplasms has been confused for decades, and a key problem has been the lack of a logical classification scheme. Postulated classifications and inferences regarding lineage have often been contradictory, a reflection of the fact that broad conclusions regarding lineage and classification were formerly based on enzyme histochemical attributes of dubious specificity[1,2].

The crucial principle to keep in mind when considering adnexal neoplasms is that the development of the eccrine apparatus is distinct from the folliculosebaceous-apocrine unit. Eccrine glands develop directly from embryonic epidermal anlage during early months of fetal development[3]. Follicles arise directly from the epidermis concurrently, but their development differs in that mesenchymal cells, precursors of the follicular papilla, descend jointly into the dermis with the developing follicle (see Ch. 2 and Fig. 2.4). Subsequently, sebaceous and apocrine glands and their ducts elaborate as secondary structures from bulges on the side of the developing follicle.

These ontogenetic relationships reflect relationships observed repeatedly in clinical disease[1]. As one would expect from ontogeny, follicular, sebaceous, and apocrine differentiation occur conjointly, and combinations of eccrine and folliculosebaceous differentiation probably do not exist.

Both the differentiation of the tumor (Fig. 111.1) and the topography of adnexal structures offer insights into logical classification. There is striking variation in anatomic distribution among adnexal neoplasms, and some of these differences hold implications regarding lineage. Based on topography, it is nonsensical to pigeonhole spiradenoma, a tumor that commonly occurs within apocrine skin and rarely, if ever, develops within acral skin, as an eccrine tumor. In contrast, an acral predilection suggests that poroma is commonly of eccrine lineage[4].

Lastly, microscopy and morphology play a role in the assessment of lineage. For some lines of differentiation, the meaning ascribed to specific attributes is indisputable. Cells with coarsely vacuolated cytoplasm and scalloped nuclei signify sebaceous differentiation. Follicular differentiation is established by the presence of bulbar basaloid cells accompanied by mesenchymal cells resembling the follicular papilla. Follicular lineage is also connoted by attributes such as matrical or outer sheath differentiation. In contrast, there are no specific attributes that permit recognition of eccrine or apocrine differentiation, although decapitation configuration at the luminal border can be considered suggestive of apocrine differentiation.

More recently, molecular pathology has been employed given the various alterations, including gene fusions, that have been observed in benign and malignant adnexal tumors[5].

NEOPLASMS AND PROLIFERATIONS WITH FOLLICULAR DIFFERENTIATION

Follicular and Folliculosebaceous-Apocrine Hamartomas

Hamartomas are benign proliferations composed of cellular elements, native to a site, in aberrant proportion. A congenital hamartoma, such as nevus sebaceus, is properly referred to as a *nevus*. Hamartomas can be acquired and present in a tumor-like fashion, although such lesions do not represent authentic neoplasms.

Proliferations of the folliculosebaceous-apocrine unit are commonly hamartoma-like. The folliculosebaceous-apocrine unit incorporates follicular epithelial, follicular mesenchymal, and sebaceous and apocrine elements; thus its microscopically diverse progeny is not surprising. Many follicular proliferations that we consider neoplastic, such as trichoblastoma, have integral stroma, and thus the distinction between follicular hamartoma and follicular neoplasm is sometimes blurred.

Hair follicle nevus

Introduction

Hair follicle nevi are authentic hamartomas, usually congenital, in which hairs and the follicles that ensheath them have abnormal morphology or size or are present in increased numbers. Recently, postzygotic gain-of-function variants in *FGFR2* were described in two patients with hair follicle nevi[5a].

Clinical features

Hair follicle nevus, also known as *vellus hamartoma*, presents as a small papule(s) from which fine hairs protrude evenly from the surface. Lesions typically involve the face and commonly reside near the ear[6]. *Accessory tragus* overlaps with hair follicle nevus, and it has been suggested that the two entities are the same[7]. *Nevus pilosus* designates hamartomas characterized by closely set, non-vellus hairs.

Pathology

Microscopically, hair follicle nevi display a domed surface with an increase in normally formed vellus follicles. The configuration may resemble normal skin. Accessory tragi exhibit an identical pattern but are uniquely identifiable if deep subjacent hyaline cartilage is present and can be found. Nevus pilosus is characterized by closely set terminal follicles.

Treatment

No therapy is required. Excision can be considered for cosmesis. In the evaluation of a hair follicle nevus or accessory tragus in a small child, parents can be counseled that the *relative* size of the lesion will diminish with time. That is, the child will grow disproportionately faster than the lesion.

Trichofolliculoma

Introduction

Trichofolliculoma does not represent an authentic neoplasm. Rather, the term designates a group of follicular hamartomas in which follicular structures emanate from a central dilated infundibular space.

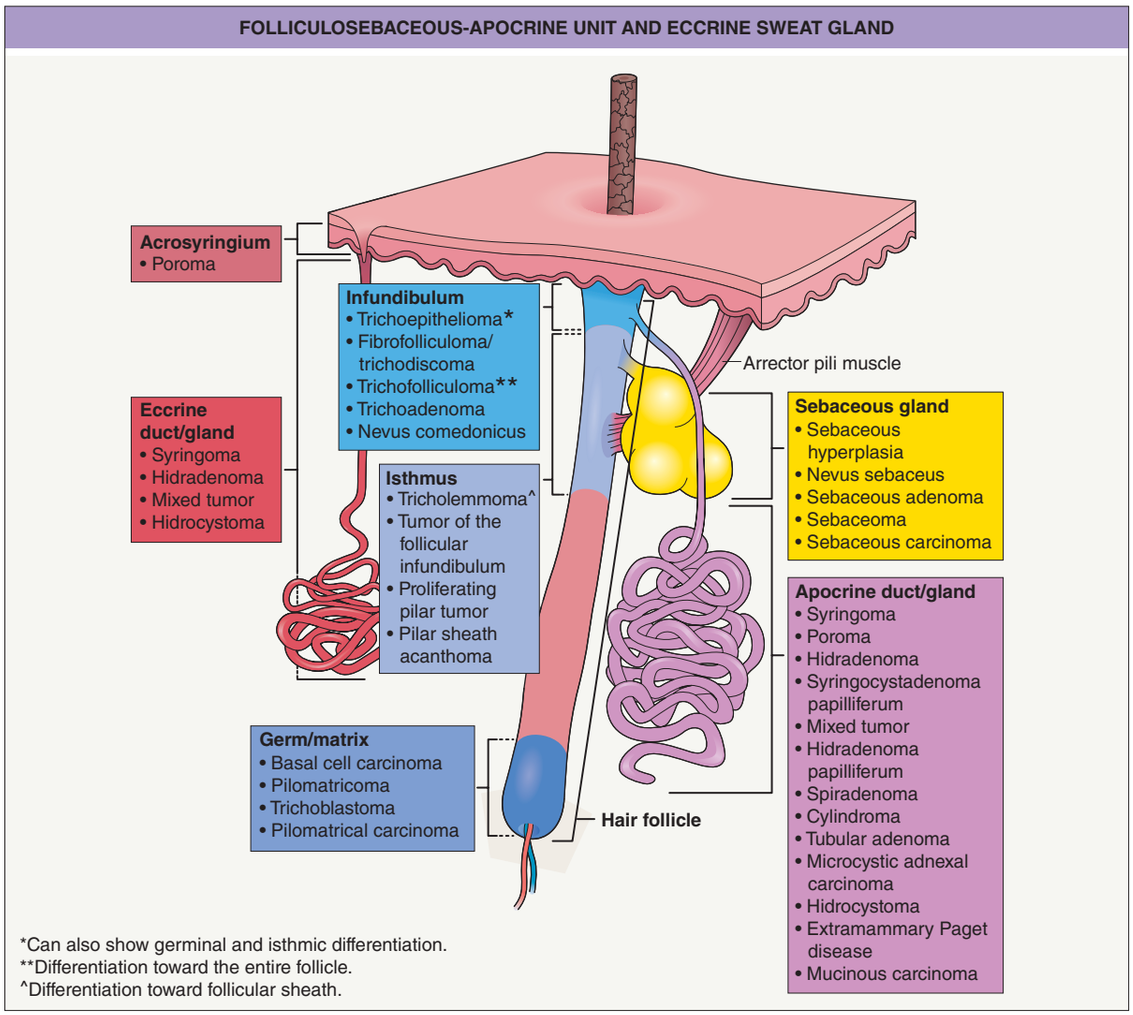

Fig. 111.1 The folliculosebaceous-apocrine unit and eccrine sweat gland with examples of adnexal tumors that differentiate toward the hair follicle, sebaceous gland, apocrine gland, and eccrine gland. *Courtesy Christine Ko, MD.*

Clinical features

Trichofolliculoma presents as a papule or nodule involving the face, scalp, or upper trunk. Many examples are not clinically distinctive. Sometimes, a central follicular ostium or punctum may be identifiable and it may harbor a small tuft of more lightly pigmented hairs (Fig. 111.2). Rarely, the clinical presentation will be as a large nodule or cyst or as multiple lesions in uncommon sites. By dermoscopy, white vellus hairs protrude from a well-defined pinkish papule and this has been likened to a "moldy peach"[8].

Fig. 111.2 Trichofolliculoma. Wispy vellus hairs emerge from a skin-colored papule with a dilated central pore.

Pathology

Prototypically, a trichofolliculoma consists of a central cystic space with infundibular cornification and central orthokeratin. Sometimes, cross-sections of hair shafts are identifiable within the cyst. Relatively well-developed and occasionally oddly formed vellus follicles protrude in radial fashion from the central structure (Fig. 111.3). The follicles usually display a bulb and papilla and exhibit inner and outer sheath and isthmic differentiation. The entire structure, including the central cyst and its associated radiating follicles, is enveloped by a vascularized fibrous (angiofibroma-like) stroma.

The radiating follicles are frequently cut on tangent, thus creating considerable microscopic variation, and deeper sections through the tissue block sometimes are required for diagnosis. If the radiating follicles are accompanied by sebaceous glands, the hamartoma can be termed a *sebaceous trichofolliculoma*[9]. This diagnostic embellishment is not of any clinical import.

The term *folliculosebaceous cystic hamartoma* has been applied to a group of nodular and cystic lesions described independently from trichofolliculoma[10–12]. Folliculosebaceous cystic hamartoma shows a central infundibular cyst from which follicular and sebaceous elements emanate, and the encompassing stroma may be fibrous or myxoid and often contains adipocytes. Rather than a unique entity, it seems likely that folliculosebaceous cystic hamartoma represents a large cystic sebaceous trichofolliculoma[10].

Pilar sheath acanthoma is characterized by a cystically dilated follicular configuration that opens to the surface epithelium, much like trichofolliculoma. However, in pilar sheath acanthoma, the lobules of cells that radiate from the cystic dilation recapitulate only the follicular isthmus and outer sheath rather than forming full follicular structures. In addition, a pilar sheath acanthoma does not have the investing fibrous stroma of a trichofolliculoma.

Treatment

Trichofolliculoma is wholly benign and no treatment is needed. If a trichofolliculoma is discovered by biopsy, no further intervention is required.

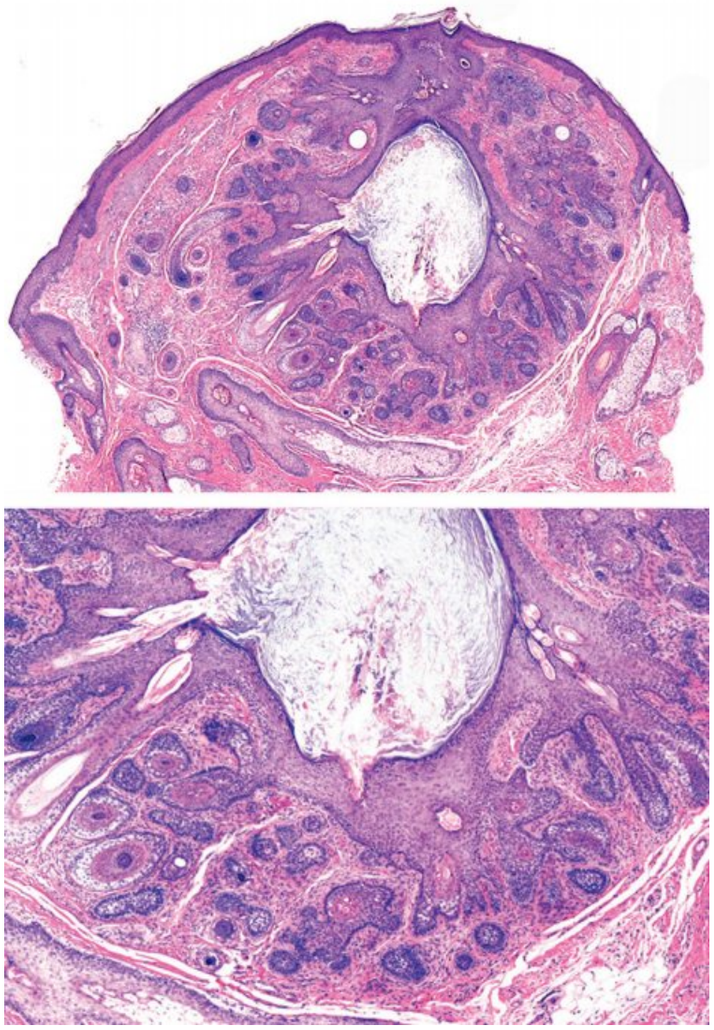

Fig. 111.3 Trichofolliculoma. There is a central patulous follicular infundibulum, from which fully formed or nearly fully formed follicles radiate. *Courtesy Luis Requena, MD.*

Fibrofolliculoma, perifollicular fibroma, and trichodiscoma

Introduction

Fibrofolliculoma represents an adnexal hamartoma that includes both follicular epithelial and mesenchymal elements. Perifollicular fibroma and trichodiscoma were described independently but probably represent purely mesenchymal proliferations on the same spectrum as fibrofolliculoma. Some authorities consider perifollicular fibroma to be related to angiofibroma.

Clinical features

Fibrofolliculomas, perifollicular fibromas, and trichodiscomas are not clinically distinctive. All present as small, skin-colored to hypopigmented papules that involve the head and neck or upper trunk. The papules commonly present in multiplicity (Fig. 111.4A–D). In this context, strong consideration should be given to the possibility of the Birt–Hogg–Dubé syndrome (Fig. 111.5), an autosomal dominant disorder typified by multiple fibrofolliculomas, trichodiscomas, and acrochordon-like lesions. The major systemic manifestations are renal tumors, the majority of which are oncocytomas or renal cell carcinomas of the chromophobe or hybrid chromophobe–oncocytoma type, pulmonary cysts, and spontaneous pneumothoraces (Table 111.1). Colonic polyps and connective tissue nevi have also been reported in affected patients as have multiple primary cutaneous melanomas[13]. However, it has not yet been determined if there is a significant increased risk for melanoma compared to the general population. Heterozygous mutations in the tumor suppressor gene *FLCN*, which encodes folliculin, a protein involved in cell–cell adhesion, underlie this syndrome (see Table 111.1).

Multiple papules of the face and pinnae can also be seen in patients with *familial multiple discoid fibromas*, but there are no systemic manifestations or mutations in *FLCN*. Mutations have been detected in *FNIP1*, which encodes a folliculin interacting protein.

Pathology

At low magnification, *fibrofolliculoma* displays slender strands of follicular mantle cells that emanate from a folliculosebaceous unit at the level of the isthmus (Fig. 111.4E). Usually, the strands are composed of cells with a slightly basaloid appearance, and sometimes, tiny integrated collections of mature sebocytes are identifiable. The epithelial component may assume a mitt-like morphology in some instances, encasing the vascularized fibrous stroma.

Perifollicular fibroma consists almost exclusively of stroma that is identical to the stromal elements of fibrofolliculoma and angiofibroma. Lesions consist of spindled and stellate cells arrayed concentrically around follicles and distributed amongst thickened collagen bundles with a proportionate number of intervening small thin-walled vessels. Sometimes, a concurrent component of follicular epithelial hyperplasia is identifiable, although the epithelium tends to be inconspicuous in comparison to fibrofolliculoma. Trichodiscoma was thought by Pinkus to represent a unique proliferation with differentiation toward the *haarscheibe* (hair disk), which is probably a mythical structure. More recently, *trichodiscomas* have been interpreted as fibrofolliculomas or perifollicular fibromas with myxoid rather than fibrous stroma. Lastly, the so-called neurofollicular hamartoma is now considered to be a type of trichodiscoma with a predominance of spindle cells.

Treatment

Fibrofolliculomas, perifollicular fibromas, and trichodiscomas are all benign and require no surgical treatment. Superficial electrodesiccation, laser ablation, or dermabrasion can be utilized to ameliorate multiple lesions. Unlike the angiofibromas of tuberous sclerosis, topical rapamycin did not result in cosmetic improvement in the fibrofolliculomas of Birt–Hogg–Dubé syndrome[14].

Nevus sebaceus

Introduction

Originally known as *organoid nevus*, nevus sebaceus is commonly thought of as a sebaceous lesion and historically has been the first entity discussed in chapters describing sebaceous tumors. In truth, nevus sebaceus is a non-neoplastic malformation that includes follicular, sebaceous, and apocrine elements[15] as well as epidermal hyperplasia.

Clinical features

Nevus sebaceus represents a classic *nevus* or congenital malformation. At birth, lesions are only slightly raised and subtly discernible. Nevus sebaceus involves the scalp or face commonly, the neck occasionally, and the trunk rarely. Lesions that are linear are distributed along the lines of Blaschko, although this may be difficult to appreciate if small in size. On the scalp, a nevus will remain hairless, or mostly so, as the infant's hair grows normally around it. During childhood, the nevus thickens slightly and assumes a yellow or orange hue (Fig. 111.6). At adolescence, progressive thickening occurs and the surface becomes pebbly or verrucous. Especially when there is more extensive involvement with nevus sebaceus, the possibility of Schimmelpenning syndrome or phakomatosis pigmentokeratotica needs to be considered (see Ch. 62).

In a study of 65 sebaceous nevi, postzygotic somatic mutations were detected in *HRAS* (95% of nevi) and *KRAS* (5%)[16]. Mosaicism for *HRAS* and *KRAS* mutations was also detected in individuals with Schimmelpenning syndrome. The more common mutations were shown to lead to activation of the MAPK and PI3K-AKT pathways (see Fig. 113.1). A syringocystadenoma papilliferum or trichoblastoma that arises within a nevus sebaceus carries the same *HRAS* mutation as the underlying nevus[17].

Nevus sebaceus represents a fertile field for the development of secondary adnexal neoplasms, commonly benign but occasionally malignant[18–20]. Past generations of dermatologists were taught that secondary carcinoma develops in 10% or more of these lesions over time, although this figure was poorly substantiated. The vast majority of secondary proliferations represent benign follicular germinative (trichoblastoma-like) foci; the actual incidence of secondary basal

Fig. 111.4 Fibrofolliculomas in association with Birt–Hogg–Dubé syndrome – clinical and histopathologic findings. cell carcinoma (BCC) is <1%[18,19]. Historically, syringocystadenoma papilliferum (papillary syringoadenoma) was believed to represent the most common secondary proliferation (Fig. 111.7), but recent analyses indicate that trichoblastoma occurs more frequently[18,19]. Other common secondary neoplasms include tricholemmoma, desmoplastic tricholemmoma, sebaceous adenoma, apocrine adenoma, and poroma. Only rarely does secondary sebaceous carcinoma or apocrine carcinoma arise in a nevus sebaceus. Malignancy probably develops only in longstanding or neglected lesions but exceptionally can be a source of mortality.

When a nodule develops within a nevus sebaceus and large blue–gray ovoid nests are noted by dermoscopy, then the pattern of the nests should be assessed. If the entire lesion is a blue–gray nest (symmetric pattern) trichoblastoma is favored whereas an asymmetric pattern of nests favors BCC.

Pathology

In nevus sebaceus, the principal malformation is of individual follicular units. An infantile nevus sebaceus can be microscopically subtle, particularly if the biopsy specimen includes only lesional skin, as the malformed follicular units are small and deviate little from normal. In an excisional specimen from the scalp during later childhood, tiny misshapen lesional follicles provide a stark contrast to normal terminal follicles at the periphery of the biopsy. Small apocrine glands may be identifiable in a specimen of sufficient depth. The epidermis also thickens and becomes progressively more papillated, gradually assuming a configuration akin to an epidermal nevus.

By late adolescence, nevus sebaceus displays an epidermal pattern identical to that of an epidermal nevus, typified by acanthosis and fibroplasia of the papillary dermis. There may be enlarged sebaceous glands in contiguity with the dermal–epidermal junction (Fig. 111.8). Buds of follicular germinative cells may jut from the junction as well. The underlying follicular units remain smallish and appear distorted but their sebaceous lobules increase in prominence. Dilated apocrine glandular structures with inspissated secretions are not uncommonly identifiable in the reticular dermis. This histopathology remains stable into adulthood.

Over time, some patients develop exaggerated verrucous epidermal hyperplasia much like a verruca vulgaris. It has been suggested that this is a consequence of human papillomavirus infection[21]. Secondary neoplasms are common, and trichoblastoma, tricholemmoma, and syringocystadenoma are frequently observed[18,19]. The strong association between syringocystadenoma and nevus sebaceus warrants careful scrutiny any time the diagnosis of syringocystadenoma is rendered, to ascertain whether a nevus sebaceus can be found in the same specimen.

Treatment

As carcinoma was formerly reputed to commonly develop within nevus sebaceus, the risk of transformation was used as justification for complete excision. In truth, the risk of development of secondary carcinoma is low[18]. However, the risk for the development of a secondary benign neoplasm, such as syringocystadenoma or trichoblastoma, is relatively high. In addition, it is clear that nevus sebaceus becomes increasingly verrucous and conspicuous over time. In light of this, conservative complete excision during late childhood represents a commonly utilized, but not required, approach. Lesions within the scalp may be difficult for the patient to follow clinically. For facial lesions, consideration can be given to excision during childhood, before the development of secondary verrucous alteration. The excisional margins can be narrow. Removal by shave or laser ablation is usually not successful.

Mixed tumor (chondroid syringoma)

Introduction

Cutaneous mixed tumor, also known as *chondroid syringoma*, represents an acquired hamartoma with folliculosebaceous-apocrine differentiation that has been interpreted as an adnexal adenoma since its

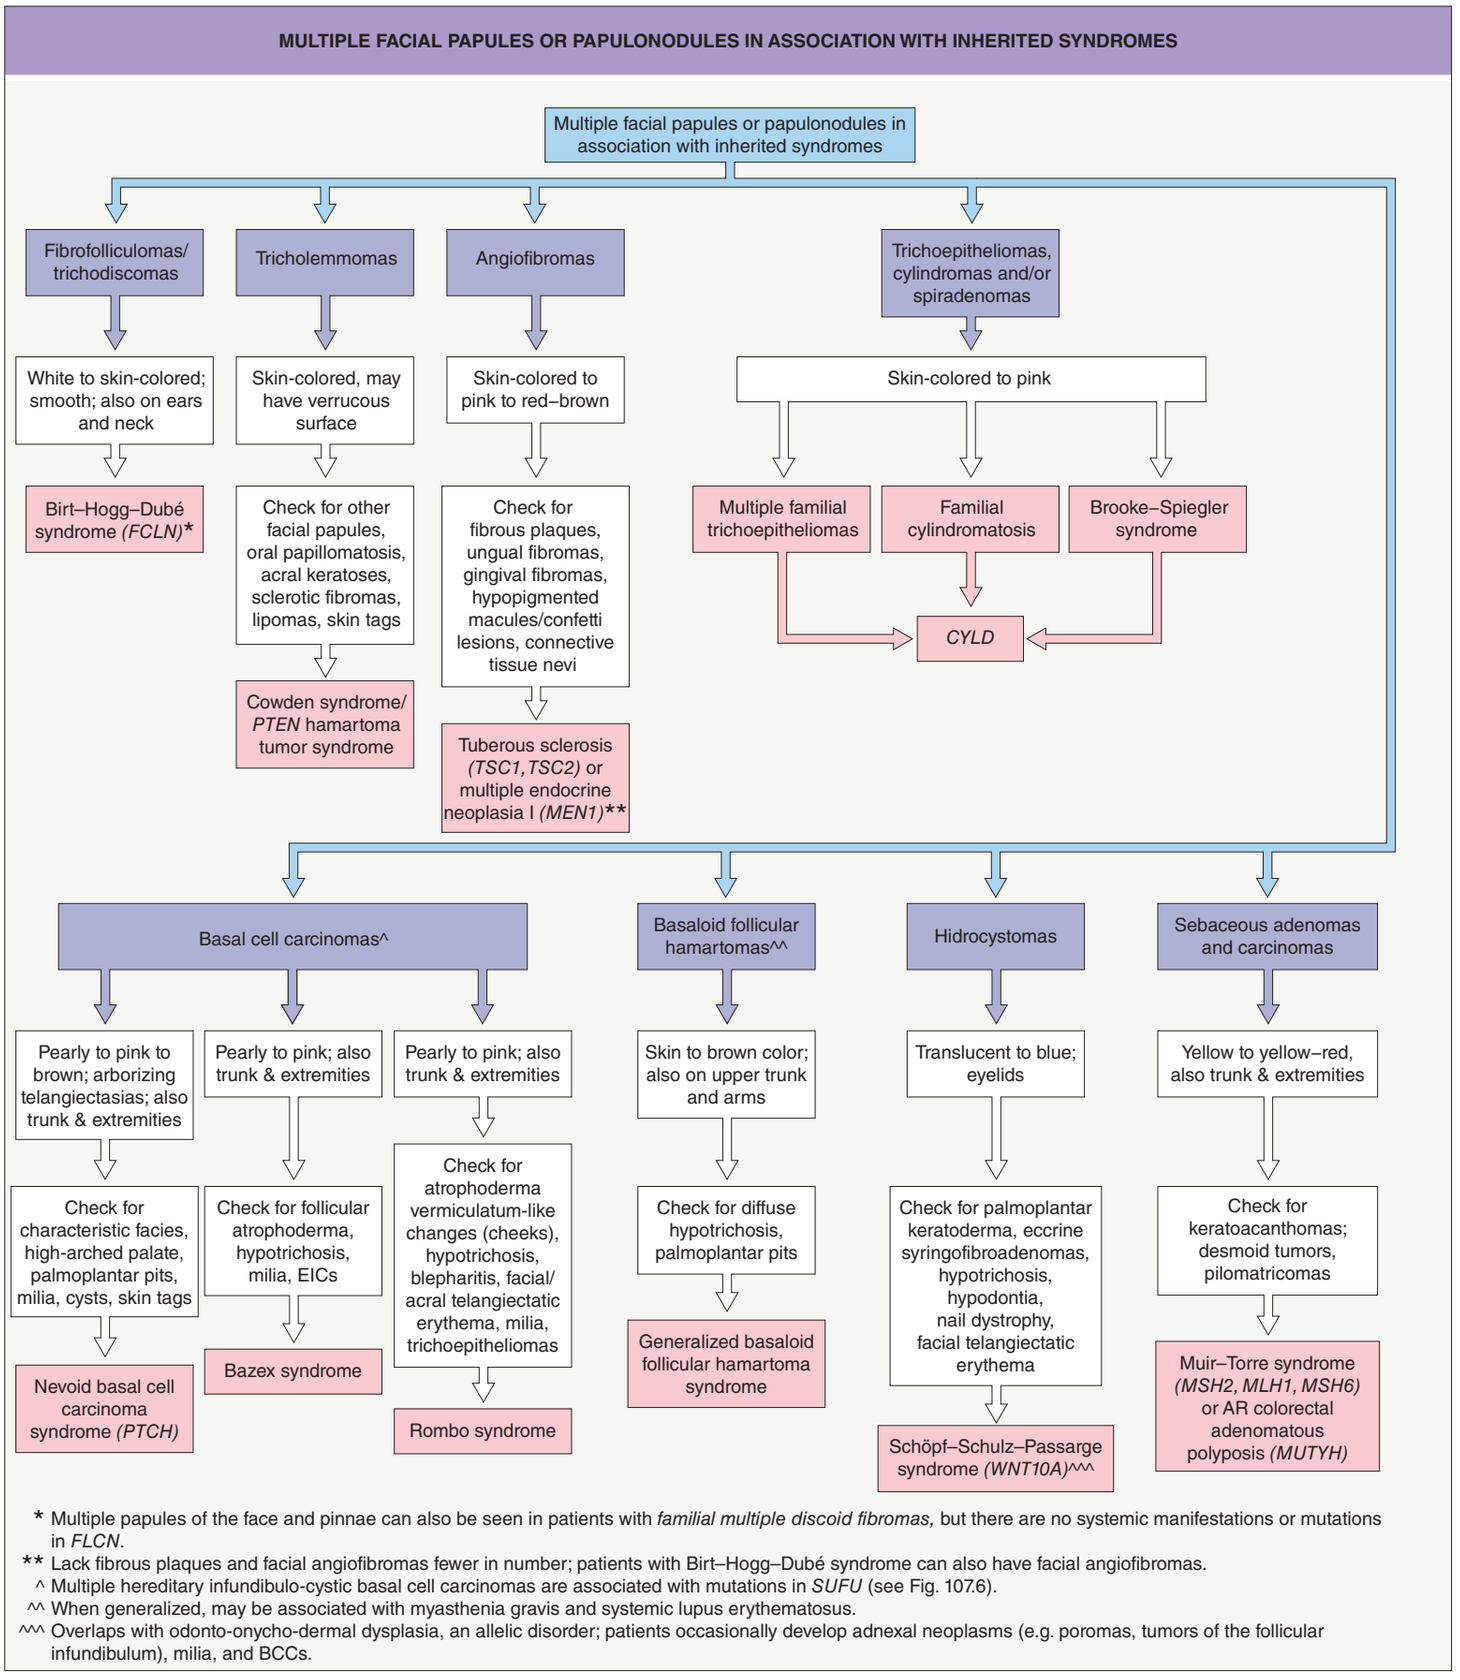

Fig. 111.5 Multiple facial papules or papulonodules in association with inherited syndromes. Patients with Gardner syndrome can develop multiple epidermoid inclusion cysts (sometimes with foci of pilomatrical differentiation) and osteomas in the head and neck region. Multiple syringomas occur with an increased frequency in patients with Down syndrome. AR, autosomal recessive; EICs, epidermoid inclusion cysts.

description. Despite this legacy, in the opinion of the authors, mixed tumor is best pigeonholed as a hamartoma. However, the presence of *PLAG1* fusion genes, including *NDRG1-PLAG1* and *TRPS1-PLAG1*, supports their classification as true neoplasms. The fusion genes lead to overexpression of PLAG1 (pleomorphic adenoma gene 1), a zinc finger transcription factor.

The stroma of a mixed tumor is always abundant and generally comprises half of the surface area of a given lesion in conventional

GUIDELINES FOR THE DIAGNOSIS AND EVALUATION OF BIRT–HOGG–DUBÉ SYNDROME (BHDS)
Diagnostic criteria
Major
• Five or more fibrofolliculomas/trichodiscomas, with at least one confirmed microscopically • Identification of a heterozygous pathogenic variant in *FLCN*
Minor
• Multiple lung cysts – bilateral basally located lung cysts with no apparent cause, with or without spontaneous primary pneumothorax • Early-onset renal cancer (age <50 years) • Multifocal or bilateral renal cancer • Renal cancer with mixed chromophobe and oncocytic histomorphology • First-degree relative with BHDS
Evaluation
Imaging studies for pulmonary and renal involvement
• Pulmonary: high-resolution CT scan of the chest to detect cysts • Renal: renal MRI scan (preferred) or abdominal/pelvic CT scan to detect tumors
Suggested surveillance and recommendations

• Cutaneous: full body skin examination
• Pulmonary: smoking cessation and judicious use of general anesthesia to reduce risk of pneumothorax
• Renal: annual renal MRI scan (preferred) or abdominal/pelvic CT scan, but if no family history of renal tumors plus 2–3 negative annual scans, screening can be done every 2 years
  • Tumors <3 cm in diameter monitored by periodic imaging
  • Tumors >3 cm in diameter treated with surgical excision

Table 111.1 Guidelines for the diagnosis and evaluation of Birt–Hogg–Dubé syndrome (BHDS). According to the European Birt–Hogg–Dubé Consortium, one major or two minor criteria are required for diagnosis whereas other diagnostic criteria require identification of a pathogenic variant in *FLCN*. CT, computed tomography; MRI, magnetic resonance imaging. *Adapted from Sattler EC, Steinlein OK. Birt-Hogg-Dubé syndrome – GeneReviews® – NCBI Bookshelf; 2020 (www.ncbi.nlm.nih.gov/books/NBK1522).*

sections, and the epithelial component is commonly heterogeneous[22]. An analogy has been drawn between cutaneous mixed tumor and mixed tumor (pleomorphic adenoma) of the salivary gland. Because they have fusion genes in common, the comparison has some validity. However, it is important to note that pleomorphic adenoma of the salivary gland functions as a neoplasm in a biological sense, as it holds a tendency for local recurrence if incompletely extirpated as well as the potential for evolution to malignancy. In contrast, chondroid syringoma represents an indolent process virtually devoid of proliferative capacity, and it rarely recurs after enucleation.

Some authors consider chondroid syringoma and cutaneous myoepithelioma to represent two ends of a spectrum, and this concept is supported by the fact that some chondroid syringomata are particularly rich in myoepithelial cells[23]. In addition, some authors consider cutaneous and salivary mixed tumors to be related myoepithelial neoplasms because they can have similar gene rearrangements involving *PLAG1*[24].

Clinical features

The clinical presentation of a mixed tumor is indistinctive. The lesions present as cutaneous papulonodules that can be misconstrued as cysts (Fig. 111.9). Involvement of the head and neck is common and lesions may also develop on the trunk or within axillary or genital skin.

Pathology

Mixed tumor presents pathologically as a well-circumscribed nodule that resides within the deep reticular dermis or subcutis. Its biphasic morphology includes epithelial structures encompassed by ample varied stroma[22]. There is always a prominent collagenous component to the stroma, but myxoid and adipocytic zones can also be found. Despite its name, stromal hyaline cartilage is found in less than half of all chondroid syringomata.

The epithelial component of a mixed tumor displays two primary patterns. Most mixed tumors demonstrate large inter-anastomosing and branching tubules lined by two cell layers – columnar cells with decapitation secretion at the luminal border and cuboidal cells peripherally; this configuration has been dubbed apocrine mixed tumor[25] (Fig. 111.10). Less commonly, mixed tumors show an epithelial component that includes many small, rounded, cuticulated ducts (Fig. 111.11). Such lesions have been interpreted by some as eccrine. Rather, it seems likely that all mixed tumors are hamartomas of folliculosebaceous-apocrine lineage and that the configuration of the epithelial component can vary.

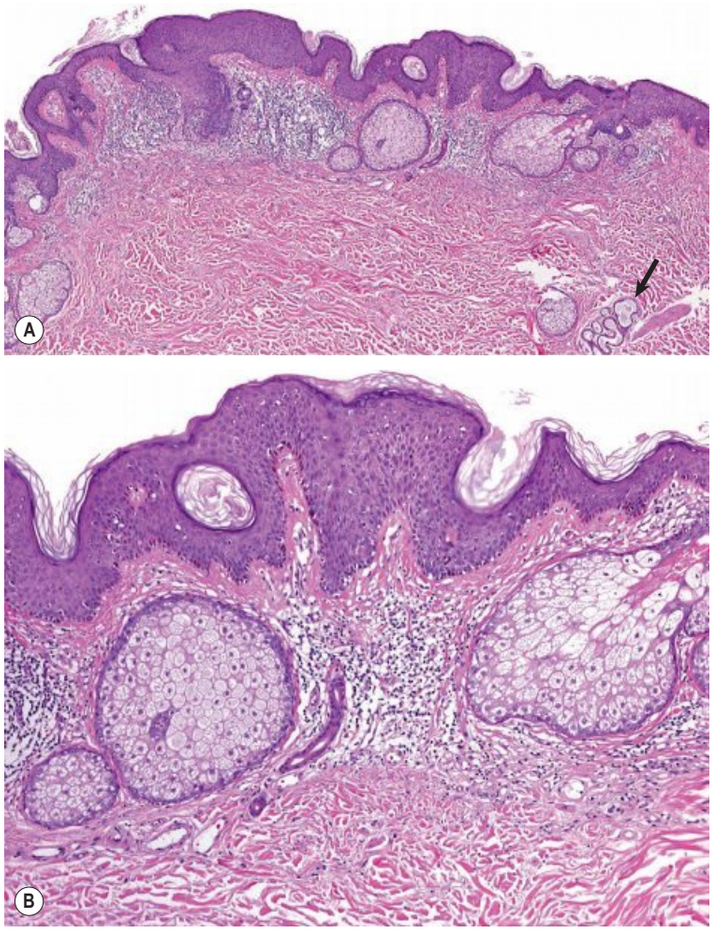

Fig. 111.8 Nevus sebaceus. A Hyperplasia of the epidermis in a papillated fashion, much like the pattern of an epidermal nevus. This is accompanied by adnexal malformation, with enlarged sebaceous lobules. Note the apocrine glands (arrow). **B** The coarsely vacuolated cytoplasm is diagnostic of sebocytes.

Fig. 111.9 Chondroid syringoma (mixed tumor). Exophytic lobulated nodule on the upper cutaneous lip. Note the several whitish areas within the lesion and telangiectatic blood vessels. *Courtesy Lorenzo Cerroni, MD.*

The epithelial component of an apocrine mixed tumor also commonly includes follicular and sebaceous elements[22,26]. Follicular differentiation can consist of small clusters of follicular germinative cells, lobules of outer sheath cells, cystic foci with isthmic or infundibular keratinization, and clusters of matrical cells. Small collections of sebocytes may also be found.

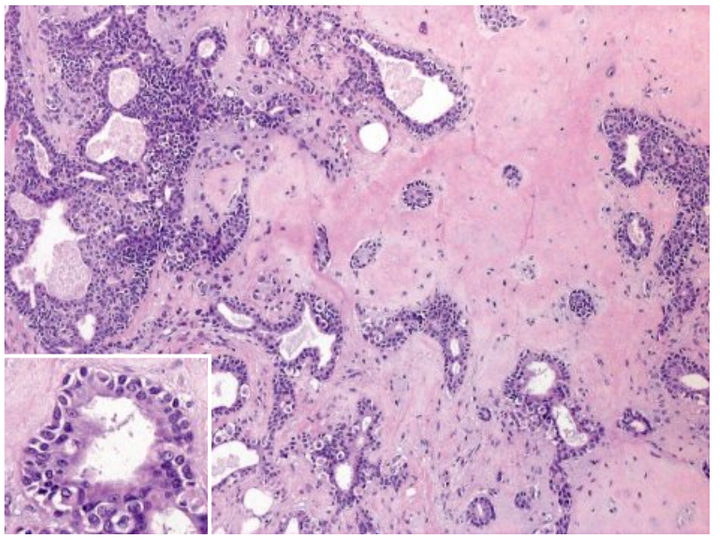

Fig. 111.10 Mixed tumor (chondroid syringoma) with overt apocrine differentiation. Clusters of dilated, branching tubules within a hyalinized stroma. The tubules are lined by columnar cells and contain secretory material within their lumina. Conspicuous apocrine differentiation with a "decapitation" pattern is evident (inset).

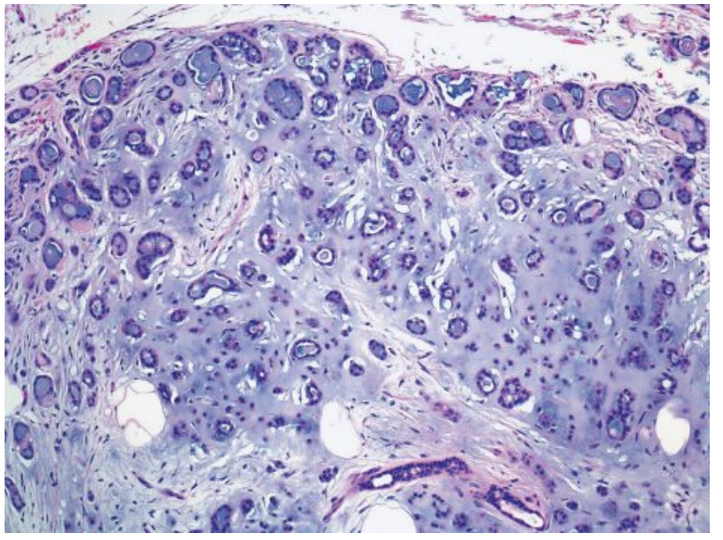

Fig. 111.11 Mixed tumor (chondroid syringoma) with ductal differentiation. This pattern, commonly referred to as the "eccrine" type of mixed tumor, shows small syringoma-like ducts within ample stroma reminiscent of hyaline cartilage.

The number of myoepithelial cells in chondroid syringomas varies. Rare tumors composed exclusively of myoepithelial cells are classified as cutaneous myoepithelioma (see below).

Treatment

Mixed tumor is benign and indolent. Most lesions are treated by simple enucleation, and the risk for persistence/recurrence is minimal. In contrast to mixed tumors of salivary origin, there is no need for excision with margins.

Neoplasms and Proliferations with Follicular Germinative Differentiation

Trichoepithelioma/trichoblastoma

Introduction

Trichoepithelioma and trichoblastoma are terms that refer to benign neoplasms with mostly follicular germinative differentiation[27]. Historically, the term *trichoepithelioma* is older and represents the name ascribed to a solitary lesion of the multiple familial form of

trichoepithelioma (epithelioma adenoides cysticum), and thus the term trichoepithelioma is clinically useful in this context. The designation *trichoblastoma* was coined more recently and was originally applied to neoplasms that showed follicular bulbar differentiation almost exclusively. Although trichoepithelioma is still used, *trichoblastoma* has evolved to be an overarching label for benign proliferations with follicular germinative differentiation[27]. For many, in the current dermatopathologic lexicon, trichoepithelioma represents a variant of trichoblastoma.

Various authors have described subtle variations within the spectrum of follicular germinative neoplasms, thereby birthing terms such as trichogerminoma, trichoblastic fibroma, and lymphadenoma (adamantinoid trichoblastoma)[27]. For purposes of this discussion, these variants will be considered as falling within the larger spectrum of trichoblastoma.

Clinical features

A classic trichoepithelioma usually presents as a skin-colored papule or nodule on the face or upper trunk. Lesions have a predilection for the nose (Fig. 111.12). When in multiplicity, constituting epithelioma adenoides cysticum or Brooke-Spiegler syndrome, lesional density is always greatest in the central face, with sparing of perioral skin. The cylindromatosis gene (*CYLD*), whose protein product functions as a tumor suppressor, underlies epithelioma adenoides cysticum. *CYLD* encodes a deubiquitinating enzyme that impedes the nuclear factor (NF)-κB and c-Jun N-terminal kinase (JNK) pathways[28]. Specifically, missense mutations lead to amino acid substitutions within the ubiquitin (Ub)-specific protease (USP) domain of the CYLD protein in patients with multiple familial trichoepitheliomas. Epithelioma adenoides cysticum can be cosmetically troublesome and is associated with a risk of secondary BCCs and parotid gland neoplasms[29]. Patients can also develop cylindromas and spiradenomas (see Fig. 111.5). The molecular features of *sporadic* trichoepitheliomas are largely unknown, with occasional tumors displaying somatic mutations in *PTCH1* (inactivating) or *CTNNB1* (activating), which have been described primarily in BCCs and pilomatricomas, respectively.

Lesions described historically as *trichoblastomas* were often larger and deeper than simple trichoepitheliomas.

Pathology

All trichoepitheliomas and trichoblastomas have in common the architectural attributes of a benign neoplasm, namely: relative symmetry, circumscription, and a lack of substantial cytologic atypicality. In addition, all are linked by a prominence of follicular germinative cells with enveloping fibrocytic stroma that varies in degree[27,30]. In classic trichoepithelioma, the fibrocytic stroma is conspicuous and constitutes as much as half of the cellularity of the lesion in a given cross-section. In other lesions that simulate BCC, follicular germinative cells may be arrayed as either small or large nodules with only scant intervening sclerotic stroma. The coarse fibrous stroma typically maintains tightly adherent contact to the lesional follicular germinative cells[30]. This is in distinct contrast to the pattern of BCC, in which clefts between basaloid cells and stromal elements often serve as a diagnostic clue.

In classic trichoepithelioma, follicular germinative cells are often disposed as small clusters or as reticulate and cribriform cords (Fig. 111.13). There are usually foci of pronounced bulbar differentiation, emulating the follicular bulb and papilla; these structures have been termed *papillary mesenchymal bodies*[30,31]. Classic trichoepithelioma does not typically show follicular germinative differentiation exclusively. Rather, small cornifying cystic spaces with surrounding pinkish keratinocytes, reflecting concurrent infundibular or isthmic differentiation, are also apparent.

In small or large nodular trichoblastoma, follicular germinative cells comprise the majority of the surface area, papillary mesenchymal bodies may be inconspicuous, and superficial follicular differentiation may be absent. *Trichoblastic fibroma* is a designation used to characterize small nodular trichoblastomas with exaggerated fibrous stroma that often constitutes over half of the cross-sectional area of the lesion[32]. Papillary mesenchymal bodies may be conspicuous in trichoblastic fibroma. With close scrutiny, other modes of differentiation can occasionally be found in a trichoblastoma. There may be tiny collections of mature sebocytes, reflecting concurrent sebaceous differentiation, and (apocrine) ductal differentiation may also be noted.

The differential diagnosis often includes BCC and differentiation is best accomplished by light microscopy. Nonetheless, the role of immunohistochemical staining with markers such as CK20 and PHLDA1 (*p*leckstrin *h*omology-*l*ike *d*omain, family *A*, member *1*) protein, a follicular stem cell marker, has been investigated. Positive

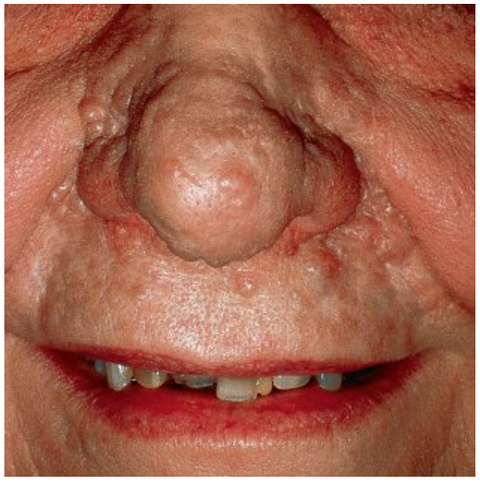

Fig. 111.12 Multiple familial trichoepitheliomas. Numerous skin-colored papules and nodules on the midface. Patients have inactivating mutations in the tumor suppressor gene *CYLD*.

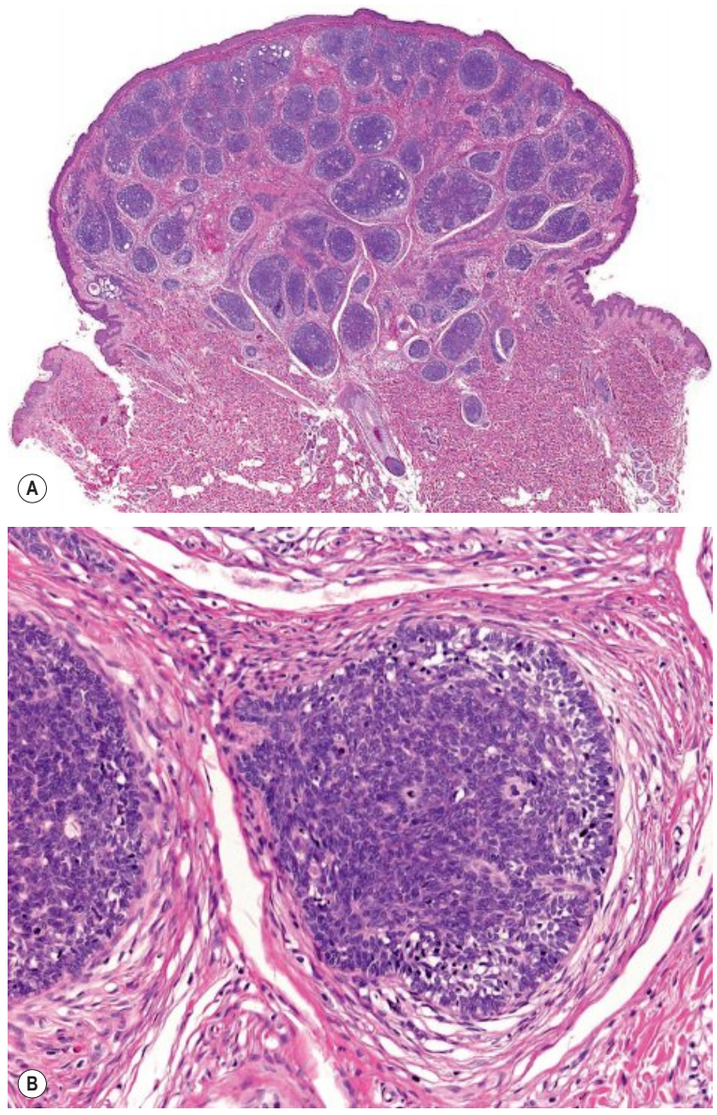

Fig. 111.13 Trichoepithelioma (trichoblastoma). A Dome-shaped papule composed primarily of clusters of follicular germinative cells. **B** A cluster of follicular germinative cells. Note that the clefts are between stromal elements, in contrast to the clefts between tumor and stroma that are characteristic of basal cell carcinoma.

CK20 labeling of Merkel cells colonizing basaloid aggregates has been shown to favor trichoepithelioma/trichoblastoma over BCC[33], and positive staining for PHLDA1 protein was observed in desmoplastic trichoepitheliomas but not in morpheaform BCCs[34]. However, a subsequent study found that while morpheaform BCCs did not express PHLDA1, a sizable minority of micronodular BCCs did[35], thus this marker appears to be most helpful if the pattern in consideration is a morpheaform BCC. The differential diagnosis of some types of trichoblastoma may also include microcystic adnexal carcinoma, syringoma, and spiradenoma.

Treatment

Trichoblastoma is benign and provokes no imperative for surgical treatment. Multiple facial trichoepitheliomas can be cosmetically disabling and many affected patients desire some type of intervention. Longitudinal evaluation for the possibility of secondary BCC is warranted[29]. Because of the number of lesions, conventional excision is not indicated. Other ablative approaches, including laser or electrosurgical destruction, have been employed with some success[36]. Partial responses with topical sirolimus (1% cream; 0.2% gel), topical imiquimod (5% cream), or oral vismodegib, either alone or in combination with CO_2 laser, have been described in case reports or small series[37].

Desmoplastic trichoepithelioma (desmoplastic trichoblastoma)

Introduction

Originally termed *sclerosing epithelial hamartoma*, desmoplastic trichoepithelioma represents a variant of trichoblastoma with exaggerated stromal sclerosis (desmoplasia)[38]. It can easily be misinterpreted as morpheaform BCC by the uninitiated.

Clinical features

Desmoplastic trichoepithelioma commonly presents as a firm skin-colored to erythematous annular plaque with a central dell. The cheek of a woman represents a stereotypical context[38]. Most examples do not exceed 1 cm in diameter. Nearly all desmoplastic trichoepitheliomas are solitary. Multiplicity is a rarity.

Pathology

Desmoplastic trichoepitheliomas are composed of cords of basaloid cells, often two cells wide, arrayed interstitially amongst coarsened collagen bundles (Fig. 111.14)[27,38]. The lesions are relatively circumscribed and are often confined to the upper two-thirds of the reticular dermis, although this is difficult to appreciate in biopsies *en parte*. Small cystic foci of isthmic or infundibular keratinization may be present, and if these cystic spaces are predominant, the designation *trichoadenoma* is apt (see below). The cornifying cysts can rupture and elicit a granulomatous reaction, and small secondary foci of calcification may also be identified[27,38]. In ~20% of cases, dermal nests of a melanocytic nevus are intermingled with complexes of the desmoplastic trichoepithelioma.

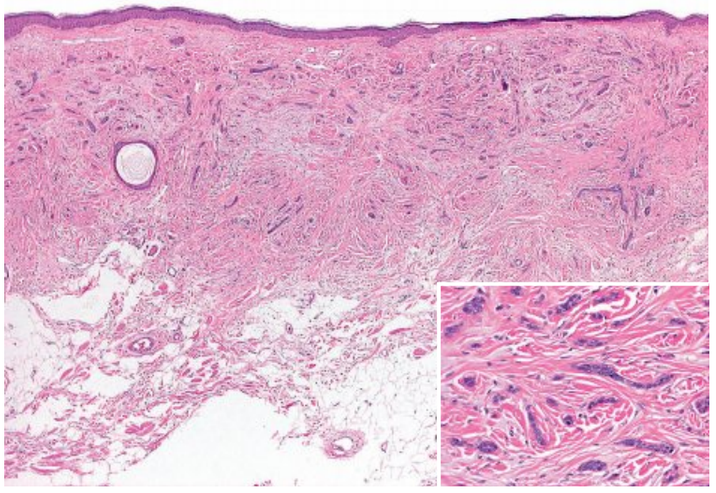

Fig. 111.14 Desmoplastic trichoepithelioma. In the upper and mid reticular dermis, thin strands of basaloid (follicular germinative) cells are arrayed within sclerotic stroma. Much like conventional trichoepithelioma, there are foci of superficial follicular keratinization, with keratinizing cystic spaces. Higher magnification of the thin strands and sclerotic stroma (inset). *Courtesy Lorenzo Cerroni, MD.*

Treatment

Desmoplastic trichoepithelioma is benign. Small or partial biopsies may yield diagnostic uncertainty with respect to morpheaform BCC or microcystic adnexal carcinoma as a consideration in the differential diagnosis, and re-excision or resampling may be necessary when the interpretation is ambiguous. Negative staining for PHLDA1 (see previous section) supports the diagnosis of morpheaform BCC. Temporary improvement has been observed with topical imiquimod.

Neoplasms and Proliferations with Matrical Differentiation

Pilomatricoma (pilomatrixoma, trichomatrioma, calcifying epithelioma)

Introduction

Pilomatricoma is a benign neoplasm or cyst typified by follicular matrical cornification. It has been demonstrated that activating mutations in *CTNNB1*, the gene that encodes β-catenin, are generally present in matrical neoplasms, including pilomatricomas[39]. β-catenin is a component of a key signaling pathway that influences cell differentiation and proliferation (see Ch. 55). Pilomatricomas also commonly demonstrate trisomy 18[40]. Some patients with multiple familial pilomatricomas have germline missense gain-of-function mutations in *PLCD1*.

Clinical features

Pilomatricoma usually presents as a solitary skin-colored, yellow, or bluish papule or nodule (Fig. 111.15). Rarely, multiple lesions are evident, sometimes in association with myotonic dystrophy, Turner syndrome, Rubinstein–Taybi syndrome, or familial adenomatosis polyposis-related syndromes including Gardner syndrome (when cystic)[41]. Firmness is typical and reflects secondary calcification as well as accompanying fibrosis and granulomatous inflammation. Some lesions are "rock-hard" and plate-like on palpation. An angulated shape can be appreciated by stretching the overlying skin ("tent sign"). Although pilomatricomas may develop on any hair-bearing surface, the majority occur on the head or upper trunk[42]. Most tumors appear during childhood and adolescence, but pilomatricomas may develop at any age and can simulate BCC, clinically or microscopically, especially in later adulthood. In rats and humans, pilomatricomas have been observed in association with vismodegib administration. Occasionally, the dermis overlying a pilomatricoma will develop anetoderma.

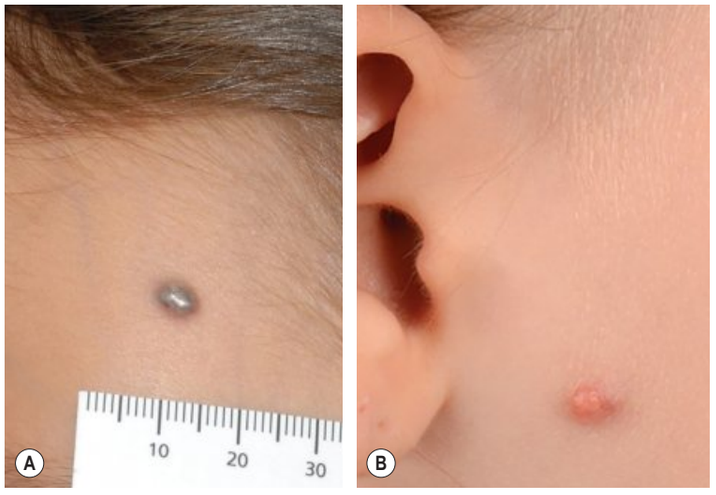

Fig. 111.15 Pilomatricomas in two children. A Firm blue–black papule on the forehead. **B** Firm yellow–pink papule in a preauricular location in a child. *Courtesy Lorenzo Cerroni, MD.*

Pathology

Histopathologically, an early pilomatricoma frequently presents as a cyst with central matrical cornification. The cyst wall consists of basaloid matrical cells that show an abrupt transition to central eosinophilic, cornified matrical cells in which barely discernible nuclear outlines remain (Fig. 111.16). Sometimes, pink trichohyalin granules, illustrative of matrical cornification, are identifiable at the transition point. The central anucleate cornified cells are commonly referred to as *ghost* or *shadow* cells.

In fully developed pilomatricomas, a cystic configuration is commonly lost. Solid collections of basaloid matrical cells and matrical corneocytes are present in varying degrees. The cornified matrical cells elicit considerable fibrosis and a secondary granulomatous infiltrate, which can become predominant in longstanding lesions. Matrical cells have a proliferative capacity as high as any human tissue and can display numerous cells in mitosis. The designation *proliferating pilomatricoma* refers to a pilomatricoma with a high mitotic index. At times, such lesions can be misinterpreted as carcinoma[43], but in contrast to pilomatrical carcinomas, they lack an infiltrative growth pattern and marked tumor necrosis. In late lesions, basaloid matrical cells may be lacking. An involutional pilomatricoma at times can present with only a few shadow cells buried in a larger fibrosing granulomatous reaction. Calcification, ossification, and occasionally transepidermal elimination also ensue in late lesions.

By immunohistochemistry, specific nuclear expression of β-catenin is found in the basaloid cells, when they are present.

Treatment

Pilomatricoma is a benign lesion that is usually treated by simple enucleation. A pilomatricoma may recur after limited excision. If multiple recurrences are observed, complete excision (with negative margins) should be performed to exclude pilomatrical carcinoma.

Pilomatrical carcinoma

Introduction

Pilomatrical (matrical) carcinoma is an uncommon malignancy that exhibits matrical cornification, much like pilomatricoma[44]. Mutations in *CTNNB1* (encodes β-catenin) are common in matrical carcinomas[39]. This suggests a partial common pathogenesis for pilomatricoma and matrical carcinoma. Although on a practical basis no clear association exists, there is a theoretical risk for the possibility of matrical carcinoma developing from conventional pilomatricoma.

Clinical features

Matrical carcinoma is typically a disease of adulthood. Lesions develop on the head and neck, often in the retroauricular area. Although a pathogenic link with ultraviolet irradiation has not been established, many matrical carcinomas develop within severely sun-damaged skin. If a diagnosis of matrical carcinoma is offered in a child or young adult at an age when the diagnosis is improbable, the case should be reassessed for the possibility of pilomatricoma.

Pathology

Much like pilomatricoma, matrical carcinomas include both basaloid matrical cells and anucleate matrical corneocytes. In contrast to pilomatricoma, the matrical carcinoma cells usually display nuclear pleomorphism. An infiltrative configuration or poor circumscription is usually apparent, especially in an excisional biopsy. Tumor necrosis is commonly present. There may be considerable squamous cornification as well, and parts of a given lesion may resemble conventional squamous cell carcinoma (SCC).

Matrical carcinoma should be distinguished microscopically from BCC with matrical differentiation[45]. The latter entity represents an otherwise conventional BCC in which small foci of matrical cornification are identifiable. The clinical behavior of this variant is thought to be identical to that of conventional BCC. As in pilomatricomas, nuclear expression of β-catenin is seen in the basaloid cells of matrical carcinomas, as well as in a relevant proportion of BCCs. Thus, negative staining of basaloid cells points to a BCC.

Treatment

Matrical carcinoma is a low-grade form of adnexal carcinoma that poses some risk for metastasis, although the risk is believed to be low[44]. Complete extirpation with negative margins represents standard care.

Neoplasms and Proliferations with Follicular Sheath (Tricholemmal) Differentiation

Tricholemmoma (trichilemmoma)

Introduction

Tricholemmoma constitutes a form of benign adnexal neoplasm with differentiation toward the follicular outer sheath[46]. Some have averred that tricholemmoma is merely a viral wart based upon conventional

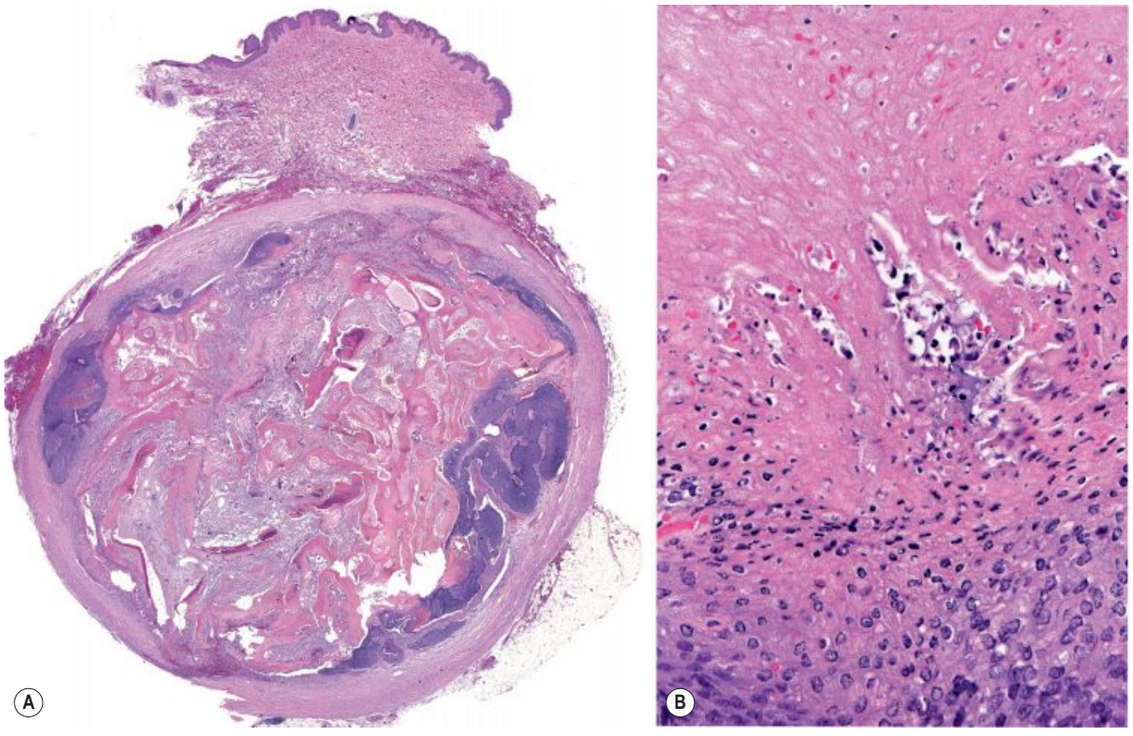

Fig. 111.16 Pilomatricoma. A At low magnification, a well-circumscribed, epithelial-lined cystic nodule is seen. A portion is lined by basaloid matrical cells. Centrally, there are anucleate keratinized matrical cells ("shadow" cells). **B** Transition between matrical cells (lower) and central anucleate "shadow" cells (upper). *Courtesy Lorenzo Cerroni, MD.*

histopathology[27]. Although one study found human papillomavirus (HPV) DNA within lesions by PCR, in general molecular analysis has failed to demonstrate intralesional HPV DNA and thus viral causation seems unlikely[47].

Clinical features

Tricholemmomas may arise as single or as multiple papules that usually have similar coloration to surrounding normal skin (see Fig. 63.3)[46,48]. Individual lesions may display hyperkeratosis or a verrucous surface. Most are distributed on the central face, including the nose or upper lip, but any non-glabrous site may be affected. Tricholemmomas can also present on genital skin and simulate condylomata acuminata if multiple. This tumor may occur as a secondary neoplasm within nevus sebaceus. The variant *desmoplastic tricholemmoma* is especially common in this context[49]. Both sporadic and nevus sebaceus-associated tricholemmomas often contain *HRAS* mutations.

Multiple tricholemmomas typically present on facial or genital skin. Multiple tricholemmomas are a common manifestation of Cowden syndrome/PTEN hamartoma tumor syndrome (see Ch. 63 & Fig. 111.5)[46,50]. In addition to tricholemmomas, manifestations of Cowden syndrome include sclerotic fibromas, acral keratoses, and adenocarcinoma of the breast, thyroid gland, or gastrointestinal tract[51]. Loss of PTEN expression within a tricholemmoma, as assessed by immunohistochemistry, is suggestive that the patient has Cowden syndrome[52].

Pathology

Microscopically, tricholemmomas present as small circumscribed lobular proliferations composed of pallid, glycogen-containing outer root sheath cells. There is often a broad connection to the surface epidermis (Fig. 111.17)[46,48,50]. A papillated surface is common, and there may be verrucous hyperplasia with hypergranulosis, thereby simulating the pattern of a verruca in a superficial biopsy. Squamous eddies are not uncommon. There is a palisade of small, compact basal keratinocytes at the periphery of a lesional lobule, and a flanking thickened basement membrane that is PAS-D (periodic acid Schiff with diastase)-positive is commonly present. Outer root sheath differentiation can also be recognized through use of CD34 immunostaining.

In desmoplastic tricholemmoma, small central angular clusters of outer root sheath cells are arrayed in an infiltrative pattern with enveloping sclerotic stroma. This creates a configuration that at times simulates carcinoma[49,53]. Most commonly, a desmoplastic focus is accompanied or surrounded by areas of conventional tricholemmoma that serve as the basis for accurate interpretation, but the diagnosis can be deceptive in partial or superficial biopsies.

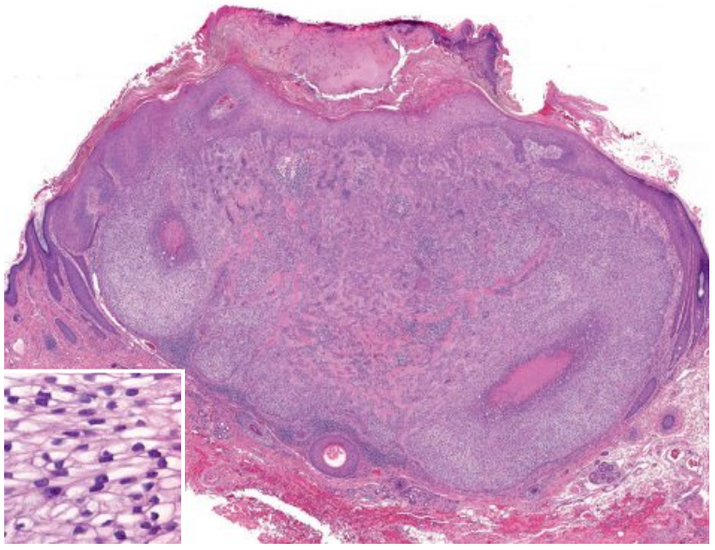

Fig. 111.17 Tricholemmoma. Circumscribed nodular proliferation of pale-staining cells with a broad connection to the overlying epidermis. There is also surface crust and focal areas of necrosis within the tumor. Sometimes these lesions are misdiagnosed as superficial carcinomas. The cells contain glycogen and display outer root sheath differentiation (inset). *Courtesy Lorenzo Cerroni, MD.*

Treatment

Tricholemmoma is a benign adnexal neoplasm with limited proliferative capacity. After recognition by biopsy, no further treatment is needed unless there is uncertainty regarding the diagnosis. If there is a desire for ablation, cryotherapy, electrosurgical destruction, shave, curettage, or excision may be employed.

Tricholemmal (trichilemmal) carcinoma

This malignant analogue of tricholemmoma represents an invasive lesion composed in part of glycogen-containing clear cells, similar to cells of the follicular outer sheath. If a thickened, PAS-positive, prominent basement membrane can be identified peripheral to areas of clear cell change, it is probably of considerable diagnostic significance. CD34 immunopositivity may also be of potential diagnostic value. Many of these carcinomas show accompanying keratinization and thus there is considerable overlap with lesions that have been pigeonholed as clear cell SCC.

Treatment

Tricholemmal carcinoma represents a carcinoma with limited metastatic potential. These lesions are probably best considered equivalent to SCC and treated as such.

Neoplasms and Proliferations with Superficial Follicular (Infundibular and Isthmic) Differentiation

Tumor of follicular infundibulum (infundibuloma; isthmicoma)

Introduction

This benign lesion is commonly known as *tumor of follicular infundibulum* (TFI) or *infundibuloma*, but the designation *isthmicoma* is more apt, as the proliferation primarily shows follicular isthmic differentiation.

Clinical features

TFI prototypically presents clinically as a subtle macule, thin papule, or plaque[54,55]. Lesions are skin-colored or sometimes slightly hypopigmented and may appear slightly atrophic[54]. Many examples are diagnosed incidentally within skin cancer excision specimens where no known clinical lesion was even identifiable. TFI may occur in multiplicity (Fig. 111.18A) and assume a reticulated pattern; patients with this presentation may defy diagnosis for a time because of the subtlety of both the clinical and the microscopic findings[54–56]. Patients with multiple atrophic-appearing TFI may display a clinical pattern reminiscent of disseminated superficial porokeratosis or multiple actinic keratoses. TFI is rarely present in Cowden syndrome.

Pathology

TFI consists of a plate-like proliferation of eosinophilic isthmic keratinocytes arrayed in reticulate fashion in the superficial dermis, in broad, but intermittent, continuity with both the surface epidermis and extant follicular structures[54]. Most of the constituent keratinocytes have cytoplasm similar to keratinocytes of the follicular isthmus, follicles in catagen phase, or the cells of an isthmic (pilar) cyst (Fig. 111.18B). The keratinocytes are paler than those of the surface epidermis, and often a few scattered dyskeratotic keratinocytes are present. Some lesions will display tricholemmal foci in which pallid keratinocytes or a thickened basement membrane can be found, and occasionally a hybrid of TFI and tricholemmoma may be encountered. Additionally, small buds of follicular germinative cells may jut from the undersurface of a TFI.

Rarely, small clusters of sebocytes may be found within TFI[57]. Sebaceous or apocrine ducts have also been documented[56].

Treatment

TFI is a benign adnexal proliferation with negligible proliferative capacity. If desired, lesions may be removed by cryotherapy, shave, or electrosurgical destruction. For multiple lesions, superficial laser ablation can be considered[54].

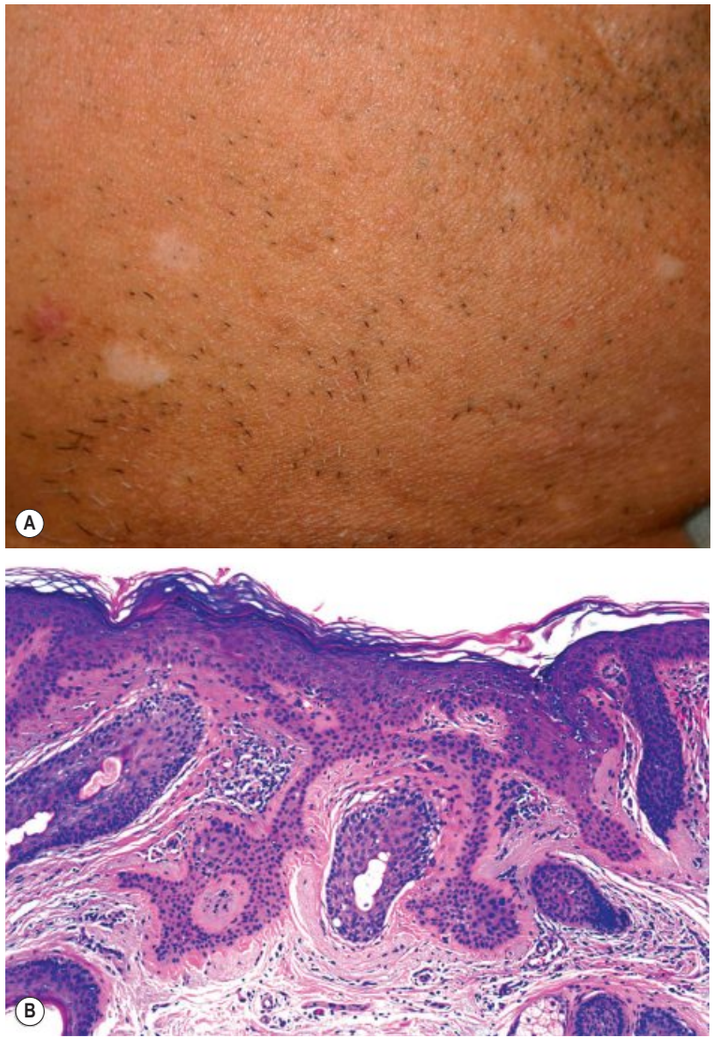

Fig. 111.18 Tumor of follicular infundibulum. A Multiple hypopigmented thin papules on the cheek. **B** The microscopic pattern is subtle, resembling a reticulated seborrheic keratosis. Strands of pale eosinophilic keratinocytes display multifocal attachment to the epidermal surface and also commonly interconnect with existent follicular structures.

Trichoadenoma (trichoadenoma of Nikolowski)

Introduction

The term *trichoadenoma* is a misnomer, as there are no adenomas of follicular lineage since the hair follicle is not a structure that exhibits glandular differentiation. Trichoadenoma represents a benign follicular neoplasm with sclerotic stroma that consists largely of small cystic spaces that exhibit infundibular and isthmic differentiation[58].

Clinical features

The clinical presentation of trichoadenoma is not distinctive. The neoplasm presents as a skin-colored papule or small plaque.

Pathology

Trichoadenoma is usually positioned in the superficial dermis. Cornifying cysts with infundibular or isthmic keratinization comprise the bulk of the proliferation (Fig. 111.19)[58]. The sclerotic stroma is often accompanied by thin strands of basaloid cells, similar to the cords observed in desmoplastic trichoepithelioma. Trichoadenoma and desmoplastic trichoepithelioma have many overlapping histopathologic features, and, in their "pure" forms, likely represent opposite poles of the spectrum of the same entity.

Treatment

Trichoadenoma is a benign adnexal neoplasm with negligible proliferative capacity. No further treatment is necessary unless the patient desires removal.

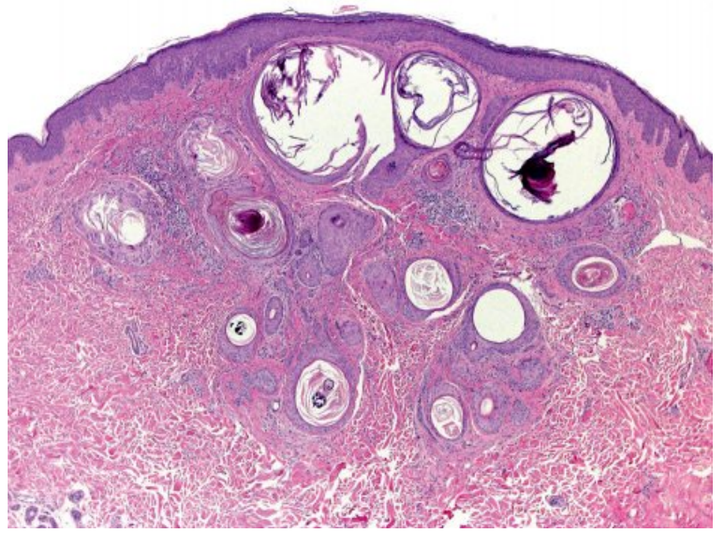

Fig. 111.19 Trichoadenoma. This lesion consists primarily of small keratinizing cystic spaces. There are also lobules and a few cords of basaloid cells. Both are surrounded by sclerotic stroma, similar to the pattern observed in desmoplastic trichoepithelioma. *Courtesy Lorenzo Cerroni, MD.*

Proliferating pilar tumor (proliferating follicular-cystic neoplasm)

Introduction

Known for decades as *proliferating pilar tumor (PPT)*, *proliferating tricholemmal cyst* or *proliferating pilar cyst*, the designation *proliferating follicular-cystic neoplasm (PFCN)* was proposed by Ackerman as a more apt designation[27]. This term describes a group of nodular/cystic neoplasms characterized microscopically by abrupt keratinization akin to that of the follicular isthmus or in a follicle in catagen phase[59]. In the past, it was known that PPT could simulate SCC microscopically, but the entity was generally regarded as a benign process, although it was recognized that, occasionally, locally destructive behavior could occur[59].

Recently, this concept has been called into question, and a proposal has been issued that PFCN represents a mix of benign and malignant neoplasms grouped together under one rubric[27]. The proposal further iterates that a benign PFCN should be designated as *proliferating follicular-cystic acanthoma* (PFCA), while a malignant PFCN should be designated as *proliferating follicular-cystic carcinoma* (PFCC). As some examples of PFCN share features with carcinoma, including clinical characteristics such as locally destructive behavior, microscopic characteristics such as nuclear atypicality, and molecular characteristics such as aberrations in ploidy, this proposal seems diagnostically practical[60,61]. Of note, an activating *PIK3CA* mutation was detected in a metastatic PFCC[61a].

Clinical features

PPT presents as a nodule, usually no more than a few centimeters in size, although there have been reports of lesions exceeding 20 cm in diameter. The lesions can develop in men but a female predominance is seen in most series. Roughly 90% of cases arise in the scalp, probably as a reflection of the density of follicles at that locale. The prototypical presentation is as a nodule on the scalp of an elderly woman. The tumors are usually well circumscribed but may be multinodular. Their circumscription is reflected in smooth borders and the fact that lesions generally shell out from adjacent tissues during surgical excision.

Pathology

PPT consists of a large and/or deep nodule that resides in the dermis or subcutis[59]. Because of its large size, the laboratory commonly receives fragmented specimens. Both solid and cystic patterns are usually evident at low magnification, with cystic areas exhibiting the pattern of an isthmic (pilar) cyst (Fig. 111.20). The constituent keratinocytes are mostly isthmic keratinocytes with dense eosinophilic cytoplasm, and centrally there is an abrupt transition to compact keratin with little intervening granular layer. Rarely, shadow cells, implying matrical keratinization, can be found. There may be focal necrosis and calcification.

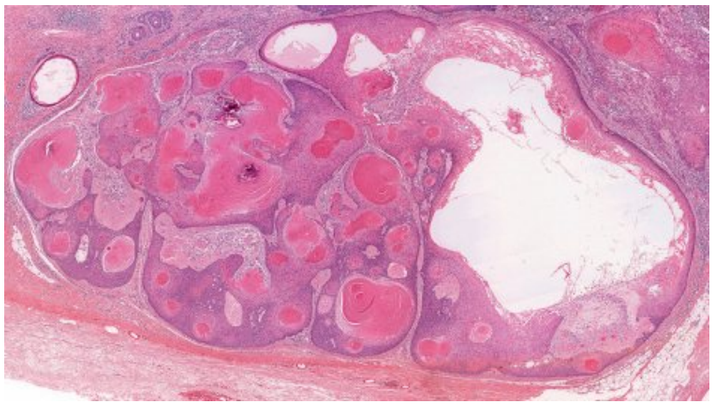

Fig. 111.20 Proliferating follicular-cystic neoplasm. This complex multicystic neoplasm shows abrupt keratinization, similar to the pattern exhibited at the follicular isthmus (proliferating pilar tumor, proliferating tricholemmal cyst). Although it can be difficult to determine whether these lesions are benign or malignant, this example was well circumscribed and showed no cytological atypia (proliferating folliculo-cystic acanthoma). *Courtesy Lorenzo Cerroni, MD.*

The degree of cytologic atypicality varies among lesions and amongst different areas of a given lesion. Commonly, the neoplastic cells contain enlarged vesicular nuclei with prominent nucleoli and some degree of nuclear hyperchromasia; mitotic figures are usually identified, but overt anaplasia is usually not present. Since some examples of PPT represent low-grade forms of carcinoma, tumors with marked cytologic atypicality, extensive necrosis, a lack of circumscription, or extraordinary numbers of mitotic figures warrant designation as PFCC[60].

Treatment

As noted, some examples of PPT may represent carcinoma. If a lesion has been enucleated in its entirety or near entirety, is circumscribed, and lacks substantial cytologic atypia, it can be interpreted as PFCA and additional surgical therapy is not necessary. If a given lesion lacks circumscription, shows substantial cytologic atypia or necrosis, or has been sampled *en parte*, then complete excision is warranted, as PFCC remains a concern.

NEOPLASMS AND PROLIFERATIONS WITH SEBACEOUS DIFFERENTIATION

Sebaceous gland hyperplasia

Introduction

Sebaceous gland hyperplasia (SGH) does not represent a true neoplasm. It represents benign enlargement of sebaceous glands. Numerous lesions can develop following systemic administration of immunosuppressive medications, in particular calcineurin inhibitors.

Clinical features

SGH is relatively common and presents with one or multiple yellowish, occasionally telangiectatic papules, usually on the central or upper face and sometimes on the upper trunk (Fig. 111.21). Commonly, the clinical lesions display a central dell that corresponds to a central follicular infundibular ostium. *Beaded lines* represent a unique expression of SGH in which a linear array of hyperplastic sebaceous glands is present in the vicinity of the clavicle or on the neck[62]. Biopsy is occasionally indicated to exclude BCC, but the dermoscopic findings of a crown of blood vessels, rather than arborizing vessels, assist in the diagnosis (see Ch. 0).

Pathology

The sebaceous gland in SGH shows normal morphology, with a thin rim of seboblasts surrounding the remainder of the gland, composed of mature sebocytes. The enlarged sebaceous lobules usually circumferentially surround a central infundibulum.

Treatment

If treatment is desired, lesions can be removed or diminished by shave, light electrosurgical destruction, cryotherapy, or laser ablation[63]. Long-term topical retinoid application may be beneficial. A short course of oral isotretinoin has been utilized for patients with extensive or disfiguring lesions.

Sebaceous adenoma, sebaceoma, and sebaceous epithelioma

Introduction

The term *adenoma* designates a benign neoplasm with glandular differentiation, and any benign proliferation with predominance of sebaceous differentiation can be grouped under this rubric. Commonly, the term sebaceous adenoma has been applied to superficial benign sebaceous neoplasms with a predominance of mature sebocytes, while sebaceous epithelioma and sebaceoma have been applied to sebaceous neoplasms with a predominance of seboblasts. Troy and Ackerman[64] coined *sebaceoma* as an alternative to describe a group of benign sebaceous proliferations that were generally more deeply situated than superficial sebaceous adenomas and in which a vertically oriented microscopic pattern was identifiable.

The dated term sebaceous epithelioma is inherently confusing, as the diagnosis has been utilized differently by various authorities. To some, a sebaceous epithelioma represents a low-grade form of sebaceous carcinoma or BCC with sebaceous differentiation. Others have utilized the term to characterize sebaceoma or sebaceous proliferations of uncertain potential. We believe that the designation sebaceous epithelioma should be abandoned.

In this chapter, the term *sebaceous adenoma* is used in broad fashion to encompass both conventional sebaceous adenoma and sebaceoma.

Clinical features

Sebaceous adenomas present clinically as papules or nodules, usually less than a centimeter in diameter, distributed on the head or neck and sometimes on the upper trunk. The lesions are not clinically distinctive except when there is a yellowish color, which is often not apparent. Superficial sebaceous adenomas are usually relatively small and papular, while sebaceomas may present as a deep nodule[64,65]. Multiple sebaceous neoplasms, especially cystic ones, may be a presenting sign of the Muir–Torre syndrome (MTS; see Table 63.5), in which patients can also develop multiple keratoacanthomas and visceral carcinomas, especially colonic adenocarcinoma[66,67]. Sebaceous neoplasms with a keratoacanthoma-like pattern point to the diagnosis of MTS (see below).

Pathology

Conventional *sebaceous adenoma* is usually captured in continuity with the surface epidermis and is relatively small and circumscribed. The relative proportions of basaloid seboblastic cells and mature sebocytic cells varies, but sebocytes usually predominate. Seboblasts comprise a thin multilayer of cells at the periphery of each lobule. Mitotic figures can be found in seboblasts but are not conspicuous. Necrosis is not typically evident in an adenoma unless the lesion has been traumatized. Significant necrosis, whether of single cells or *en masse*, raises concern for the possibility of carcinoma.

Sebaceoma is usually more deeply situated, often involving the deep reticular dermis and sometimes the superficial subcutis[64]. The lesions are sharply circumscribed in an excisional specimen, but this may be difficult to fully appreciate in a biopsy *en parte*. Seboblasts predominate in sebaceoma and sebocytic differentiation may be only focal, yielding a microscopic pattern not unlike a large nodular trichoblastoma (Fig. 111.22). If sebaceous differentiation is only focal, then epithelial membrane antigen (EMA) or adipophilin immunoperoxidase staining can be considered as a diagnostic supplement. EMA labels mature sebocytes in the normal sebaceous gland, while adipophilin labels multivacuolated lipid-containing cells.

Use of immunohistochemistry to assess for loss of expression of mismatch repair proteins encoded by MTS-associated genes, e.g. MSH2, MSH6, MLH1, and PMS2, has been reported to be an effective screening technique[68]. However, it should be noted that loss of expression, as detected by immunohistochemistry, does not necessarily reflect underlying germline mutations. Occasionally, mutations can occur in sporadic neoplasms[69]. Additionally, protein expression can sometimes be detected within tumors in patients who actually harbor a germline mutation in the gene encoding that particular protein; this is usually due to the presence of a protein that, despite being dysfunctional, can react with the antibody utilized for the test[68]. For these reasons, assessment for loss of expression of a mismatch repair protein is most helpful as a screening technique for MTS, but, if found, is not fully diagnostic, and confirmatory genetic testing should be considered after assessing risk for MTS (see Table 63.5). In the same context, assessment of microsatellite instability may also serve as a screening technique.

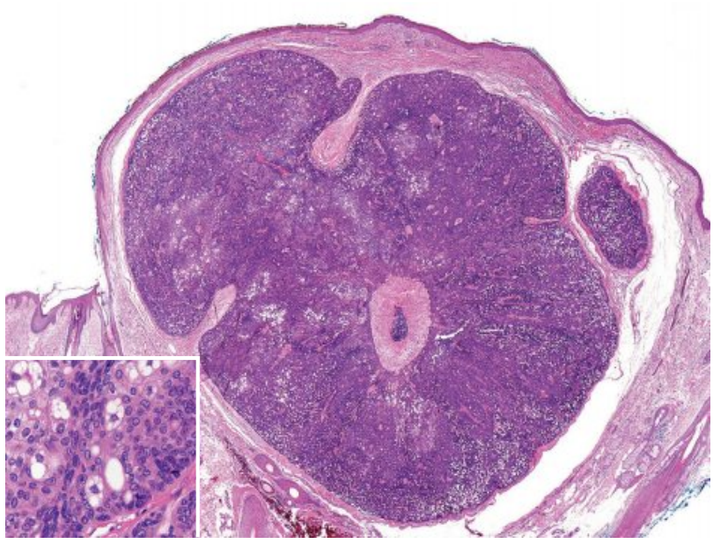

Fig. 111.22 Sebaceous adenoma (sebaceoma). Well-circumscribed proliferation of both basaloid seboblastic cells and scattered mature sebocytes with coarsely vacuolated cytoplasm (inset).

Treatment

Once a definite microscopic diagnosis has been achieved, no further treatment is obligatory. It is often difficult to establish the circumscription of lesions captured in superficial or partial biopsies. Complete excision of such lesions is appropriate to exclude the possibility of BCC with sebaceous differentiation or sebaceous carcinoma. Deeply situated lesions of MTS may be prone to rapid growth.

Sebaceous carcinoma

Introduction

The term sebaceous carcinoma designates an adenocarcinoma with sebaceous differentiation. By historical convention, these carcinomas have been separated into ocular and extraocular types. Originally, periorbital sebaceous carcinomas were thought to hold a graver prognosis, but more recent data suggest that tumors in this location have a similar overall survival rate as sebaceous carcinomas arising elsewhere[70].

Clinical features

The clinical presentation of sebaceous carcinoma is not distinctive. Typical clinical lesions include erythematous nodules or plaques that may be ulcerated or crusted and only occasionally display yellowish coloration. More commonly, the lesions display an erythematous or pearly morphology that is indistinguishable from common forms of keratinocyte carcinoma. Early in presentation, ocular lesions are very commonly misdiagnosed as blepharitis or ocular rosacea.

Sebaceous carcinomas commonly develop in the periorbital area but also occur elsewhere on the head and neck and less commonly on the trunk. Carcinomas from the trunk often display a nodular pattern, and superficial biopsies from such lesions may be deceptive and can be misinterpreted[70]. Sebaceous carcinoma can occur in patients with Muir–Torre syndrome (MTS), but the identification of a sebaceous carcinoma alone is not sufficient to diagnose the syndrome[66]. However, any unusual sebaceous neoplasm is probably sufficient provocation for consideration of the disease (see Table 63.5).

Pathology

Like many malignancies, sebaceous carcinoma often exhibits asymmetry, a lack of circumscription, and areas with an infiltrative pattern. In nodular sebaceous carcinoma, cells are arrayed as large nests and lobules. In infiltrative sebaceous carcinomas, jagged nests and thin strands are found. Sebaceous carcinoma can involve the surface epidermis or conjunctiva in a pagetoid pattern, especially in ocular lesions[71,72]. This can be confused with Bowen disease or melanoma.

The degree of sebaceous differentiation in sebaceous carcinoma varies greatly, as does the degree of nuclear atypicality (Fig. 111.23). Some carcinomas display obvious sebocytic differentiation, while other examples may be largely seboblastic or undifferentiated in appearance. Differentiation from sebaceous adenoma may be difficult, but loss of expression of bcl-2 and p21 as well as higher p53 and Ki-67 expression represent useful immunohistochemical markers that point to sebaceous carcinoma. Recently, it has been shown that TERT promoter mutations are present in a minority of sebaceous carcinomas and absent in sebaceous adenomas[73].

Stains for lipid, such as oil red O or Sudan black, have been utilized in the past as a tool to confirm sebaceous differentiation through labeling of cytoplasmic fat. However, such stains have little routine practical applicability as they require the use of frozen tissue substrate. EMA and adipophilin immunohistochemical staining represent the best supplemental tests for confirmation of sebaceous differentiation. When authentic sebaceous differentiation is present, coarsely vacuolated cytoplasmic positivity can be seen with either stain.

Crateriform or cystic sebaceous neoplasms that display a clinical appearance and microscopic architecture reminiscent of keratoacanthoma are uncommon lesions that probably represent low-grade carcinomas[66]. Sebaceous neoplasms with a keratoacanthoma-like pattern probably only occur in the context of MTS.

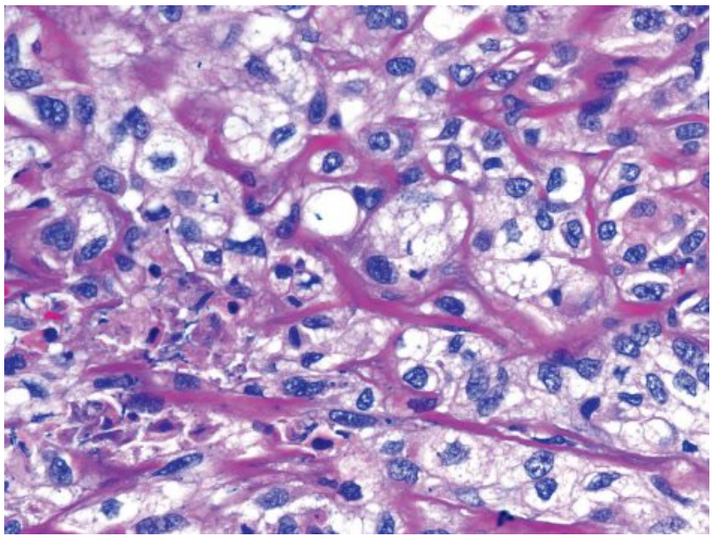

Fig. 111.23 Sebaceous carcinoma. At high magnification, there are cells with atypical nuclei and ample coarsely vacuolated cytoplasm. There are also many necrotic cells with pyknotic nuclei.

Treatment

Sebaceous carcinoma is an adnexal carcinoma with significant, albeit variable, metastatic potential. The primary treatment remains surgical extirpation, including removal via Mohs micrographic surgery. Although the risk of metastatic disease was formerly believed to be high, particularly for ocular carcinomas, the data contained within many older reports may be skewed by inclusion of carcinomas diagnosed late in their evolution. Extensive disease of the eye has been treated with ocular enucleation, especially when ocular conjunctival involvement was present. The metastatic potential of both superficial sebaceous carcinoma and sebaceous carcinoma with an infiltrative pattern may be limited, although additional study will be necessary to fully establish this as well as the possibility that missense mutations in *PCDH15* are associated with metastatic ocular sebaceous carcinoma.

NEOPLASMS AND PROLIFERATIONS WITH APOCRINE (OR ECCRINE) DIFFERENTIATION

In most textbooks, adnexal neoplasms with glandular and ductular differentiation have been rigorously separated into eccrine and apocrine neoplasms. Commonly, the distinction was based upon enzyme histochemistry, an imprecisely applied technique that is no longer available. Discrimination has also been based upon conventional microscopic assessment, a useful but imprecise tool, at least for the distinction of eccrine and apocrine attributes.

A few authorities have responded to this difficulty by grouping apocrine and eccrine neoplasms together, in recognition of the fact that it is impossible to determine whether a given lesion, such as a given syringoma, is of apocrine or eccrine lineage. In the sections that follow, the traditional categorization as apocrine or eccrine will be maintained, but areas of overlap will be expressly noted. For entities such as syringoma, poroma, and hidradenoma, which can be of either apocrine or eccrine lineage, the presentation will be included in the discussion of apocrine lesions.

Benign Neoplasms and Proliferations with Apocrine (or Eccrine) Ductal and Tubular Differentiation

Syringoma

Introduction

Syringoma represents a benign adnexal neoplasm with mostly ductal (syringeal) differentiation. Historically, syringomas have been interpreted as neoplasms of eccrine lineage[74,75]. The term syringoma can be used to describe neoplasms of either apocrine or eccrine lineage, and it is currently impossible to judge the lineage of any given lesion other than by its context[1,2].

Fig. 111.24 Syringomas. **A** Aggregated skin-colored papules with a periorbital distribution. **B** Multiple skin-colored to pink, smooth papules on the neck and upper chest. The lesions favor the ventral surface of the trunk, a distribution pattern referred to as *"en demi-cuirasse"*. *B, Courtesy Jean L. Bolognia, MD.*

Clinical features

A syringoma manifests clinically as a small, firm, skin-colored papule. Syringomas commonly present in multiplicity (Fig. 111.24) and may be eruptive[76]. The lesions are removed from women more commonly than men, although it is not clear that this represents treatment bias. There is an increased incidence in Asian populations as well as an association with Down syndrome. Clear cell syringomas are associated with diabetes mellitus. Patients with Nicolau–Balus and Costello syndromes can also develop syringomas (see Chs. 99 and 55), and rarely they are seen in patients with Brooke–Spiegler syndrome (see below).

Syringomas may occur at any site on the body but are prone to occur in the periorbital area, especially the eyelids[77]. Sometimes, lesions involve the upper trunk (favoring the ventral surface) or genital skin[76,78]. Eruptive syringomas most commonly involve the trunk but may involve the extremities, including the palms and soles. Some cases of eruptive syringomas may be familial with autosomal dominant inheritance. Acral syringomas, which are rare, are those that are most clearly of eccrine lineage, as the acini of glabrous (non-hair-bearing) skin are exclusively eccrine[79].

Syringoma-like foci can be found in biopsy specimens of cicatricial alopecias. Although initially thought to represent authentic syringomas and to play a role in pathogenesis[80], later studies aptly demonstrated that, in fact, these foci represented reactive changes in response to the inflammation and scarring from the cicatricial alopecia. That is, these foci were simply bystanders[81]. Occasionally, syringoma-like changes can also be seen in non-scarring alopecia.

Pathology

From scanning magnification, a syringoma is small and circumscribed and is usually confined to the superficial dermis. The encompassing stroma is sclerotic. The epithelial component of the proliferation is composed of cells with pale or pinkish cytoplasm forming nests and

tubules of relatively uniform size. Depending upon the exact plane of section, the nests of a syringoma vary in shape, and some nests may assume a morphology that resembles a comma or a tadpole (Fig. 111.25). Tubular areas exhibit ductular differentiation with central lumina lined by a compact eosinophilic cuticle. Typically, half or more of the nests in a given plane of section will show central ductal differentiation.

Usually, a syringoma lacks keratinization, although at times superficial cornification can be seen. Syringomas also typically lack evidence of follicular differentiation. If either follicular differentiation or keratinization is identified, other differential diagnostic possibilities should be strongly considered. The combination of superficial cornification, poor circumscription, and extension into the deep reticular dermis (or subcutis) favors microcystic adnexal carcinoma over syringoma. A lesion with strands of basaloid cells, focal superficial cornification, and focal calcification probably represents desmoplastic trichoepithelioma rather than syringoma. If there are only cornifying cysts present and authentic ductal differentiation is lacking, then the most likely diagnosis is trichoadenoma.

Treatment

Syringoma is a benign adnexal neoplasm with negligible proliferative capacity. After definitive diagnosis, no further surgical intervention is needed unless adnexal carcinoma remains a clinicopathologic consideration. Syringomas may be treated with careful application of trichloroacetic acid, cryotherapy, punch excision or electrosurgical destruction, with variable results. This can be difficult in the common situation in which multiple lesions are present on eyelids. Disseminated lesions can be cosmetically disabling and therapeutically challenging, and laser ablation might be the best choice[82].

Poroma

Introduction

Poroma designates a group of benign adnexal neoplasms with poroid (terminal ductal) differentiation. Like syringomas, poromas were widely interpreted historically as neoplasms of eccrine lineage because of dubious enzyme histochemistry[74,75]. The words *eccrine* and *poroma* became seemingly inextricably linked in the dermatologic lexicon, and thus poromas are often referred to as eccrine in reflexive fashion[2]. Poroma can be a proliferation of either apocrine or eccrine lineage[83–85]. Eccrine and apocrine poromas probably occur in nearly equal numbers.

The term *acrospiroma* is used by some authorities as a synonym for poroma and is used by other authorities as a broad designation that encompasses both poroma and hidradenoma.

Clinical features

Poromas usually present as solitary papules, plaques, or nodules (Fig. 111.26)[4]. When sessile vascular plaques surrounded by thin indented moats appear on the palms and soles, an astute dermatologist can strongly suspect the diagnosis. They can appear on any cutaneous surface, where they are less readily identified with specificity. The scalp is another common site, with or without an associated nevus sebaceus[18]. Presumably, poromas arising secondarily within nevus sebaceus represent apocrine poromas. Occasionally, a poroma will be pigmented. Poromas commonly display highly vascularized stroma, and a clinical pattern suggestive of pyogenic granuloma is common, especially in poromas that involve acral skin. Rarely, multiple poromas will develop, either in an acral or in a widespread distribution, a clinical pattern referred to as poromatosis. Poromatosis can occur following chemotherapy and/or radiation therapy.

Up to 90% of sporadic poromas contain *YAP1-MAML2* and *YAP1-NUTM1* fusion genes that can lead to tumorigenesis presumably via transactivation of the transcription factor TEAD[86]. Less often, *WWTR1-NUTM1* fusions and additional fusions involving *NUTM1* are detected. NUT immunohistochemical staining may be used to differentiate poroid neoplasms with *NUTM1* fusions from other types of adnexal tumors[86a].

Pathology

The principal finding in all forms of poroma consists of a circumscribed proliferation of compact cuboidal keratinocytes with small monomorphous nuclei and scant eosinophilic cytoplasm. Poromas can be wholly intraepidermal, a pattern known historically as hidroacanthoma simplex; can occur in broad continuity with the epidermis (juxta-epidermal poroma; Fig. 111.27); or can develop wholly (or nearly so)

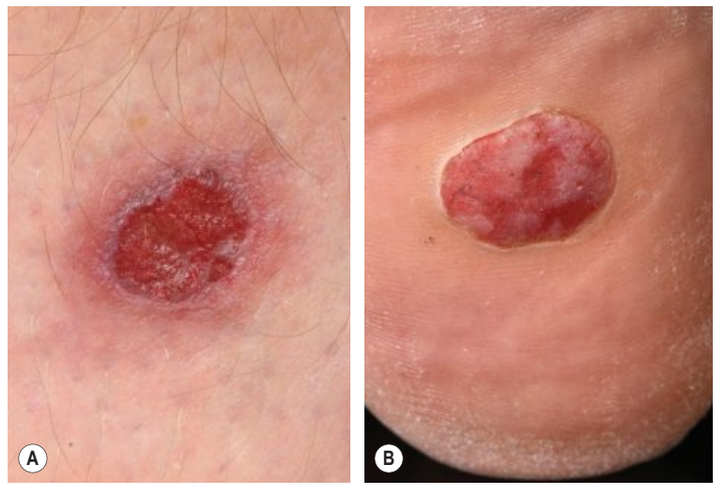

Fig. 111.26 Poromas. Solitary eroded red plaques on the distal lower extremity (**A**) and the plantar surface (**B**). There is resemblance to granulation tissue and a distinct rim is seen. The differential diagnosis often includes amelanotic melanoma and pyogenic granuloma. *A, Courtesy Department of Dermatology, Medical University of Graz; B, Courtesy Lorenzo Cerroni, MD.*

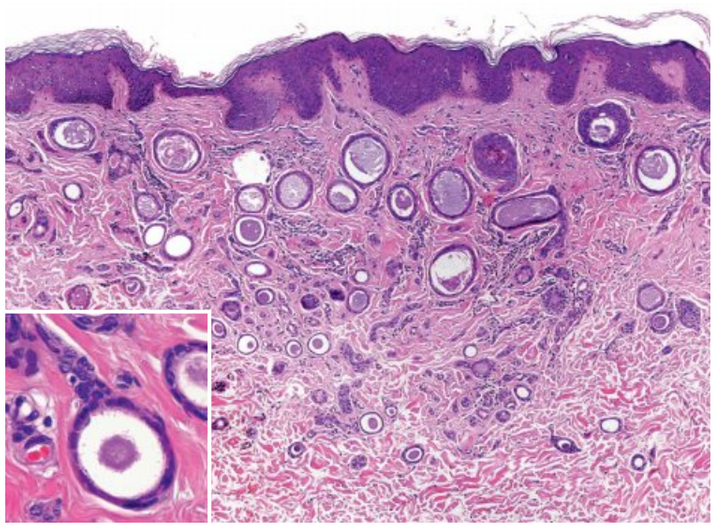

Fig. 111.25 Syringoma. This superficial adnexal neoplasm consists of multiple nests of cells with pale cytoplasm positioned within sclerotic stroma. Many nests show central ductal differentiation with a compact eosinophilic cuticle. A tadpole shape may be seen (inset).

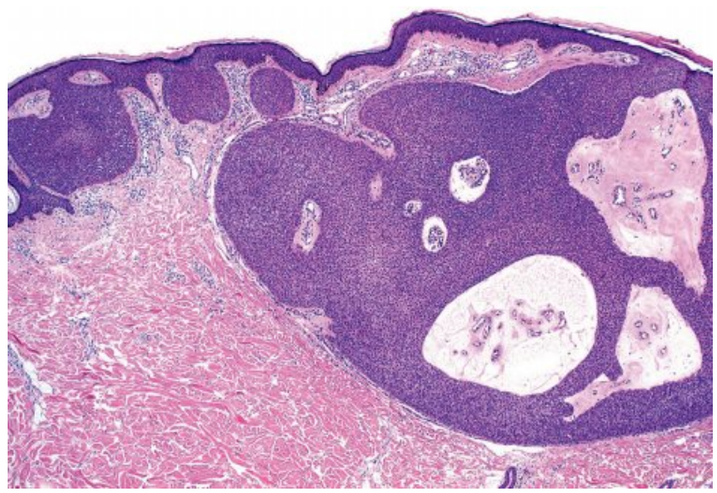

Fig. 111.27 Poroma, juxta-epidermal pattern. This poroma displays a pattern common to both eccrine and apocrine poroma. There are inter-anastomosing cords composed of small compact "poroid" cells, and the intervening stroma is well vascularized.

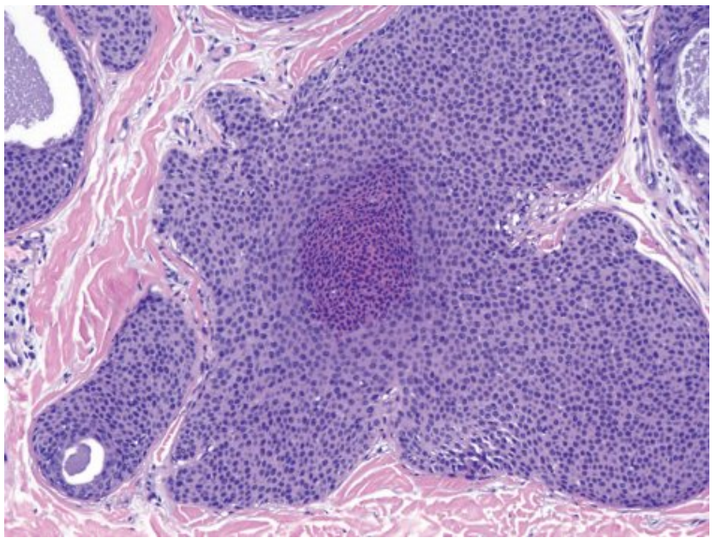

Fig. 111.28 Poroma, intradermal pattern. At low magnification, this lesion was a well-circumscribed dermal nodule. This higher magnification shows conspicuous foci of ductal differentiation at the edges and also a central focus of necrosis *en masse*, a finding common to poroma that is uncommon in other benign neoplasms.

within the dermis (intradermal poroma; Fig. 111.28), a pattern known historically as dermal duct tumor[3]. Accompanying stroma may be scant in association with intraepidermal poroma.

The degree of ductal differentiation varies greatly in individual neoplasms. Some poromas display innumerable foci in which poroid cells form small cuticulated ductal spaces. In other lesions, ducts may be difficult to identify, and a resemblance to seborrheic keratosis may ensue. Expression of GATA3 has been proposed as a useful feature for distinguishing clonal seborrheic keratosis (negative) from hidroacanthoma simplex (positive)[87]. Carcinoembryonic antigen (CEA) immunostaining, which labels the luminal surface of both apocrine and eccrine ducts, can be employed as a tool to confirm the presence of ductal differentiation. Poromas may occasionally display tubular (rather than ductal) foci in which a central cuticle is lacking. If such tubular foci are lined by columnar cells with holocrine secretion at the luminal border, a presumptive diagnosis of apocrine poroma can be offered.

At times, a poroma may display striking clear cell change. The constituent nuclei in such lesions are small but are surrounded by ample pale cytoplasm. Poromas are an exception to the rule that necrosis *en masse* is a clue to a malignancy. Curiously, poromas commonly display small collections of cells in coagulation necrosis. In malignant tumors, necrosis is usually a consequence of rapid growth (growth beyond the capacity of perfusion), but this is an unlikely explanation for necrosis in poroma, in which cellular proliferation is low. Poromas may occasionally display small foci of sebaceous differentiation, which usually consists of clusters of mature sebocytes near the lesion base[83,88].

Treatment

Poroma is a benign adnexal neoplasm and thus treatment is optional. Superficial lesions may be treated by shave or electrosurgical destruction. Superficial or deeper lesions may also be treated with simple excision.

Hidradenoma

Introduction

Hidradenoma is a form of benign adnexal neoplasm that is a close relative of poroma but is usually characterized by cells with ample cytoplasm, is never wholly intraepidermal, and does not commonly have a broad-based connection to the epidermis. As has been mentioned, some authorities use the broad designation *acrospiroma* to refer to both hidradenoma and poroma jointly. Although commonly classified as an eccrine neoplasm, hidradenomas are thought to be of either apocrine or eccrine lineage[74,75]. The majority of hidradenomas show histopathologic features suggestive of apocrine lineage[1,89]. In approximately half of hidradenomas, a t(11;19) translocation, resulting in a *CRTC1-MAML2* fusion gene, is present[90,91]. Fusions of *CRTC3-MAML2* or *EWSR1-POU5F1* have also been described.

Clinical features

Hidradenoma lacks any distinctive clinical attributes. The lesion presents as a solitary dermal or subcutaneous nodule; sometimes, a cystic quality or serous drainage can be detected.

Pathology

Hidradenomas are mostly dermal neoplasms with a nodular, sharply circumscribed pattern when viewed at low magnification. Some hidradenomas may display a juxta-epidermal pattern superficially with multifocal attachment to the epidermis, much like poroma. Although the stroma of hidradenoma is commonly sclerotic and may contain ectatic vessels, usually the granulation tissue-like quality that typifies the stroma of a poroma is not present. If desmoplastic stroma is conspicuous and exaggerated, the designation *desmoplastic hidradenoma* is recommended. The cells of hidradenoma are large with ample cytoplasm but uniform nuclei, which are generally somewhat larger than the nuclei of poroma. Overt clear cell change (clear cell hidradenoma) is common, as is cystic degeneration (solid-cystic hidradenoma)[92] (Fig. 111.29). Ductal differentiation can be found with scrutiny, although the degree observed may be minimal. Some lesions contain tubules lined by columnar cells with a decapitation pattern along their luminal border; such lesions can be designated as apocrine hidradenoma without question. Not surprisingly, tumors with features of both hidradenoma and poroma can be encountered, and the term *poroid hidradenoma* has been applied in this setting to denote a variant of poroma with some features of hidradenoma[93].

Treatment

Hidradenoma is a benign adnexal neoplasm. Complete conservative excision is curative. There are rare reports of hidradenomas with extension isolated to regional lymph nodes[94]; the possibility of a primary nodal hidradenoma has also been raised.

Benign Neoplasms with Apocrine Differentiation

Apocrine adenoma

Introduction

Any benign neoplasm with apocrine differentiation, including poroma and hidradenoma, could be grouped under the broad roof of this rubric. On a practical basis, only adenomas with conspicuous glandular differentiation are included in this category. Usually, these proliferations exhibit abundant apocrine epithelium and conspicuous decapitation secretion, in which part of the cytoplasm pinches off into a lumen. Apocrine adenomas may present with a tubular or papillary microscopic pattern or a combination of the two. Entities within this conglomeration include *tubular adenoma, papillary adenoma, syringocystadenoma papilliferum*, and *hidradenoma papilliferum*. The latter entity, also known as *papillary hidradenoma*, is a source of potential semantic confusion with conventional hidradenoma. Papillary hidradenoma (hidradenoma papilliferum) is an apocrine adenoma that usually exhibits a pronounced frond-like pattern with apocrine epithelium lining the constituent papillae. In contrast, conventional hidradenoma (acrospiroma) exhibits a mostly solid configuration.

Tubular, papillary, or tubulopapillary adenomas with conspicuous apocrine differentiation may develop within the parenchyma or secretory apparatus of the breast. Apocrine adenomas in continuity with the nipple commonly exhibit a tubulopapillary pattern and have been referred to as *erosive adenomatosis*[95,96]. In addition to a tubulopapillary pattern, apocrine adenomas of the nipple may display small foci with solid and cribriform patterns, but usually necrosis is not identifiable. Since such lesions are usually solitary, as erosion is commonly not present, and as the designation erosive adenomatosis is somewhat provocative, it is probably best to employ the simple term *nipple adenoma* in this context. The distinction between nipple adenoma and ductal adenocarcinoma can sometimes be challenging, and consultation with an experienced breast pathologist should be sought in difficult cases.

Clinical features

The presentation of *tubular or papillary adenoma* is not distinctive. These tumors present as smooth papules or nodules, and biopsy is required for diagnosis.

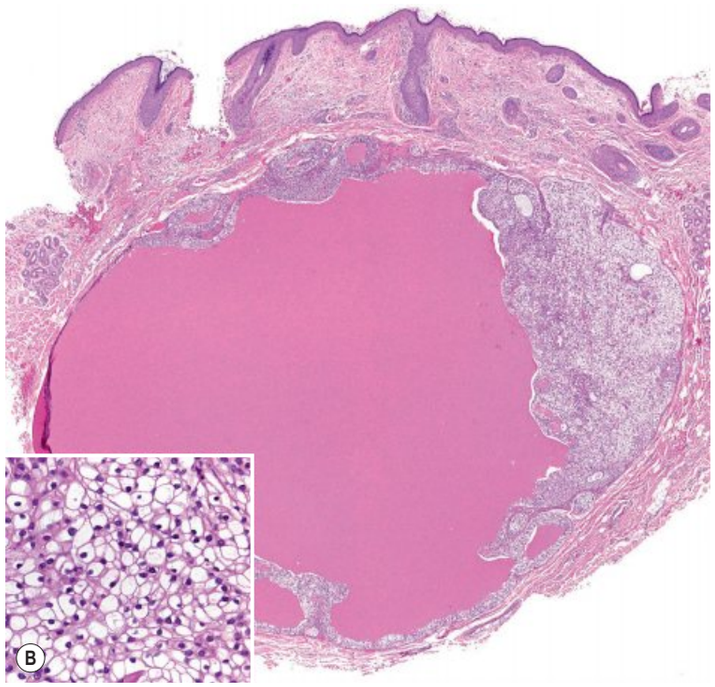

Fig. 111.29 Hidradenoma. A Solitary violaceous nodule on the abdomen with serous drainage. **B** Well-circumscribed nodule with prominent cystic architecture in this solid-cystic variant of hidradenoma. The cells have small uniform nuclei and ample cytoplasm that often is pale or shows overt clear cell change (inset). *B, Courtesy Lorenzo Cerroni, MD.*

Fig. 111.30 Syringocystadenoma papilliferum. Grouped papules and nodules with scale-crust. The possibility of an associated nevus sebaceus needs to be considered.

Syringocystadenoma papilliferum presents as a papule or plaque almost exclusively on the head or neck. Syringocystadenomas usually exhibit a crusted surface that may ooze serosanguinous fluid (Fig. 111.30); this is a reflection of the fact that the papillae of a syringocystadenoma are in continuity with the epidermal surface, permitting extrusion of secretory products. Most papillary syringocystadenomas present on the scalp in association with nevus sebaceus (see Fig. 111.7)[18,97]. Sporadic forms of syringocystadenoma papilliferum can harbor either *BRAF* V600E mutations or activating mutations in *HRAS* (or less often *KRAS*), while those that arise within a nevus sebaceus carry the same *HRAS* mutation as the underlying nevus[17].

Hidradenoma papilliferum usually presents as a smooth dermal or subcutaneous nodule, usually no more than a centimeter in diameter. Most papillary hidradenomas arise on the vulva, but development within skin of the breast, axilla, and inguinal or perianal areas has also been documented[98].

Pathology

At low magnification, *tubular and papillary adenomas* are usually well-circumscribed neoplasms positioned within the dermis, the superficial subcutis, or a combination of the two. Adenomas with a tubular pattern are composed mostly of rounded glandular spaces that vary in size and are lined by one or several layers of cuboidal cells with pale cytoplasm and small nuclei. Most spaces have small lumina and some display columnar apocrine cells apically. Papillary adenomas contain conspicuous tufts, with luminal cells that display an apocrine pattern. A combination of tubular and papillary patterns is not uncommon.

Papillary syringocystadenoma (*syringocystadenoma papilliferum*) is distinctive for its wide papillary fronds that are in continuity with the surface squamous epithelium (Fig. 111.31A,B). Syringocystadenomas are only rarely cystic. The fronds are lined by a bilayer, with basal cuboidal cells and apical columnar apocrine cells, and the cores of fronds virtually always contain a dense infiltrate of lymphocytes and plasma cells (Fig. 111.31C). A plasmacytic infiltrate commonly accompanies neoplasms of apocrine lineage, and thus the mere presence of plasma cells in a given lesion is not sufficient to confirm a diagnosis of syringocystadenoma.

At low magnification, *papillary hidradenoma* (*hidradenoma papilliferum*) consists of a well-circumscribed nodule within the dermis and usually lacks both a connection to the surface epithelium and the prominent plasmacytic infiltrate of syringocystadenoma papilliferum. Both tubules and papillary fronds are usually present, and broad elongated fronds with delicate fibrous cores are usually identifiable (Fig. 111.32). Both tubules and fronds are usually lined by a bilayer, with basal cuboidal myoepithelial cells and apical apocrine cells, and the apical cells usually display a conspicuous holocrine secretion. At least some of the basal layer cells represent authentic myoepithelial cells with contractile function, and labeling of the myoepithelial layer through immunohistochemical staining for actin filaments can sometimes be of diagnostic value in the distinction from adenocarcinoma, which often lacks a complete myoepithelial layer.

Treatment

Apocrine adenomas are completely benign lesions. Complete conservative excision is curative.

Undifferentiated Neoplasms of Apocrine Lineage

Most adnexal neoplasms contain foci of differentiation that may be rudimentary but that are readily interpretable as representing normal structures. For example, while trichoblastoma is largely undifferentiated, it contains foci such as papillary mesenchymal bodies that clearly indicate follicular germinative lineage. In contrast, two closely related entities, spiradenoma and cylindroma, display either a general lack of differentiation or display differentiation not readily identifiable as indicative of a normal structure. Both spiradenoma and cylindroma

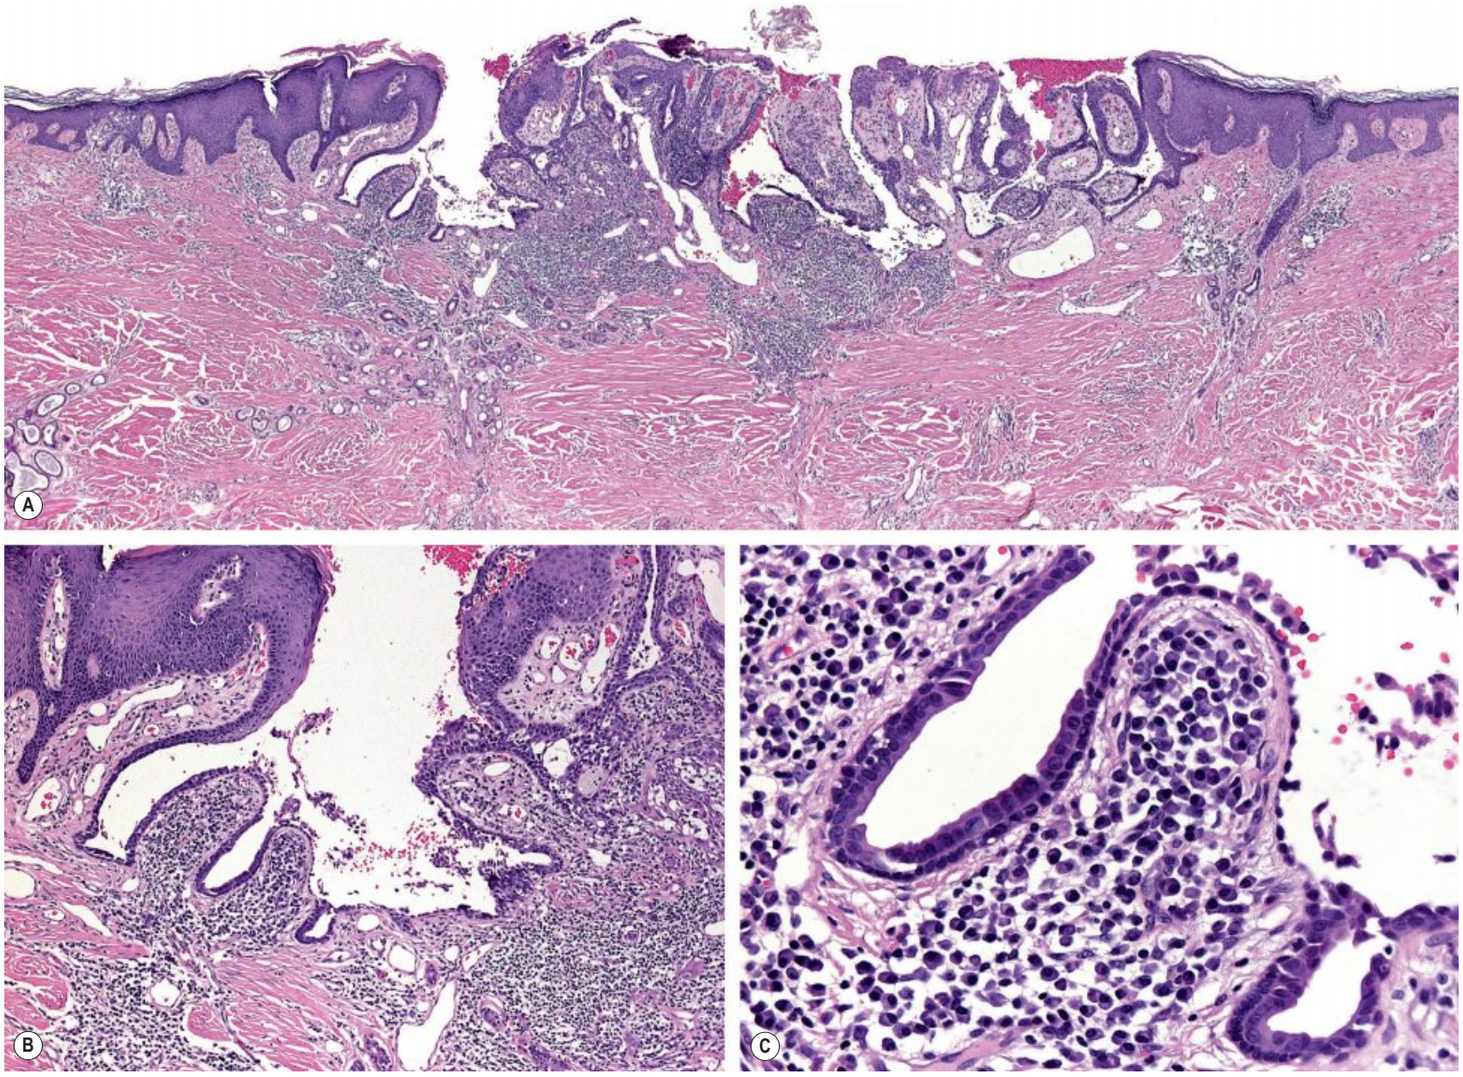

Fig. 111.31 Syringocystadenoma papilliferum. A This neoplasm has an eroded surface and consists of multiple papillary projections composed of dilated ducts surrounded by dense inflammatory infiltrates. **B, C** The papillae are lined by columnar cells that usually display overt apocrine differentiation. The dermal cores of papillae are usually stuffed with lymphocytes and typically many plasma cells. *Courtesy Lorenzo Cerroni, MD.*

occasionally display tubular foci with a decapitation luminal pattern, suggesting apocrine lineage, but mostly these neoplasms display uninterpretable/unrecognizable differentiation.

Spiradenoma

Definition

The term *spiradenoma* connotes a benign adnexal neoplasm that has been historically designated as being of eccrine lineage, although reassessment indicates an apocrine process[1,74,75]. Spiradenoma not uncommonly occurs jointly with cylindroma and both occur jointly with trichoepithelioma/trichoblastoma (see Fig. 111.5); the most parsimonious explanation for this complex juxtaposition is that both spiradenoma and cylindroma are of folliculosebaceous-apocrine lineage[99]. Both spiradenomas and cylindromas occur jointly with trichoepitheliomas in the Brooke–Spiegler syndrome that is due to mutations in *CYLD*, again implying kinship rather than disparate lineage. To date, spiradenoma has never been observed on glabrous (non-hair-bearing) skin. If spiradenoma were truly eccrine, occurrence on the palm or sole would be the rule and not the exception.

Clinical features

Spiradenoma typically presents as a dermal or subcutaneous papule or nodule in nearly any location; extraordinary lesions may achieve a diameter of several centimeters. Sometimes, spiradenomas are painful. The clinical lesions are not distinctive and biopsy is required for diagnosis, although an astute dermatologist can suspect the diagnosis in the setting of a painful nodule with a bluish hue. Spiradenomas may occur in multiplicity and

in concert with cylindromas and trichoepitheliomas/trichoblastomas, and multiple lesions should prompt consideration of a diagnosis of Brooke–Spiegler syndrome. In sporadic spiradenomas, *CYLD* mutations have also been described as has a recurrent, mutually exclusive, missense mutation in the kinase domain of *ALPK1* (α-kinase 1).

Pathology

At low magnification, spiradenoma assumes a multinodular pattern with relatively large nodules positioned within the dermis and subcutis. Although the nodules may be asymmetrically distributed, each is sharply circumscribed. The nodules are composed of basaloid cells without obvious differentiation, although tubular apocrine foci can be observed on occasion. Upon close scrutiny, individual nodules exhibit a trabecular internal morphology, with compact basophilic cells lining the borders of trabeculae and larger cells with scant pale cytoplasm within their centers (Fig. 111.33). Usually, small lymphocytes are scattered throughout trabecular areas. Some large (giant) spiradenomas develop cystic areas of degeneration or striking vascular ectasia as secondary events. Compact eosinophilic basement membrane material, arrayed either as tiny PAS-positive droplets or as circumferential bands, can occasionally be found within a spiradenoma, although such deposits are more commonplace in cylindroma.

Treatment

Spiradenoma is a benign adnexal neoplasm. Despite its basaloid appearance, spiradenoma holds negligible proliferative capacity and recurrence is uncommon after simple enucleation or conservative excision.

Cylindroma

Introduction

The term *cylindroma* describes a form of benign adnexal neoplasm that is closely related to spiradenoma.

Clinical features

Cylindromas can present singly or in multiplicity and are not clinically distinctive; thus a biopsy is required for diagnosis. Solitary lesions commonly appear on the head and neck, especially the scalp (Fig. 111.34), but they can also develop within skin of the trunk or genitalia. Multiple cylindromas may coalesce and form giant mosaic plaques on the scalp, which has been pejoratively referred to as a turban tumor[100,101]. The recognition of multiple cylindromas should prompt consideration of the Brooke–Spiegler syndrome or multiple cylindromatosis (both autosomal dominant conditions), most examples of which are associated with *CYLD* mutations. An *MYB–NFIB* gene fusion, similar to that identified in adenoid cystic carcinoma of the breast or the head and neck, has been described in sporadic cylindromas by some, but not all, investigators.

Pathology

At low magnification, cylindromas consist of sharply circumscribed nodules arrayed within the dermis and/or subcutis. The nodules are composed of nests of basaloid cells in close apposition, arrayed in a complex pattern that has been likened to a jigsaw puzzle. A rim of densely eosinophilic, PAS-positive basement membrane material commonly envelops the individual nests, and droplets of similar composition are often scattered in the centers of small nests (Fig. 111.35). Foci of ductular and apocrine tubular differentiation can sometimes be found but are inconspicuous.

Treatment

Cylindroma is a benign adnexal proliferation. Despite its basaloid appearance, cylindroma holds negligible proliferative capacity and recurrence is uncommon after complete excision.

Carcinomas of apocrine lineage

Introduction

Adnexal carcinomas with tubular and ductular differentiation (adnexal adenocarcinomas) are relatively uncommon, and their rarity has contributed to confusion with respect to diagnosis, classification, and therapy. Adnexal carcinomas can develop *de novo* or they can arise in association with extant benign adnexal neoplasms. The semantics of carcinomas that arise in association with benign neoplasms has been

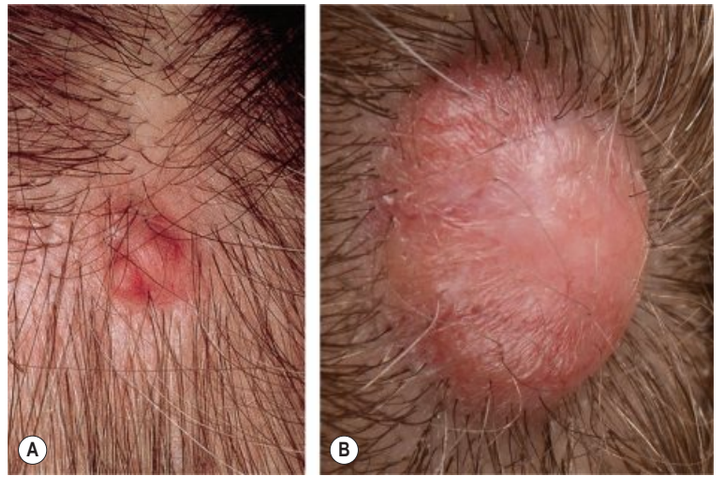

Fig. 111.34 Cylindromas. A, B While numerous tumors aggregated on the scalp are called turban tumors, solitary lesions usually present as smooth erythematous nodules which can vary in size. *B, Courtesy Lorenzo Cerroni, MD.*

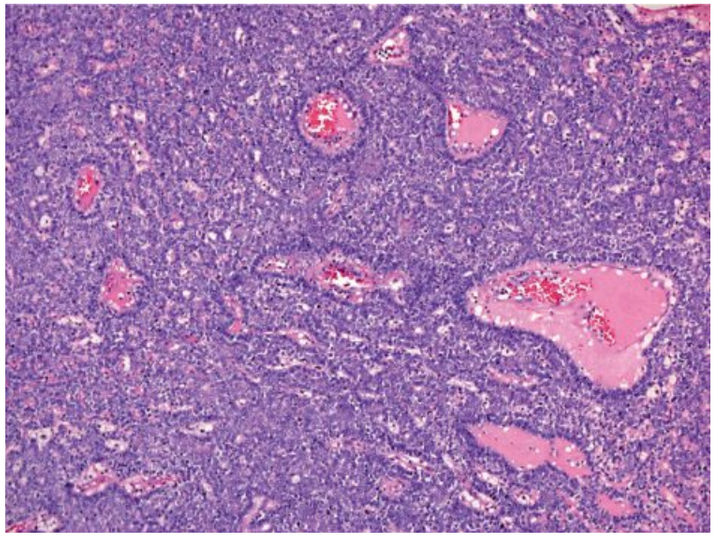

Fig. 111.33 Spiradenoma. Basaloid cells arranged partly in trabecular and mostly in cohesive aggregates with ductal differentiation. Note in larger lumina eosinophilic secretory material. *Courtesy Lorenzo Cerroni, MD.*

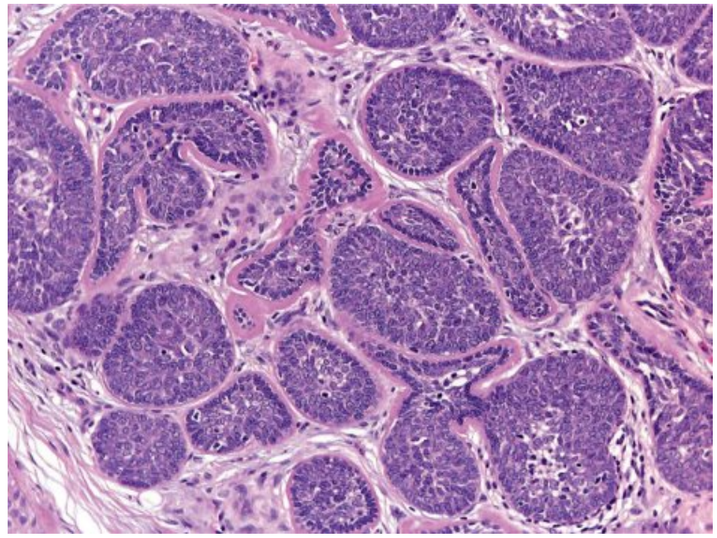

Fig. 111.35 Cylindroma. Nests of basaloid cells in a jigsaw puzzle-like pattern. Many nests are circumferentially enveloped by a dense eosinophilic cylinder of basement membrane material.

problematic, as there has been a historical tendency to create an oxymoronic nomenclature by modifying the name of the benign analogue with the simple addition of the adjective *malignant*. Going forward, correct designations such as porocarcinoma and spiradenocarcinoma should be employed while the oxymoronic designations malignant poroma and malignant spiradenoma should be eschewed[2].

For certain types of adnexal carcinoma, such as spiradenocarcinoma or cylindrocarcinoma, the adenocarcinomas that develop from the benign neoplasm often lack a decisive pattern of differentiation and may only be specifically diagnosable through recognition of a remnant of the residual benign lesion. A spiradenocarcinoma in the absence of detectable spiradenoma will likely only be recognizable as poorly differentiated adenocarcinoma. Some forms of adnexal adenocarcinoma, such as porocarcinoma, display distinctive differentiation that is recognizable in a *de novo* lesion or in a carcinoma that developed within an existent tumor.

Clinical features

In general, the presentation of adnexal adenocarcinomas is not distinctive. Patients who develop adnexal carcinoma within an existent benign neoplasm often relate a history of recent rapid (or explosive) enlargement of a previously stable, longstanding plaque or nodule (Fig. 111.36). Ulceration and bleeding are common associated findings. Adnexal adenocarcinoma presents as a plaque or nodule, and biopsy and microscopy are required for diagnosis.

Perhaps the most is known about the presentation of *microcystic adnexal carcinoma* (MAC), a low-grade form of adnexal carcinoma (also known as *sclerosing sweat duct carcinoma*) that has been carefully evaluated in several large series[102]. MAC typically presents in young or middle-aged adults, most commonly in women and occasionally in children, and lesions slowly enlarge over years and are often misdiagnosed prior to the time of definitive recognition (Fig. 111.37)[102]. The most common location is the lip. Curiously, a left-sided predominance was noted in the largest series from the US, suggesting that UV light exposure (from driving) might be contributory to carcinogenesis, much like common forms of keratinocyte carcinoma.

Pathology

All forms of adnexal adenocarcinoma share architectural attributes of malignancy, such as asymmetry, lack of circumscription, and an infiltrative configuration. There is considerable variability in the degree of cytologic atypia, and no standard currently exists for the grading of these neoplasms. Some forms of adnexal carcinoma may display overtly anaplastic cytomorphology while other carcinomas, such as MAC or syringomatous carcinoma, display very subtle nuclear atypia.

Syringomatous carcinoma refers to a rare form of carcinoma with distal ductal differentiation[103,104]. It may be of either apocrine or eccrine lineage, and generally lineage cannot be discerned microscopically. Syringomatous carcinoma is characterized by poor circumscription and an infiltrative pattern at low magnification and is composed of small nests and tubules of pale cells with central cuticulated ducts. The degree of nuclear atypia is usually modest, and thus a superficial biopsy, which hides the lack of circumscription, can lead to misinterpretation as syringoma. To date, syringomatous carcinoma has only been observed as a *de novo* malignancy.

MAC is a close relative of syringomatous carcinoma that is distinctive for its biphasic or multiphasic differentiation. MAC displays a ductal component identical to that of syringomatous carcinoma coupled with follicular and (sometimes) sebaceous differentiation (Fig. 111.38)[102,105,106]. The follicular component of MAC consists most notably of small cystic (microcystic) foci with follicular infundibular and isthmic keratinization, similar to the superficial follicular keratinization observed in desmoplastic trichoepithelioma or trichoadenoma. Areas resembling the follicular outer sheath may also be present. Extensive infiltration of the reticular dermis and perineural extension of tumor cells are common findings. Although desmoplastic trichoepithelioma and MAC exhibit overlapping features and both are characterized by foci of superficial follicular keratinization, follicular germinative (basaloid) cells are a hallmark of trichoepithelioma but are rarely, if ever, present in MAC. In a minority of cases of MAC, mutually exclusive molecular alterations – inactivation of *TP53* or insertions within *JAK1* – are observed.

Fig. 111.36 Porocarcinoma. Rapid growth and erosion or ulceration accompany this malignant adnexal tumor.

Fig. 111.37 Microcystic adnexal carcinoma. This tumor presents as a slowly expanding, firm plaque that can be subtle clinically.

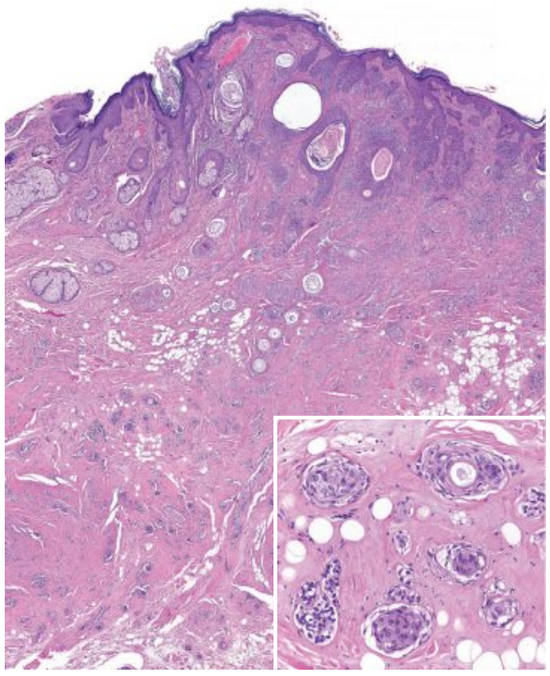

Fig. 111.38 Microcystic adnexal carcinoma. This deeply infiltrative carcinoma shows a biphasic microscopic pattern, with both ductular differentiation and superficial follicular keratinization. The high-magnification inset shows conspicuous ductal differentiation without cytologic atypism, which sometimes leads to misdiagnosis as a benign lesion. *Courtesy Lorenzo Cerroni, MD.*

Porocarcinoma may develop *de novo* or in association with an existent poroma[107]. Like poroma, porocarcinoma may be of apocrine or eccrine lineage, and it is generally impossible to determine the exact lineage of any given tumor. The degree of cytologic atypia is variable[104,108], and some examples of porocarcinoma display little cytologic atypia. Thus, close attention must be paid to other attributes of malignancy and small or partial biopsies may defy exact diagnosis. Porocarcinoma is composed of nests of eosinophilic or pallid cuboidal cells that infiltrate the dermis and perhaps subjacent deeper tissues, and ductal differentiation is usually conspicuous (Fig. 111.39). Porocarcinoma may display intraepidermal growth, with a pagetoid or nested pattern within the epidermis in some cases[104,108]. The same molecular alterations observed in poromas have been described in porocarcinoma (see above), together with mutations in *TP53, RB1, CDKN2A,* and *HRAS* (see Ch. 107).

Hidradenocarcinoma may develop *de novo* or in association with an existent hidradenoma. Hidradenocarcinoma may be of apocrine or eccrine lineage. Cases reported in the older literature were notable for the presence of marked clear cell change, much like clear cell hidradenoma. *CRTC1–MAML2* fusion genes (also seen in up to half of hidradenomas) and amplification of *ERBB2* have been described. The differential diagnosis includes cutaneous metastases of mucoepidermoid carcinoma of the salivary glands.

Spiradenocarcinoma and *cylindrocarcinoma* are usually poorly differentiated carcinomas that develop *de novo* or more commonly in association with an existent spiradenoma or cylindroma[109,110]. Both are extremely rare and may come to medical attention late in their course, as their evolution within longstanding stable lesions may contribute to a delay in pursuit of care by the patient. In addition to the molecular alterations found in their benign counterparts (with the possible exception of *MYB–NFIB* gene fusions), loss-of-function *TP53* mutations and *ALPK1* hotspot mutations have been described in spiradenocarcinoma.

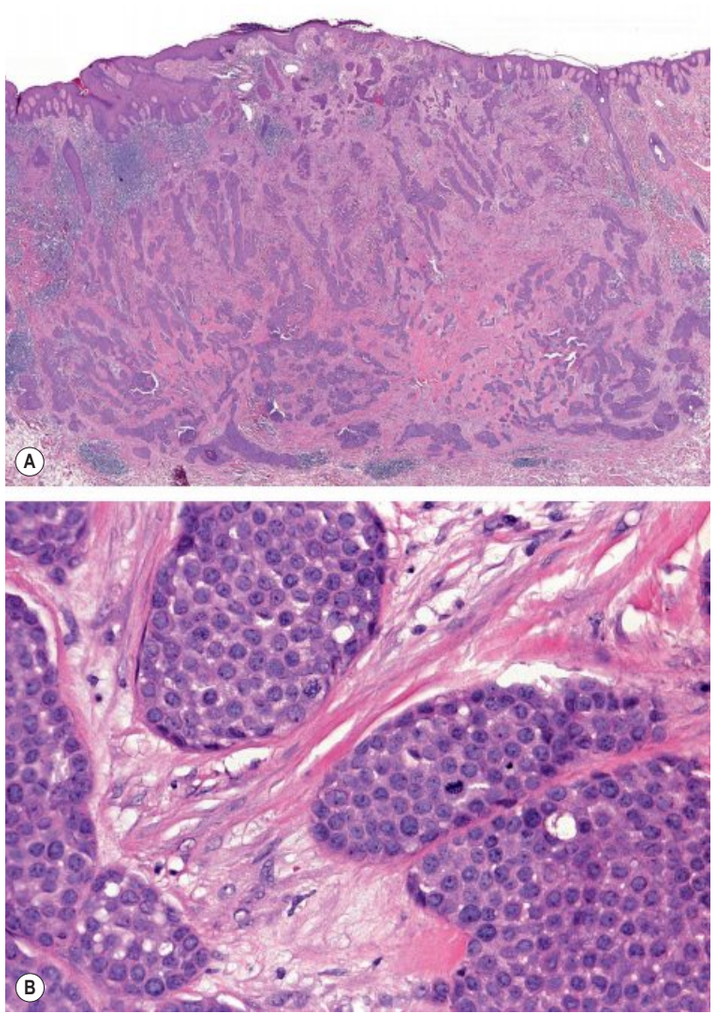

Fig. 111.39 Porocarcinoma. A There are irregularly shaped nests and strands of neoplastic cells that infiltrate deeply. **B** The largest nest shows foci of ductular differentiation. *Courtesy Lorenzo Cerroni, MD.*

Adenoid cystic carcinoma is a type of relatively undifferentiated adnexal carcinoma that resembles micronodular BCC but is generally distinctive for the presence of cribriform (net-like) glandular differentiation and a paucity of accompanying myxoid stroma. Primary cutaneous adenoid cystic carcinomas have been misinterpreted as metastatic lesions. Although initially postulated to represent a type of eccrine carcinoma, most authorities believe the entity represents a neoplasm of apocrine lineage. Adenoid cystic carcinoma tends to display considerable local invasiveness and most examples remain confined to the skin over years or even decades, but metastasis to lymph nodes and parenchymal organs can also rarely occur[111]. CD117 immunopositivity has been reported in association with adenoid cystic carcinoma and may be of value in providing additional diagnostic support. Fusion genes involving *NF1B*, most commonly mutually exclusive *MYB–NFIB* or *MYBL1–NFIB* fusions, have been reported.

Primary cutaneous cribriform carcinoma is a partially circumscribed tumor composed of interconnected solid aggregations of basophilic epithelial cells perforated by empty round spaces resulting in a sieve-like or cribriform pattern. Intraluminal bridges are typically present. This tumor has some resemblance to adenoid cystic carcinoma and is often in the differential diagnosis of the latter. The most reliable microscopic findings that favor adenoid cystic carcinoma over cribriform carcinoma include a poorly circumscribed pattern of growth, the presence of basophilic mucinous material within lacunae, and a lack of intraluminal bridges.

Mucinous carcinoma, another form of adnexal adenocarcinoma, is characterized by small collections of epithelial cells floating in large pools of mucin. The epithelial cells can sometimes assume a cribriform configuration. An associated *in situ* component is present in some cases. In our view, the relatively recently described entity *endocrine mucin-producing sweat gland carcinoma* is a variant of mucinous carcinoma rather than a unique entity. Lastly, *extramammary Paget disease* may represent extension of an underlying apocrine carcinoma and this entity is discussed in detail in Chapter 73.

Secretory carcinoma of the skin is another form of adnexal adenocarcinoma[111a]. It is characterized by a well-circumscribed proliferation of relatively cytologically bland cells configured as nodules. The nodules contain tubular and microcystic spaces with abundant eosinophilic secretions. Foci of more solid growth are also seen. Most cases of secretory carcinoma of the skin are associated with an *ETV6-NTRK3* fusion gene[111b].

Treatment

As a generality, the majority of adnexal adenocarcinomas are low-grade forms of carcinoma that are locally invasive but pose a low risk for metastasis. Many adnexal carcinomas that yield metastatic spread are large or were diagnosed late in their evolution. Surgical extirpation, including removal via Mohs micrographic surgery, remains the primary therapeutic modality. Careful microscopic classification is crucial to developing experience with larger groups of histopathologically homogeneous lesions in order to assess natural history as well as proper medical and surgical care.

NEOPLASMS AND PROLIFERATIONS WITH ECCRINE DIFFERENTIATION

Eccrine nevus (hamartoma)

Nevi or malformations with an eccrine glandular component are extremely uncommon. The clinical morphology of such lesions is not distinctive. Some lesions are alleged to maintain function of the eccrine apparatus. This can manifest clinically as mucinous discharge or localized hyperhidrosis.

Microscopically, the judgment as to whether eccrine glands are normal in number or increased can be difficult, especially in a partial biopsy. The absolute number of eccrine units is increased and the constituent units are of increased size in eccrine nevi. The surrounding stroma may be exclusively fibrotic or may include adipocytes. When the stroma also harbors an increase in small vascular channels, the designation *eccrine angiomatous hamartoma* can also be applied (see Fig. 39.5). For skin tag-like lesions on the coccygeal area, the term *coccygeal polypoid eccrine nevus* has been applied.

Fig. 111.40 Porokeratotic eccrine ostial and dermal duct nevus. Markedly hyperkeratotic spines arise from dilated eccrine ostia, corresponding to the histologic findings of cornoid lamellae. Note the linearity of several of the lesions. *Courtesy Julie V. Schaffer, MD.*

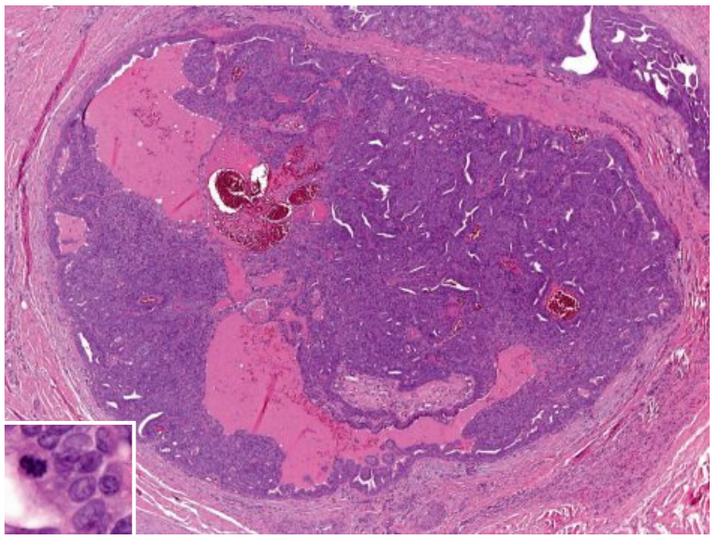

Fig. 111.41 Papillary adenocarcinoma of the digit. Partly cystic, irregular tumor with tubular and papillary foci. Mitotic figures are easily identified (inset). *Courtesy Lorenzo Cerroni, MD.*

So-called porokeratotic eccrine ostial and dermal duct nevi are probably not eccrine nevi at all. These lesions are typically congenital and present as papules or plaques on the hands or feet, with digitate hyperkeratosis (Fig. 111.40). The focal hyperkeratosis corresponds to cornoid lamellae that are often situated within acanthotic acrosyringia. Eccrine acini are qualitatively and quantitatively normal in porokeratotic nevi, suggesting that these lesions should not be classified as a form of adnexal nevus. From the standpoint of nosology, these lesions probably fit best on the spectrum of epidermal nevi. Somatic mosaicism for mutations in *GJB2*, which encodes connexin 26 (see Ch. 58), has been reported in patients with porokeratotic eccrine ostial and dermal duct nevi.

Treatment

Eccrine nevi are benign and require no treatment. Excision can be completed as an optional step.

Syringoma, poroma, hidradenoma, adnexal adenocarcinoma

(See above.)

Syringofibroadenoma

Syringofibroadenomas are rare tumors, usually located on the limbs. They may be associated with Clouston syndrome or Schöpf–Schulz–Passarge syndrome. They are characterized by an irregular network of thin cords and strands of epithelial cells extending down from the epidermis. Ductal structures are usually present. A similar pattern may be observed in some cases of chronic stasis dermatitis or in a site of trauma or chronic ulceration. This has prompted some authorities to view syringofibroadenoma as a reactive process rather than an authentic neoplasm.

Papillary adenoma and adenocarcinoma

Introduction

The concept of *papillary adenoma* was originally put forth under the designation *aggressive digital papillary adenoma*[112–114]. These neoplasms are uncommon and often occur on acral skin of the fingers, toes, palms and soles, a topographic restriction that suggests that many or most are of eccrine lineage. Papillary adenoma was deemed aggressive because the neoplasms were prone to local recurrence if not completely excised, and some lesions were found to erode bone or infiltrate adjacent soft tissue[113]. Some neoplasms first classified as aggressive papillary adenoma have metastasized[114], and thus it appears this spectrum includes both adenomas and adenocarcinomas. It has also been suggested that all acral papillary lesions represent adenocarcinomas, but this seems biologically unlikely. Of note, human papillomavirus 42 has recently been described as a tumor driver in aggressive digital papillary adenocarcinoma[115].

Clinical features

Papillary adenoma/adenocarcinoma presents as a solitary nodular lesion in an adult of any age. Lesions up to several centimeters in diameter have been observed. There is a male predilection. The lesions may be deeply situated and can impinge upon or erode underlying bone. The favored metastatic route appears to be hematogenous, and metastases involving the lung can occur.

Pathology

Papillary adenocarcinomas are extraordinarily cellular and display a combination of solid and papillary areas; they are occasionally cystic (Fig. 111.41)[113]. A cribriform pattern can sometimes be found. For carcinomas with a largely cribriform or tubular configuration, the designation tubulopapillary carcinoma can be employed. Irrespective of the architecture of the lesion, its constituent cells have hyperchromatic nuclei and relatively little cytoplasm, and mitotic figures are usually readily identifiable. There may be necrosis of individual cells or necrosis *en masse*. The enveloping stroma is commonly sclerotic. In overtly malignant lesions, vascular invasion or infiltration of bone may be observed. However, superficial biopsies that contain the cystic portions of the tumor may fail to show atypical features and can lead to the misdiagnosis of hidrocystoma or cystadenoma.

Treatment

It is difficult to predict the clinical course based upon the microscopic pattern. Complete surgical extirpation of papillary adenocarcinoma remains the standard of care, sometimes requiring partial amputation of the affected finger or toe. Because of diagnostic ambiguity, papillary adenomas should also be fully excised.

INTRODUCTION

Melanocytic nevi are benign melanocytic neoplasms that most commonly develop within the epidermis or dermis. Histologically, there is a proliferation of melanocytes, both in nests and as solitary cells, with the nests defined as aggregates of three or more melanocytes in direct contact. Melanocytic nevi are usually caused by genomic aberrations (oncogenic mutations or translocations) that activate oncogenes and result in a clonal proliferation of affected melanocytes.

The non-nevus melanotic lesions discussed in this chapter can also be tan to dark brown or black in color, but in contrast to melanocytic nevi, they have minimal, if any, increase in melanocyte density. In addition, there is no nesting of melanocytes. Their hyperpigmentation is due to an increase in melanin synthesis and its subsequent transfer to keratinocytes. Other benign and malignant tumors (e.g. seborrheic keratoses, keratinocyte carcinomas) that can also be hyperpigmented are discussed in Chapters 108–111 and 115.

CIRCUMSCRIBED MELANOTIC LESIONS

EPHELIDES

Synonym: ■ Freckles

Key features

- Small, uniformly pigmented macules in sun-exposed sites
- More common in fair-skinned individuals and more noticeable in summer than in winter
- Hyperpigmentation of the basal layer of the epidermis without an increase in melanocyte density

Epidemiology and Pathogenesis

Ephelides are common in fair-skinned individuals, especially those with red hair, and occur more frequently in women. They first appear in early childhood and usually stabilize in number during adulthood, followed by gradual fading. Ephelides result from an increase in sun-induced melanin synthesis and transport of melanosomes from melanocytes to keratinocytes. Frequent sunburns and variants of the melanocortin-1 receptor gene (*MC1R*) play an important role in the development of ephelides (see Fig. 65.13)[1].

Clinical Features

Ephelides are limited to sun-exposed sites – primarily the face, upper trunk, and dorsal aspects of the arms. Ephelides are well demarcated, uniformly pigmented, oval to irregular-shaped macules that are usually 1 to 3 mm in size. Depending upon the intensity of sun exposure, ephelides vary in color from light to medium brown. In the summer, they are more conspicuous and then fade during the winter. Ephelides are benign with no potential for malignant transformation. However, higher numbers of ephelides correlate with an increased risk of acquired melanocytic nevi and melanoma[2].

Pathology

There is hyperpigmentation of the basal layer of the epidermis without an increase in the number of melanocytes. Compared to adjacent uninvolved epidermis, melanocytes in ephelides are larger and have more branching of dendrites and stronger DOPA positivity, indicating increased activity[3].

Differential Diagnosis

Ephelides must be distinguished from simple lentigines, solar lentigines, small café-au-lait macules, and junctional nevi. In addition to being confined to sun-exposed skin, the clinical appearance of ephelides varies depending upon the amount of exposure to UVR (Table 112.1). Café-au-lait macules are usually solitary and larger than ephelides.

Treatment

If ephelides are a cosmetic concern, sun exposure should be minimized and use of sunscreens, hats, and protective clothing recommended. Topical retinoids and hydroquinone may lighten lesions, but it is difficult to achieve an homogeneous clinical effect and potential side effects (e.g. irritation, dyspigmentation) need to be considered. Pigment-specific lasers represent an additional treatment option, but recurrences are common[4].

COMPARATIVE CLINICAL FEATURES OF EPHELIDES AND SOLAR LENTIGINES		
	Ephelides (freckles)	**Solar lentigines (see Ch. 109)**
Epidemiology		
Age of appearance	Early childhood	By 20–30 years (I, II)
Skin color	Light pigmentation	Light to dark pigmentation
Hair color	Often red or blond hair	Any type
Skin phototype	More common in I, II	More common in I and II, but also in III and IV
History		
Precipitating factors	Bursts of high-intensity sun exposure activate latent predetermined melanocytes, leading to permanent freckles	Repeated sun exposure over time alters melanocytes within a circumscribed area to overproduce melanin
Duration of lesions	Fade without sun exposure	Persist for life
Relation to season	Much darker in summer, fade in winter and over time with aging	May darken in summer but do not fade in winter
Heredity	Probably AD; also AR when related to *MC1R* variants	No data
Physical examination		
Type of lesion	Macule	Macule
Size	1–5 mm	5–15 mm or larger
Color	Light or medium brown	Medium or dark brown
Shape	Oval to irregular	Oval to irregular
Border	Smooth to jagged	Smooth to jagged
Distribution	Favor the face, extensor forearms, and back; rare on the dorsal aspect of the hands	Sites of chronic sun exposure, especially the face, arms (including dorsal aspect of the hands), and upper trunk
Dermoscopic features		
	Uniform pigmentation and a moth-eaten edge	Diffuse light brown structureless areas, sharply demarcated and/or moth-eaten borders, fingerprinting, and a reticular pattern with thin lines that are occasionally short and interrupted

Table 112.1 Comparative clinical features of ephelides and solar lentigines. I, II, III, IV = skin phototypes (see Ch. 134); AD, autosomal dominant; AR, autosomal recessive; MC1R, melanocortin-1 receptor.

CAFÉ-AU-LAIT MACULES

Key features

- Well-circumscribed, uniformly light to dark brown macules or patches
- Usually 2 to 5 cm in diameter (in adults), but can vary from a few mm to >20 cm in size
- Hyperpigmentation of the basal layer of the epidermis without an increase in melanocyte density
- Found in 10%–20% of the normal population, but multiple lesions raise the possibility of an underlying genetic disorder

Epidemiology

Café-au-lait macules (CALMs) may be present at birth, but usually become clinically apparent during the first year of life. The number of CALMs in an individual can vary from one to more than a dozen. Single CALMs are found in 10% to 20% of the normal population, and up to 1% of healthy children have up to three CALMs, especially African-American children[5].

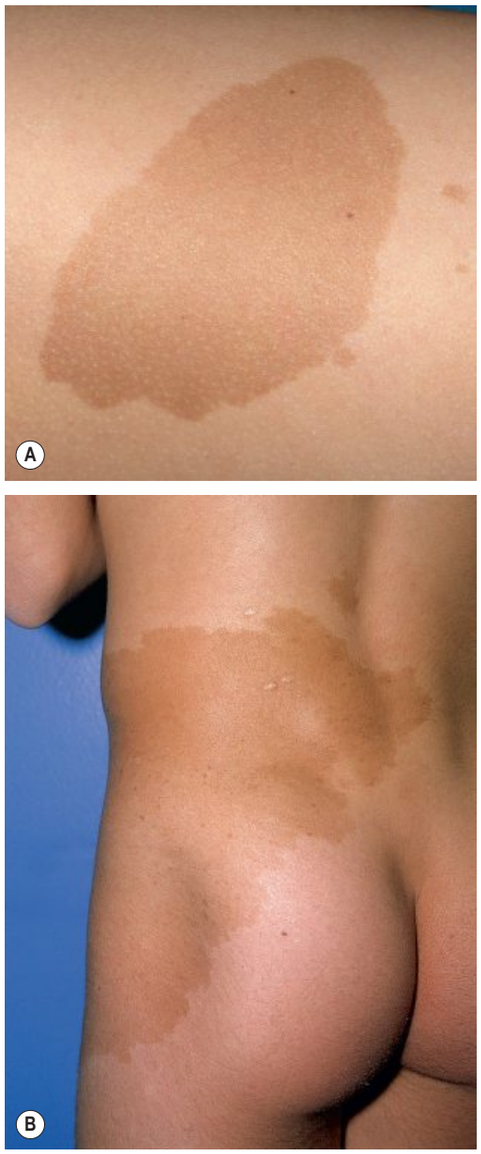

Fig. 112.1 Café-au-lait macules (CALMs). **A** Typical CALM with well-defined and regular margins in a patient with neurofibromatosis 1. **B** Large tan patch in a geographic pattern on the lateral trunk. The patient did not have McCune–Albright syndrome. *A, Courtesy Julie V. Schaffer, MD.*

Pathogenesis

The hyperpigmentation observed in CALMs is due to an increase in the melanin content within keratinocytes. While the underlying pathogenesis is not fully understood, UVR-independent mediators that stimulate melanin synthesis and transfer are likely involved (see Ch. 65). In patients with neurofibromatosis 1, biallelic *NF1* inactivation has been identified in melanocytes from CALMs (see Fig. 61.8), and in patients with McCune–Albright syndrome, affected skin contains activating mutations in the gene that encodes $G_s\alpha$ (see Fig. 65.14).

Clinical Features

The term café-au-lait refers to the characteristic homogeneous color of CALMs, reminiscent of coffee with milk. Their color varies from light to dark brown and correlates with the individual's background constitutive pigmentation. CALMs are macular and most have an oval shape with a distinct regular border and uniform color ("typical" CALMs; Fig. 112.1A). CALMs are usually 2–5 cm in diameter in adults but can vary from freckle-like lesions (≤2 mm) to patches that are >20 cm in diameter (Fig. 112.1B). CALMs enlarge proportionately with overall body growth and then remain stable in size during adulthood.

CALMs are benign lesions that may be located anywhere on the body, with the exception of the mucous membranes. By dermoscopy, a homogeneous brown patch is seen with perifollicular hypopigmentation; a faint reticular pattern may also be present. When multiple CALMs are present, the possibility of an underlying genetic disorder needs to be considered (Table 61.3). Compared with neurofibromatosis type 1 (NF1), the CALMs of McCune–Albright syndrome are typically fewer in number, larger, have a midline demarcation, and tend to be unilateral. If present, superimposed lentigines (due to widespread "freckling" extending beyond the axillae) can point to NF1-associated CALMs.

Pathology

Light microscopy shows a normally configured epidermis with a slight increase in melanin within basilar keratinocytes, but no or a minimal increase in melanocyte number. The adnexal epithelium is spared of hyperpigmentation. Melanin macroglobules (large pigment particles resulting from fusion of autophagosomes containing varying numbers of melanosomes) are often seen in NF-associated CALMs[6], but are also found in normal skin, isolated CALMs, and other pigmented lesions.

Differential Diagnosis

Hyperpigmented macules or patches that might be confused with CALMs include pigmentary mosaicism (segmental pigmentation disorder, Blaschko-linear hyperpigmentation), early nevus spilus (before the "speckles" have appeared), Becker melanosis (without obvious hypertrichosis), mastocytoma, mosaic (segmental) neurofibromatosis, and postinflammatory hyperpigmentation. Smaller lesions may resemble lentigines or acquired melanocytic nevi, while larger lesions may be confused with relatively flat congenital melanocytic nevi. Café-noir spots are hyperpigmented patches that have an even darker hue (relative to background skin) than CALMs and are seen in LEOPARD syndrome (Noonan syndrome with multiple lentigines) and Carney complex.

Treatment

Topical agents (e.g. hydroquinone) and sun protection have no effect on CALMs. The clinical response to pigment-specific laser therapy is difficult to predict (see Ch. 137), and recurrence rates are frequent[4]. In addition to recurrence, risks of laser surgery include transient hyperpigmentation or hypopigmentation, slight scarring, permanent hyperpigmentation, and incomplete clearance.

BECKER MELANOSIS (NEVUS)

Synonyms: ■ Becker's nevus ■ Becker's pigmentary hamartoma ■ Nevoid melanosis

Key features

- Unilateral, hyperpigmented, often hypertrichotic patch or slightly elevated plaque
- Most commonly on the anterior or posterior chest of male patients
- Onset usually during adolescence

Epidemiology

Becker melanosis occurs in ~1 in 200 individuals, with no racial predilection. This cutaneous hamartoma is usually unilateral and can initially appear as a light brown patch during late childhood to adolescence, followed by an increase in thickness, pigmentation, and hair growth. The latter changes are thought to reflect its androgen dependence. While Becker melanosis is often reported to be six times more common in males than in females, a more equal sex distribution has been suggested with androgen-dependent changes leading to a higher incidence of its diagnosis in men[7].

Pathogenesis

Postzygotic mutations in *ACTB*, which encodes beta-actin, have been detected in the majority of Becker nevi and in Becker nevus syndrome. There is some evidence that the *ACTB* mutations may lead to activation of the Hedgehog signaling pathway in these organoid hamartomas[8]. Other investigators observed an increase in androgen receptors in dermal fibroblasts, and an increased sensitivity to androgens has been postulated[9]. This would provide an explanation for the onset of Becker melanosis during or after puberty, as well as its clinical and histologic manifestations, which include hypertrichosis, dermal thickening, acne, and hypertrophic sebaceous glands.

Clinical Features

The onset of Becker melanosis is usually noted during the second decade of life. Lesions are usually unilateral and involve an upper quadrant of the anterior or posterior chest (Fig. 112.2A,B). However, they have also

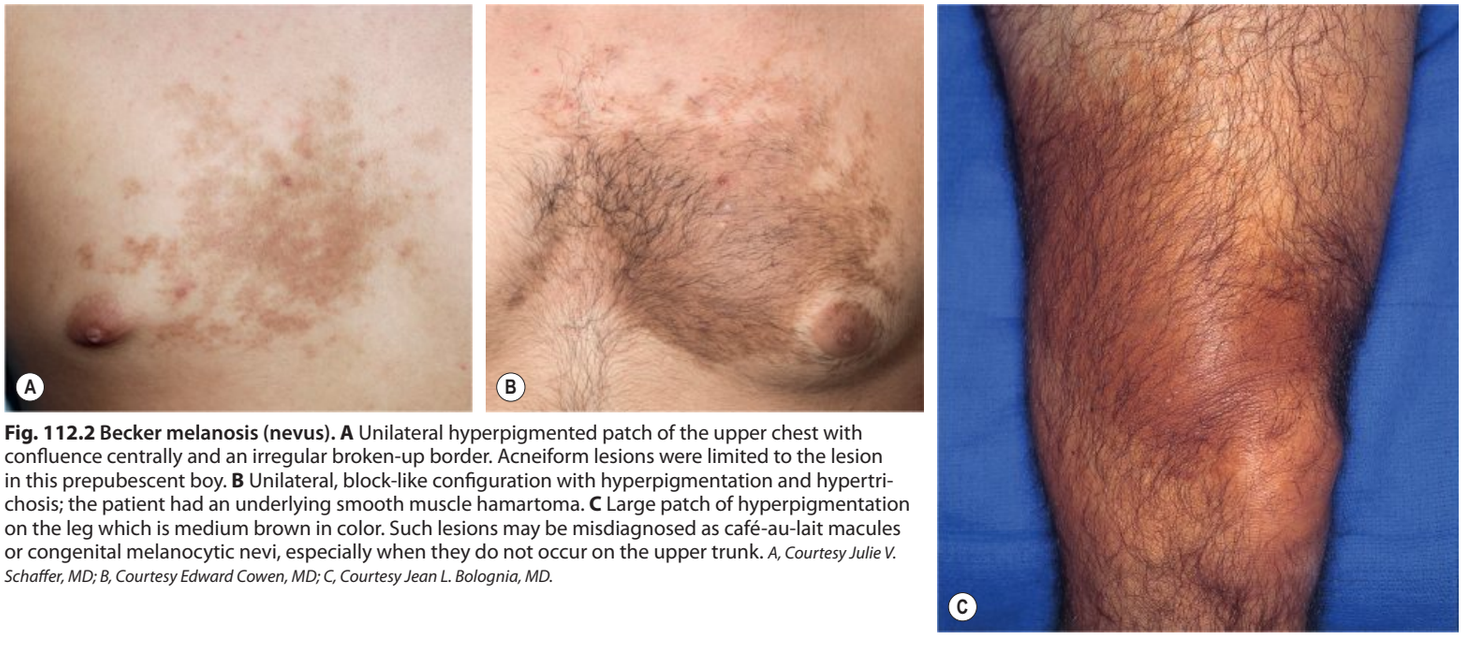

Fig. 112.2 Becker melanosis (nevus). A Unilateral hyperpigmented patch of the upper chest with confluence centrally and an irregular broken-up border. Acneiform lesions were limited to the lesion in this prepubescent boy. **B** Unilateral, block-like configuration with hyperpigmentation and hypertrichosis; the patient had an underlying smooth muscle hamartoma. **C** Large patch of hyperpigmentation on the leg which is medium brown in color. Such lesions may be misdiagnosed as café-au-lait macules or congenital melanocytic nevi, especially when they do not occur on the upper trunk. *A, Courtesy Julie V. Schaffer, MD; B, Courtesy Edward Cowen, MD; C, Courtesy Jean L. Bolognia, MD.*

been described on the face, neck, lower trunk, extremities, and buttocks (Fig. 112.2C). Normally, Becker melanosis appears as a single lesion, but multiple lesions have occasionally been observed. The diameter ranges from a few centimeters to >15 cm, and the most common configuration is block-like, although linear patterns have been reported.

The hyperpigmentation varies from uniformly tan to dark brown, and while the lesions are well demarcated, the margins are usually irregular. The center of the lesion may show slight thickening and corrugation of the skin. Hypertrichosis usually develops after the hyperpigmentation, and the hairs become coarser and darker with time (see Fig. 112.2B). Sometimes, the hypertrichosis is subtle and can only be appreciated by comparison with the contralateral side. The hypertrichosis and pigmentation may not overlap completely. After its initial appearance, Becker melanosis may enlarge slowly for a year or two but then remains stable in size. The color can fade with time, but hypertrichosis usually persists.

Normally, Becker melanosis is asymptomatic, but some patients report pruritus. Firmness to palpation may point to an associated smooth muscle hamartoma. In some patients, perifollicular papules may be a sign of coexistent proliferation of the arrector pili muscle. Acneiform lesions strictly limited to the area of hyperpigmentation have also been reported.

Becker melanosis is a benign lesion, and malignant transformation has not been reported. In contrast to the hyperplasia of the ectodermal and mesodermal tissues in Becker melanosis, developmental anomalies that are generally hypoplastic in nature have occasionally been associated with Becker melanosis (often referred to as Becker nevus syndrome). These abnormalities include hypoplasia of the ipsilateral breast, areola, nipple and arm, ipsilateral arm shortening, lumbar spina bifida, thoracic scoliosis, and pectus carinatum, as well as enlargement of the ipsilateral foot. Accessory scrotum and supernumerary nipples have also been reported. In cases of Becker melanosis with associated abnormalities, the male : female ratio is reversed at 2 : 5 (in comparison to the reported 6 : 1 in those without abnormalities)[10].

Pathology

There is a variable degree of acanthosis, hyperkeratosis, and sometimes mild papillomatosis. Regular elongation of the rete ridges and hyperplasia of the pilosebaceous unit may be observed. The melanin content of the keratinocytes is increased, whereas the number of melanocytes is normal or only slightly increased, without nesting. Melanophages may be found in the papillary dermis. A concomitant smooth muscle hamartoma is often, but not invariably, present in the dermis.

Differential Diagnosis

The differential diagnosis primarily includes CALM, congenital melanocytic nevus, plexiform neurofibroma, and congenital smooth muscle hamartoma. The latter hamartoma tends to be smaller in size, but some authors consider Becker melanosis and congenital smooth muscle hamartoma to be two ends of a clinical spectrum (see Ch. 117). Surface corrugation, noted with side-lighting, is not seen in CALMs. A congenital melanocytic nevus, plexiform neurofibroma, and congenital smooth muscle hamartoma can all have cutaneous hyperpigmentation plus hypertrichosis. By dermoscopy, Becker melanosis, as compared to congenital nevi, is less likely to have focal thickening of network lines, globules, or homogeneous diffuse pigmentation. In an occasional patient, histologic evaluation is required to confirm the diagnosis, especially if the lesion is in an unusual location and there is an associated smooth muscle hamartoma.

Treatment

Patients with Becker melanosis should be examined for possible soft tissue and bone abnormalities (see above). When there are cosmetic concerns, electrolysis, waxing, camouflage makeup, and laser treatments represent therapeutic options. The hypertrichosis is often easier to address than the hyperpigmentation via laser therapy (see Ch. 137). As with CALMs, incomplete clearance and recurrences are commonly observed[4].

SOLAR LENTIGINES

Synonyms: ■ Lentigo senilis ■ Liver spot ■ Old age spot ■ Senile freckle

Key features

- Tan to dark brown or black macules, primarily in sun-exposed sites in middle-aged and older adults
- Hyperpigmentation of the basal layer of the epidermis, usually in association with elongation of the rete ridges
- No or only a slight increase in the number of melanocytes

Solar lentigines are common benign lesions resulting from chronic UVR exposure that results in epidermal hyperplasia. These lesions are found in >90% of the White population older than 60 years of age (Fig. 112.3 & Fig. P1), but are also seen in Asians, especially on the face (see Ch. 87). The clinical differential diagnosis includes macular seborrheic keratosis (oftentimes considered on a spectrum with solar lentigo), pigmented actinic keratosis, pigmented Bowen disease, and lentigo maligna as well as benign pigmented lesions such as lentigo simplex, ephelis, small CALM, and junctional melanocytic nevus. Solar lentigines are discussed in detail in Chapter 109.

LENTIGO SIMPLEX AND MUCOSAL MELANOTIC MACULES

Synonyms:

- Lentigo simplex: • simple lentigo • lentiginosis (if multiple)
- Mucosal melanotic macules: • mucosal melanotic lesions • lentiginosis • melanosis
- Anatomic subtypes: • oral melanotic macules • labial melanotic macules • genital lentiginosis • anogenital lentiginosis

Key features

- Persistent brown macule that appears at an early age (when compared to a solar lentigo)
- Little or no relationship to sun exposure
- Hyperpigmentation of basilar keratinocytes with a slightly increased number of singly arranged melanocytes

Epidemiology

Lentigines are more common in those with lightly pigmented skin, but can occur in all skin phototypes. There is no sex predilection. Lentigines often appear during childhood and then increase in number

Fig. 112.3 Solar lentigines. Numerous light brown macules, some of which have an irregular border, on chronically sun-exposed skin.

from puberty into early adulthood. Of note, isolated lesions may be present at birth. Sometimes there is an eruptive form called lentiginosis, with or without obvious precipitating factors. After melanocyte activation, lentigo simplex represents the most common histology in matrix biopsies of longitudinal melanonychia (see Ch. 71). In darkly pigmented individuals, lentigo simplex is the most common histologic pattern for cutaneous pigmented lesions in acral sites.

Oral melanotic macules are found primarily in adults over 40 years of age. The most common sites are the vermilion border, followed by the gingiva, the buccal mucosa, and the palate. From 30% to 60% of melanomas within the oral cavity are preceded by melanosis for several months or years. The *labial (lip) melanotic macule* usually appears between the second and fourth decades of life and has a strong predilection for White women.

The incidence of *lentiginosis or melanosis* of the female *genital area* is probably higher than reported. For example, 15% of 106 females between the ages of 16 and 42 years had genital "nevi", and in a study of 100 random autopsies, three cases showed melanosis of the genitalia. Most lesions are found on the labia minora, but they can also occur on the labia majora, the vaginal introitus, the cervix, the periurethral area, and the perineum as well as perianally. In general, lentiginosis and melanosis of the female genitalia are benign conditions; atypia is uncommon and progression to melanoma has rarely been observed[11].

In a study of 10 000 men between 17 and 25 years, 14% were noted to have "pigmented nevi" of the genitalia[12]. It is uncertain what proportion represented penile lentiginosis or melanosis since no clinical descriptions or histologic studies were reported. In the literature, the ages of patients with penile lentiginosis or melanosis range from 15 to 75 years. The glans penis, penile shaft, and perianal region are the most common sites of involvement of anogenital lentiginosis in men.

The incidence of primary acquired melanosis (PAM) of the *conjunctiva* is unknown. It is nearly always unilateral and is subdivided into two groups: PAM with no atypia and PAM with atypia. The latter can progress to melanoma. PAM must be distinguished from conjunctival nevi (thicker and more circumscribed) and complexion-associated melanosis (bilateral and around the limbus) as well as melanoma.

Pathogenesis

Hyperpigmentation of the basilar keratinocytes likely arises from an increased production of melanin and the slightly increased number of singly arranged melanocytes. To date, insights into lentigo formation have not been forthcoming despite the discovery of the genetic bases of several syndromes associated with lentiginosis. In contrast to solar lentigines (see Ch. 109), somatic activating mutations in *FGFR3* or *PIK3CA* are absent in lentigo simplex[13]. Some penile lesions have been reported to follow injury, irritation, or PUVA therapy; in women, hormonal factors are thought to play a role. Acral lentigines may be influenced by genetic factors since they are frequently found in darkly pigmented individuals.

Clinical Features

Lentigines simplex are light brown to black, homogeneously pigmented macules. They are well circumscribed and round or oval, have regular borders, and are usually <5 mm (often <3 mm) in diameter. These lentigines can occur anywhere on the body, including palmoplantar skin, without any predilection for sun-exposed sites. Mucosal melanotic macules frequently have irregular, ill-defined borders as well as mottled non-homogeneous pigmentation with areas devoid of pigment (Fig. 112.4); in contrast to cutaneous lesions, they can slowly increase in size over months to years, with or without changes in the degree of pigmentation. By dermoscopy, mucosal lentigines have a fingerprint pattern with narrow parallel lines and broader track-like pigmentation interrupted by dots and globules.

Lentigines simplex occur as solitary or multiple lesions. Multiple or generalized lentigines may be an isolated phenomenon, either present at birth or appearing during childhood or adulthood, or it may be a sign of a genetic disorder (Table 112.2).

Fig. 112.4 Genital lentiginosis. Biopsy of the clinically most atypical lesion (at 7 o'clock) showed no cellular atypia. Over a period of 10 years, several of the macules faded. *Courtesy Jean L. Bolognia, MD.*

DISORDERS ASSOCIATED WITH MULTIPLE LENTIGINES	
Disorders	**Comments**
Generalized	
LEOPARD syndrome (now referred to as Noonan syndrome with multiple lentigines)	• Autosomal dominant inheritance (high penetrance, variable expressivity); mutations in *PTPN11* > *RAF1* > *BRAF* • *L*entigines present in infancy/early childhood • Café-noir macules • *E*CG changes (conduction defects, hypertrophic cardiomyopathy), *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormal genitalia, growth *r*etardation and *d*eafness
Generalized lentigines	• Autosomal dominant inheritance; mapped to 4q21.1–q22.3 • Café-au-lait macules
Deafness plus lentiginosis*	• ? Forme fruste of LEOPARD syndrome
Carney complex (NAME/LAMB syndrome)	• Autosomal dominant inheritance; mutations in *PRKAR1A* (second locus on 2p16) • Lentigines, mucocutaneous myxomas, blue nevi (including epithelioid) • Psammomatous melanotic schwannomas • Atrial myxoma • Myxoid mammary fibroadenomas • Pigmented nodular adrenocortical disease; testicular (calcifying Sertoli cell), thyroid, and pituitary tumors
Arterial dissection plus lentiginosis	• ? Inheritance pattern • Cutaneous lentigines with onset in childhood • Dissection of aortic, internal carotid, and vertebral arteries

Table 112.2 Disorders associated with multiple lentigines.

Continued

DISORDERS ASSOCIATED WITH MULTIPLE LENTIGINES	
Disorders	**Comments**
Generalized	
Gastrocutaneous syndrome*	• Autosomal dominant inheritance; see Table 61.3 for details
Tay syndrome*	• ? Autosomal recessive inheritance • Growth retardation, intellectual disability; triangular face; cirrhosis; trident hands • Café-au-lait macules; premature canities; vitiligo
Pipkin syndrome*	• Autosomal dominant inheritance • Nystagmus; strabismus
Localized	
Head and neck (including oral mucosa) ± acral	
Peutz–Jeghers syndrome	• Autosomal dominant inheritance; mutations in *STK11* • Lentigines favor perioral region†, oral mucosa‡ and hands; longitudinal melanonychia • Multiple hamartomatous GI polyps • Pancreatic carcinoma; ovarian (adenoma malignum)/testicular tumors
Bandler syndrome*	• Autosomal dominant inheritance • Distribution of lentigines similar to Peutz–Jeghers • GI bleeding with small intestine "hemangiomas" rather than polyps
Laugier–Hunziker syndrome	• Similar distribution of lentigines as in Peutz–Jeghers, including lips, oral mucosa, and digits • Longitudinal melanonychia and genital melanosis
Hyperkeratosis-hyperpigmentation (Cantú) syndrome	• Autosomal dominant inheritance • Punctate palmoplantar keratoderma • Multiple small (1 mm) macules on the face, forearms, hands/feet
Cowden disease	• Autosomal dominant inheritance; mutations in *PTEN* • Periorificial and acral pigmented macules (see Table 63.3)
Centrofacial lentiginosis (neurodysraphic)	• Autosomal dominant inheritance • Lentigines in a butterfly distribution on the nose, cheeks > forehead, eyelids, upper lip • Onset in infancy; increase in number in childhood • Possibly associated with neuropsychiatric illness and osseous anomalies
Inherited patterned lentiginosis	• Autosomal dominant inheritance • African-Americans with light brown skin • Pigmented macules appear in early childhood • Present on central face and lips > buttocks, elbows, hands/feet • Rare oral mucosal involvement
Cronkhite–Canada syndrome	• Typically affects older men • Lentigines of buccal mucosa, face, hands/feet • Alopecia (diffuse, non-scarring), nail dystrophy, intestinal polyposis, diarrhea, malabsorption
Genital	
Bannayan–Riley–Ruvalcaba syndrome	• Autosomal dominant inheritance; mutations in *PTEN* • Penile > vulvar pigmented macules (see Table 63.3)
"Photodistribution"	
Xeroderma pigmentosum	• Autosomal recessive inheritance; mutations in genes encoding proteins that repair UV-induced DNA damage • Lentigines favor, but are not limited to, chronically sun-exposed sites • Multiple skin cancers
Segmental	
Partial unilateral lentiginosis (PUL)	• Multiple lentigines in a segmental distribution • Café-au-lait macules in same distribution • Both PUL and "zosteriform" speckled lentiginous nevus can be seen in patients with mosaic NF1 (segmental NF)

*To date, observed in 1–2 families.
†May fade.
‡Persists.

Table 112.2 Disorders associated with multiple lentigines. ECG, electrocardiogram; GI, gastrointestinal; LEOPARD, *l*entigines/*E*CG abnormalities/*o*cular hypertelorism/*p*ulmonary stenosis/*a*bnormalities of genitalia/*r*etardation of growth/*d*eafness syndrome; NAME, *n*evi/*a*trial myxoma/*m*yxoid neurofibroma/*e*phelides syndrome; LAMB, *l*entigines/*a*trial myxoma/*m*ucocutaneous myxoma/*b*lue nevi syndrome. *Adapted from Bolognia JL. Disorders of hypopigmentation and hyperpigmentation. In: Harper J, Oranje A, Prose N (eds). Textbook of Pediatric Dermatology, 2nd edn. Oxford: Blackwell Science, 2006:997–1040.*

Associated syndromes

In *LEOPARD syndrome* (now referred to as Noonan syndrome with multiple lentigines), the acronym refers to: *l*entigines, *e*lectrocardiographic conduction defects, *o*cular hypertelorism, *p*ulmonary stenosis, *a*bnormalities of genitalia, *r*etardation of growth, and *d*eafness (see Table 112.2). Multiple lentigines are present at birth or appear during early infancy and may increase in number during childhood. The lesions are generalized, occurring in both sun-exposed and sun-protected sites, including genitalia, palms, and soles.

The *Carney complex* is an autosomal dominant syndrome characterized by multiple lentigines and multiple neoplasias, including: myxomas of the skin, heart (atrial), and breast; psammomatous melanotic schwannomas; epithelioid blue nevi of skin and mucosae; growth hormone-producing pituitary adenomas; and testicular Sertoli cell tumors (Fig. 112.5A). Components of the Carney complex have been described previously as the *NAME* (*n*evi, *a*trial myxoma, *m*yxoid neurofibroma, *e*phelides) and *LAMB* (*l*entigines, *a*trial myxoma, *m*ucocutaneous myxoma, *b*lue nevi) syndromes.

Fig. 112.5 Genetic disorders associated with multiple lentigines. A Numerous, variably shaped, tan to dark brown lentigines, with the greatest number on the midface in a patient with Carney complex (NAME/LAMB syndrome). **B** Lentiginosis of the vermilion and mucosal lips in a patient with Peutz–Jeghers syndrome. *Courtesy Edward Cowen, MD.*

Peutz–Jeghers syndrome is also an autosomal dominant disorder characterized by mucocutaneous lentigines which are present at birth or appear during childhood in combination with intestinal polyposis (Fig. 112.5B). The skin lesions have an acrofacial distribution pattern and favor the perioral region (see Fig. 53.31). Mucosal lesions may affect the palate, tongue, buccal mucosa, and conjunctivae. The major differential diagnosis is *Laugier–Hunziker syndrome* in which there are acromucosal lentigines and longitudinal melanonychia, but no consistent internal manifestations (Fig. 112.6).

In *partial unilateral lentiginosis*, also referred to as segmental lentiginosis, there is unilateral clustering of lentigines, suggesting a developmental abnormality of melanocytes. The onset is often during childhood. There is no background hyperpigmentation (as in nevus spilus) and the lesion can expand in a wavefront-like manner. Patients with facial lesions may have ocular involvement and CALMs may also be present. Partial unilateral lentiginosis may be associated with mosaic (segmental) NF1 (see Table 61.2).

Pathology

Lentigo simplex is characterized by increased melanin in the basal layer and sometimes even in the upper layers of the epidermis and the stratum corneum. The number of melanocytes in the basal layer is slightly increased, but there are no melanocytic nests. Melanophages and a mild inflammatory infiltrate are often present in the superficial dermis.

Lesions on mucous membranes, including the lips, show acanthosis with or without elongation of the rete ridges (Fig. 112.7). Slight melanocytic hyperplasia is usually observed, but may be absent. Hyperkeratosis, telangiectasia, activated fibroblasts, and large dendritic melanocytes have been described in labial melanotic macules. Ultrastructurally, melanin macroglobules have been observed within the melanocytes, as well as in keratinocytes and melanophages. These are not specific for lentigo simplex since they have been described in other pigmented lesions (see above).

Differential Diagnosis

The differential diagnosis of a solitary lentigo simplex consists primarily of a junctional melanocytic nevus, a flat form of compound melanocytic nevus, solar lentigo, and ephelis. In some instances, cutaneous melanoma, pigmented spindle cell nevus, and cutaneous intracorneal hemorrhage might enter into the differential diagnosis. Although there is a continuum from simple lentigo to junctional melanocytic nevus, the former is often smaller than the latter and it may not show distorted skin markings when viewed with side-lighting. Lentigo simplex is usually distinguished from a solar lentigo by its smaller size, symmetry, uniform pigmentation, and lack of relationship to sun-exposed sites. However, this clinical distinction may not be possible in some instances.

Fig. 112.6 Labial and acral lentigines in two patients with Laugier–Hunziker syndrome. A Multiple hyperpigmented macules on the lower lip and a few on the tongue; Peutz–Jeghers syndrome can have a similar clinical appearance. **B** Numerous lentigines on the palms. *B, Courtesy Drs. Tello Flores and Sánchez Félix.*

Treatment

In general, there is no need to treat a benign-appearing lentigo simplex. Lesions on acral or mucous membranes should be evaluated carefully and, if clinically atypical, should be considered for biopsy to assess for melanocytic atypia. Patients with both generalized and localized lentiginosis should undergo investigation to exclude systemic disease (see Table 112.2).

DERMAL MELANOCYTOSIS

Synonyms: ■ Congenital dermal melanocytosis: • Mongolian spot

Key features

- Blue to blue–gray patch present at birth that is most commonly located in the lumbosacral region
- Usually resolves during childhood
- More common in Asians
- Sparse dendritic melanocytes in the deeper dermis

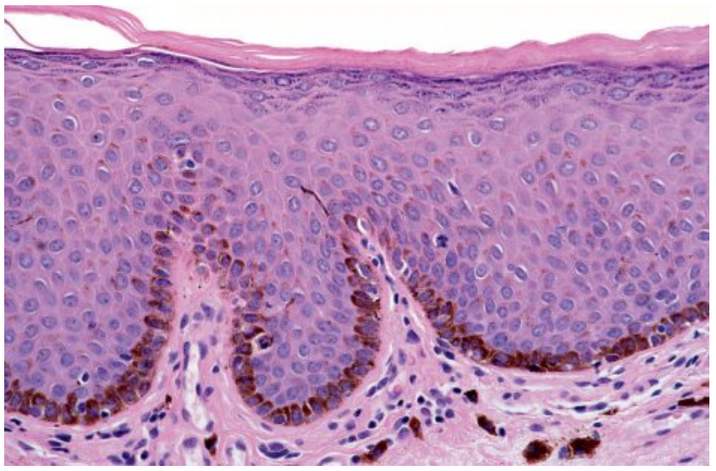

Fig. 112.7 Labial melanotic macule (lentigo) – histopathologic features. Hyperpigmented rete ridges are broader than in the typical lentigo. In addition to basilar hyperpigmentation and melanophages, a few dendritic processes of melanocytes are seen. *Courtesy Lorenzo Cerroni, MD.*

Epidemiology

Dermal melanocytosis is usually present at birth or appears within the first weeks of life; rarely, lesions appear after early childhood. Dermal melanocytosis usually regresses during early childhood, but it can persist and was seen in 4% of Japanese males between 18 and 22 years of age. While there is no sex predilection, the frequency varies widely depending upon ethnicity, e.g. 100% in Malaysians, 90%–100% in Mongolians, Japanese, Chinese and Koreans, 87% in Bolivian Indians, 65% of Black individuals in Brazil, 17% of White individuals in Bolivia, but only 1.5% of White persons in Brazil. These differences suggest that genetic factors influence survival of dermal melanocytes. Microscopically, histologic findings consistent with dermal melanocytosis can be found in the presacral area of 100% of newborns, irrespective of race[14].

Pathogenesis

The blue color in dermal melanocytosis is secondary to melanin-producing melanocytes in the middle to lower dermis. Melanocytes appear in the dermis during the 10th week of gestation and then either migrate into the epidermis or undergo cell death, except for melanocytes in the dermis of the scalp, extensor aspects of the distal extremities, and the sacral area. The latter is the most common site for dermal melanocytosis. The bluish coloration results from the Tyndall phenomenon: dermal pigmentation appears blue because of decreased reflectance of light in the longer-wavelength region compared with the surrounding skin. Longer wavelengths, such as red, orange and yellow, are not reflected, compared with the shorter wavelengths of blue and violet, which are reflected.

Clinical Features

The classic location is the sacrococcygeal and lumbar regions and the buttocks, followed by the back. Dermal melanocytosis may consist of a single or multiple patches and usually involves <5% of the body surface area. The lesions are macular and have a round, oval, or angulated shape. The size varies from a few to more than 20 cm with the color varying from light blue to dark blue to blue–gray. Extrasacral variants tend to be more persistent, and there is overlap between persistent lesions and the entities adult-onset dermal melanocytoses, nevus of Ito, and patch blue nevus. Extensive dermal melanocytosis should raise the possibility of phakomatosis cesioflammea (type II phakomatosis pigmentovascularis [PPV]) and phakomatosis cesiomarmorata (type V PPV; see Table 104.4). When CALMs and satellite congenital melanocytic nevi reside within areas of dermal melanocytosis, a rim that lacks dermal melanocytes may be seen around each lesion (Fig. 112.8).

Pathology

Bipolar, pigmented dendritic melanocytes are dispersed singly in the lower half of the dermis. These melanocytes are DOPA-positive and lie parallel to the epidermis between the collagen bundles without disturbing the normal architecture of the skin. Occasionally, persistent dermal melanocytosis has the histology of a blue nevus with involvement of the subcutis, muscle, and fascia by melanocytes, but lacks thick collagen bundles. On electron microscopy, dermal melanocytosis shows fully developed melanocytes with mature, electron-dense melanosomes and few premelanosomes.

Fig. 112.8 Dermal melanocytosis (Mongolian spots) in a child with neurofibromatosis 1. Surrounding each café-au-lait macule there is an absence of the characteristic blue discoloration.

Differential Diagnosis

The differential diagnosis of dermal melanocytosis includes nevus of Ota, nevus of Ito, and patch blue nevus. The latter has many names in the literature, including dermal melanocyte hamartoma, acquired dermal melanocytosis, and acquired linear dermal melanocytosis; clearly there is overlap with the rare adult-onset dermal melanocytosis. The clinical differential diagnosis may also include venous malformations or deep infantile hemangiomas and a contusion. Although the distinctive clinical presentation of dermal melanocytosis generally allows easy distinction from these entities, there have been reports of the misdiagnosis of child abuse.

Treatment

Persistent lesions may be treated with cover-up cosmetics or lasers (see nevus of Ota).

NEVUS OF OTA, NEVUS OF ITO, AND RELATED CONDITIONS

Synonyms:

- Nevus of Ota: • nevus fuscoceruleus ophthalmomaxillaris • oculodermal melanocytosis • congenital melanosis bulbi • oculomucodermal melanocytosis
- Nevus of Ito: • nevus fuscoceruleus acromiodeltoideus
- Nevus of Ota-like macules: • Hori nevus

Key features

- Blue to blue–gray to blue–brown unilateral patch on the face (nevus of Ota) or the shoulder region (nevus of Ito)
- More common in Asians
- More dermal dendritic melanocytes than in dermal melanocytosis, but less than in blue nevus

Nevus of Ota

Epidemiology

Nevus of Ota occurs predominantly in individuals with darker skin phototypes, especially in Asians, but has also been described in White individuals[15]. Approximately 80% of all reported cases have been in women; however, this figure may be somewhat skewed as a result of greater cosmetic concerns in women. In Japan, nevus of Ota is seen in ~0.4%–0.8% of all dermatologic patients. The lesion has two peaks of onset: the first (~50%–60% of all cases) is during infancy (before the age of 1 year), with the majority present at birth, and the second (40%–50%) is around puberty. Although rare familial forms of nevus of Ota have been reported, the condition is generally not considered hereditary.

Pathogenesis

The blue to blue–gray color in nevus of Ota is due to melanin-producing melanocytes in the dermis. The larger concentration of melanocytes in nevus of Ota in comparison to dermal melanocytosis is thought to indicate a hamartoma. Somatic activating mutations in *GNA11* or *GNAQ* were detected in up to 15% of cases of nevus of Ota, as compared to 65%–75% of blue nevi (primarily *GNAQ*) and 80%–85% of primary uveal melanomas[16]. In mice, germline mutations in *Gnaq* lead to an increase in dermal pigmentation. The possibility of a hormonal influence in women has been raised.

Clinical features

Nevus of Ota is usually characterized by a confluence of individual macules varying from pinhead-sized to several millimeters in diameter (Fig. 112.9A). The shape of the individual macules may be round, oval, or serrated, whereas the overall appearance is that of an irregularly demarcated and often mottled patch. The overall size varies from a few centimeters to extensive unilateral and occasionally bilateral involvement. The color varies from shades of brown to gray, blue, black, and purple.

Nevus of Ota is usually unilateral and favors the distribution of the first two branches of the trigeminal nerve. The most common sites of involvement are the periorbital area, temple, forehead, malar area, earlobe, pre- and retroauricular regions, nose, and conjunctivae. In approximately two-thirds of patients, the ipsilateral sclera is involved. Rarely, nevus of Ota affects the cornea, iris, fundus oculi, retrobulbar fat, periosteum, retina, and optic nerve. Iris mammillations and glaucoma (~10% of patients)[17] have been reported, but vision is usually not impaired. Other frequent sites of involvement include the tympanum (55%), nasal mucosa (30%), pharynx (25%), and palate (20%). Occasionally, the external auditory canal, mandibular area, lips, neck, and thorax are involved. In 5% to 15% of patients, the lesion is bilateral.

Nevus of Ota may extend over time and persists for life. Variations in color intensity have been described, especially in association with periods of hormonal flux such as menstruation, puberty, or menopause.

Melanomas arising within nevi of Ota are unusual, with uveal melanomas estimated at 1 in 400 in White individuals and even less often in Asians. Cutaneous melanomas are rare, but typically have presented as new subcutaneous nodules, although other tumors such as atypical cellular blue nevi have also been described[18]. In addition to the uveal tract, primary melanomas of the orbit, chiasma, and meninges have been observed in association with nevus of Ota, as it is one of the entities that can have associated neuromelanosis and meningeal melanocytomas. Of note, *BAP1* mutations have been detected in cases that progressed to melanoma, pointing to a role in malignant transformation.

Pathology

The non-infiltrated areas in nevus of Ota show pigmented, elongated, and dendritic melanocytes scattered between the collagen bundles (Fig. 112.9B). In comparison to dermal melanocytosis, the cells are more numerous and located within the upper third of the reticular dermis. Occasionally, cells are found also in the papillary dermis and deep in the subcutaneous fat.

Hyperpigmentation of the basal epidermis and an increase in basilar melanocytes may occur. The DOPA reactivity of the melanocytes in nevus of Ota varies: slightly pigmented cells are often strongly reactive, whereas heavily pigmented melanocytes often are not reactive, indicating minimal residual enzymatic activity. Melanocytes can be found clustering around blood vessels as well as sweat and sebaceous glands. Raised or infiltrated areas show a larger number of dendritic melanocytes forming cellular aggregates or clumps resembling blue nevi histologically.

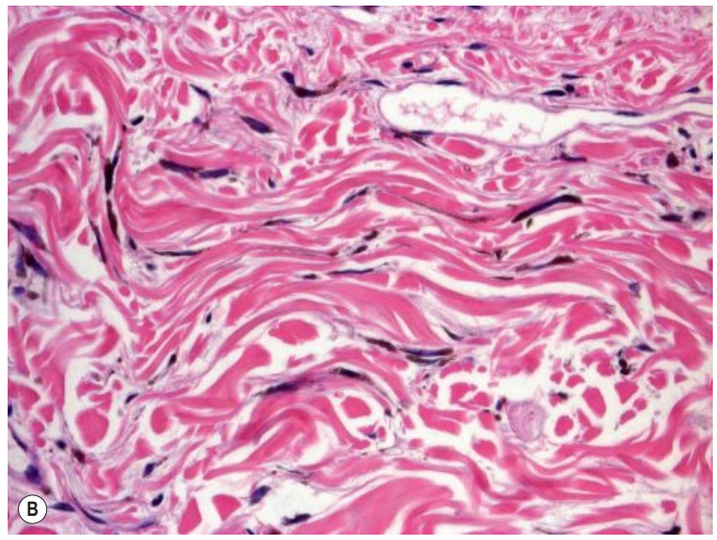

Fig. 112.9 Nevus of Ota (oculodermal melanocytosis) – clinical and histopathologic features. A Unilateral blue–gray discoloration of the face, which is either mottled or confluent. There is also involvement of the sclera. **B** Scattered pigmented elongated and dendritic melanocytes within the reticular dermis. *B, Courtesy Lorenzo Cerroni, MD.*

Differential diagnosis

The differential diagnosis of nevus of Ota includes dermal melanocytosis (Mongolian spot), adult-onset dermal melanocytosis, blue nevus (patch or plaque), melasma, partial unilateral lentiginosis (when it involves the face), a nevus spilus that develops blue nevi, venous malformations, and ecchymoses. Dermal melanocytosis differs from nevus of Ota and other dermal melanocytoses due to its location in the lumbosacral region and its spontaneous regression during childhood.

Treatment

Nevus of Ota and nevus of Ota-like macules have been treated successfully by Q-switched ruby, alexandrite, and Nd:YAG lasers[4,19]. Although malignant changes are rare in patients with nevus of Ota, patients with eye involvement should be followed more carefully by an ophthalmologist, since the majority of associated melanomas are ocular in origin and some patients develop glaucoma. Suspicious lesions, especially a new subcutaneous nodule, should be biopsied. Any complaint of neurologic symptoms requires further investigation.

Nevus of Ito and Related Conditions

Nevus of Ito involves the shoulder with extension onto the lateral upper trunk, corresponding to the distribution of the lateral cutaneous and

posterior supraclavicular brachial nerves. While its location differs from that of nevus of Ota, the clinical appearance and histologic features are the same. Occasionally, there is an associated ipsilateral or bilateral nevus of Ota.

Acquired nevus of Ota-like macules (Hori nevus) are characterized by bilateral, grouped, blue–gray to gray–brown macules of the zygomatic area. Less often, similar lesions are on the forehead, upper outer eyelids, and nose. This entity has been reported primarily in Chinese or Japanese women ranging from 20 to 70 years of age. In contrast to nevus of Ota, the eye and oronasal mucosa are not involved. It is often misdiagnosed as melasma, but the distinction is important as nevus of Ota-like macules can be successfully treated with laser surgery, similar to nevus of Ota.

Patch blue nevus overlaps with the rare disorder adult-onset dermal melanocytosis and presents as a diffusely gray–blue area that may have superimposed darker macules. The age of onset and sites of involvement vary, with some lesions having a linear distribution.

MELANOCYTIC NEVI

The term "nevus" is used to describe a hamartoma (e.g. epidermal nevus, sebaceous nevus) or a proliferation of melanocytes. Melanocytic nevi are defined histologically by nests of melanocytes, with a nest representing an aggregate of three or more melanocytes in direct contact. Melanocytic nevi are usually caused by genomic aberrations (mutations, translocations) that activate oncogenes, resulting in a clonal proliferation of melanocytes (Table 112.3). Genetic syndromes in which patients develop numerous melanocytic nevi are summarized in Table 112.4.

BLUE NEVUS AND ITS VARIANTS

Synonyms: ■ Blue nevus of Jadassohn–Tièche ■ Dermal melanocytoma ■ Nevus bleu ■ Blue neuronevus

Key features

- Blue to blue–black, firm papule, nodule or plaque, often with an onset during childhood or adolescence
- Aggregates of heavily pigmented, dendritic, spindled, or epithelioid melanocytes within the dermis

Epidemiology

In White populations, the estimated prevalence of blue nevi is 0.5%–1% while in Japanese adults, it is up to 4%. The ratio of common blue nevi to cellular blue nevi is at least 5 : 1. In general, congenital blue nevi are unusual, with most blue nevi arising during childhood or adolescence and up to a quarter first appearing in middle-aged adults. However, ~25% of cellular blue nevi are congenital, and they are more common in women (female : male ratio = 2 : 1).

Pathogenesis

Blue nevi are benign tumors of dermal melanocytes[20]. During the second half of gestation, dermal melanocytes disappear, but some residual melanin-producing cells remain in the dermis of the scalp, sacral region, and dorsal aspect of the distal extremities. These are the sites where blue nevi most commonly occur. The blue coloration is the result of the Tyndall phenomenon (see above).

Blue nevi frequently contain somatic activating mutations in *GNAQ* (50–60%) or *GNA11* (7–15%); less commonly there are mutations in *CYSLTR2* (~3%), *NRAS* (~3%), or *BRAF* (~1%) and *GRM1* fusions (see Table 112.3)[21,21a].

Clinical Features

Common *blue nevi* are well-circumscribed, dome-shaped papules that are blue, blue–gray, or blue–black in color (Fig. 112.10A–D)[15]. They are usually 0.5 to 1.0 cm in diameter, rarely larger. These nevi may occur anywhere, but about 50% are found on the dorsal aspect of the hands and feet, with other common sites the face and scalp. Blue nevi have also been observed in the oral and genital mucosae, cervix, prostate, spermatic cord, and lymph nodes. Over time, hypopigmentation may develop within the center of blue nevi, and an "achromic" variant has been described.

Usually, blue nevi are solitary, but they may be multiple, agminated, or arise within a nevus spilus or plaque blue nevus. Concentric, target-like lesions (target blue nevi) have also been described. Dermoscopically, a blue nevus is characterized by homogeneous blue–gray to blue–black pigmentation (see Ch. 0).

Cellular blue nevi are blue to blue–gray or black nodules or plaques, generally 1 to 2 cm in diameter but sometimes larger (Fig. 112.11A,B)[20]. Their surface is often smooth but sometimes irregular. The most common sites are the buttocks, sacrococcygeal area, and scalp, followed by the face and feet. Rarely, a cellular blue nevus can have satellitosis.

Occasionally, lymph nodes draining the anatomic site of a cellular blue nevus contain blue nevus cells. The foci, found either in the marginal sinuses or in the capsule, are usually small and discrete. They may result from passive transport or represent arrested migration from the neural crest. This type of nodal involvement ("benign metastasis") has been described in a minority of the reported cases of cellular blue nevi.

GENES AND GENE FUSIONS IMPLICATED IN THE DEVELOPMENT OF MELANOCYTIC NEVI	
Genes or gene fusions	**Type of melanocytic nevus**
Genes	
BRAF	Common acquired melanocytic nevi (65%–80%); small minority of blue nevi
NRAS	Congenital melanocytic nevi (~80%), small minority of common acquired melanocytic nevi and blue nevi, congenital melanocytic nevus with hypophosphatemia (single case)
HRAS	Spitz nevi*,† (~15%), deep penetrating nevi (6%), nevus spilus/speckled lentiginous nevi (100% in one series); also phakomatosis pigmentokeratotica
GNAQ	Blue nevi (50%–60%, depending upon the study); also nevus of Ota and related conditions, phakomatosis pigmentovascularis
GNA11	Blue nevi (7%–15%); also nevus of Ota and related conditions, phakomatosis pigmentovascularis
CYSLTR2	Small minority of blue nevi
PRKAR1A	Pigmented epithelioid melanocytomas, epithelioid blue nevi (mutation in the second allele in Carney complex); sometimes a second mutation in a combined melanocytic nevus
BAP1	BAP1-inactivated melanocytic nevi
CTNNB1	WNT-activated deep penetrating/plexiform nevi
PTEN	Nevi in patients with xeroderma pigmentosum (~60%)
Gene fusions	
• Spitz nevi/tumors: translocations (fusions) of receptor tyrosine kinases (*ROS1*, *NTRK1/2/3*, *ALK*, *RET*, *MET*, *MERTK*) or kinases in the MAPK pathway (*BRAF*, *RAF1*, *MAP3K8*) • Pigmented spindle cell nevi: fusions of *NTRK3*, less commonly involving *MERTK*, *RET*, or *ROS1* • Minority of blue nevi: fusions of *GRM1*[21a] • Group of dermal melanocytic tumors that histologically resemble clear cell sarcoma or metastatic melanoma, but have an indolent behavior: CRTC1::TRIM11 fusion[86]	
*Also copy number increases of chromosome 11p where *HRAS* resides. †Also Spitz nevi arising within a nevus spilus (sometimes mistakenly termed "agminated Spitz nevi").	

Table 112.3 Genes and gene fusions implicated in the development of melanocytic nevi. NTRK3, neurotrophic receptor tyrosine kinase 3.

GENETIC SYNDROMES ASSOCIATED WITH NUMEROUS ACQUIRED MELANOCYTIC NEVI
Familial atypical mole and melanoma syndrome*
BAP1 cancer syndrome – atypical epithelioid nevi/tumors, uveal melanomas, mesothelioma
Carney complex (NAME/LAMB syndromes) – see Table 112.2
Turner syndrome – webbed neck, congenital lymphedema (partial or complete loss of X chromosome in females)
Noonan syndrome (mutations in multiple genes including *PTPN11*, *RAF1*, *KRAS*, *SOS1*) > other RASopathies (e.g. LEOPARD [Noonan with multiple lentigines] syndrome, cardiofaciocutaneous syndrome, Costello syndrome; see Ch. 55)
Ectrodactyly, ectodermal dysplasia, and cleft lip/palate syndrome (EEC syndrome; *TP63* mutations)
Goeminne syndrome – torticollis, keloids, cryptorchidism, and renal dysplasia
Kuskokwim syndrome – congenital joint contractures, skeletal deformities (*FKBP10* mutations)
Mulvihill Smith syndrome – progeroid short stature with pigmented nevi
Trichorhinophalangeal syndrome type II (Langer–Giedion syndrome)
Tricho-odonto-onychial dysplasia
*OMIM designation is "Susceptibility to cutaneous melanoma".

Table 112.4 Genetic syndromes associated with numerous acquired melanocytic nevi. *Adapted from reference 87.*

Pathology

Common blue nevi are composed of elongated, often slightly wavy melanocytes with long, branching dendrites (Fig. 112.10E,F). The melanocytes, with their long axes parallel to the epidermis, lie grouped or in bundles in the upper and mid dermis. Occasionally, they extend into the subcutaneous tissue or approach the epidermis but do not alter it. Most melanocytes are filled with fine melanin granules that obscure their nuclei and extend into their dendrites. Variable numbers of melanin-laden macrophages are also present. The amount of collagen is usually increased, giving the lesion a fibrotic or sclerotic appearance. In the hypopigmented variant, melanin content is minimal centrally[20].

Cellular blue nevi are well-circumscribed, nodular dermal tumors that are larger in diameter and have a higher cellular density than common blue nevi. Most often, well-defined nests of fusiform to ovoid melanocytes are surrounded by collagen and numerous melanophages (see Fig. 112.11C). Most of the melanocytes are usually lightly pigmented, with the majority of pigment residing in melanophages.

Aggregates of spindle cells may be arranged in intersecting bundles extending in various directions, a disposition resembling the storiform pattern of a neurofibroma. In cellular blue nevi, penetration of rounded, well-defined cellular islands into the subcutaneous tissue is frequently noted. Some of the cells may appear atypical, with nuclear pleomorphism accompanied by multinucleated giant cells, rare mitoses, and inflammatory infiltrates. Lastly, while there are classic histopathologic differences between common and cellular blue nevi, overlapping features are seen in some lesions[20].

Atypical cellular blue nevi demonstrate one or more of the following features compared to conventional cellular blue nevi: larger size (>1–2 cm), asymmetry, ulceration, infiltrating features, cytologic atypia, mitoses, and necrosis[22]. Such lesions have been associated with lymph node metastases and evolution to frank melanoma.

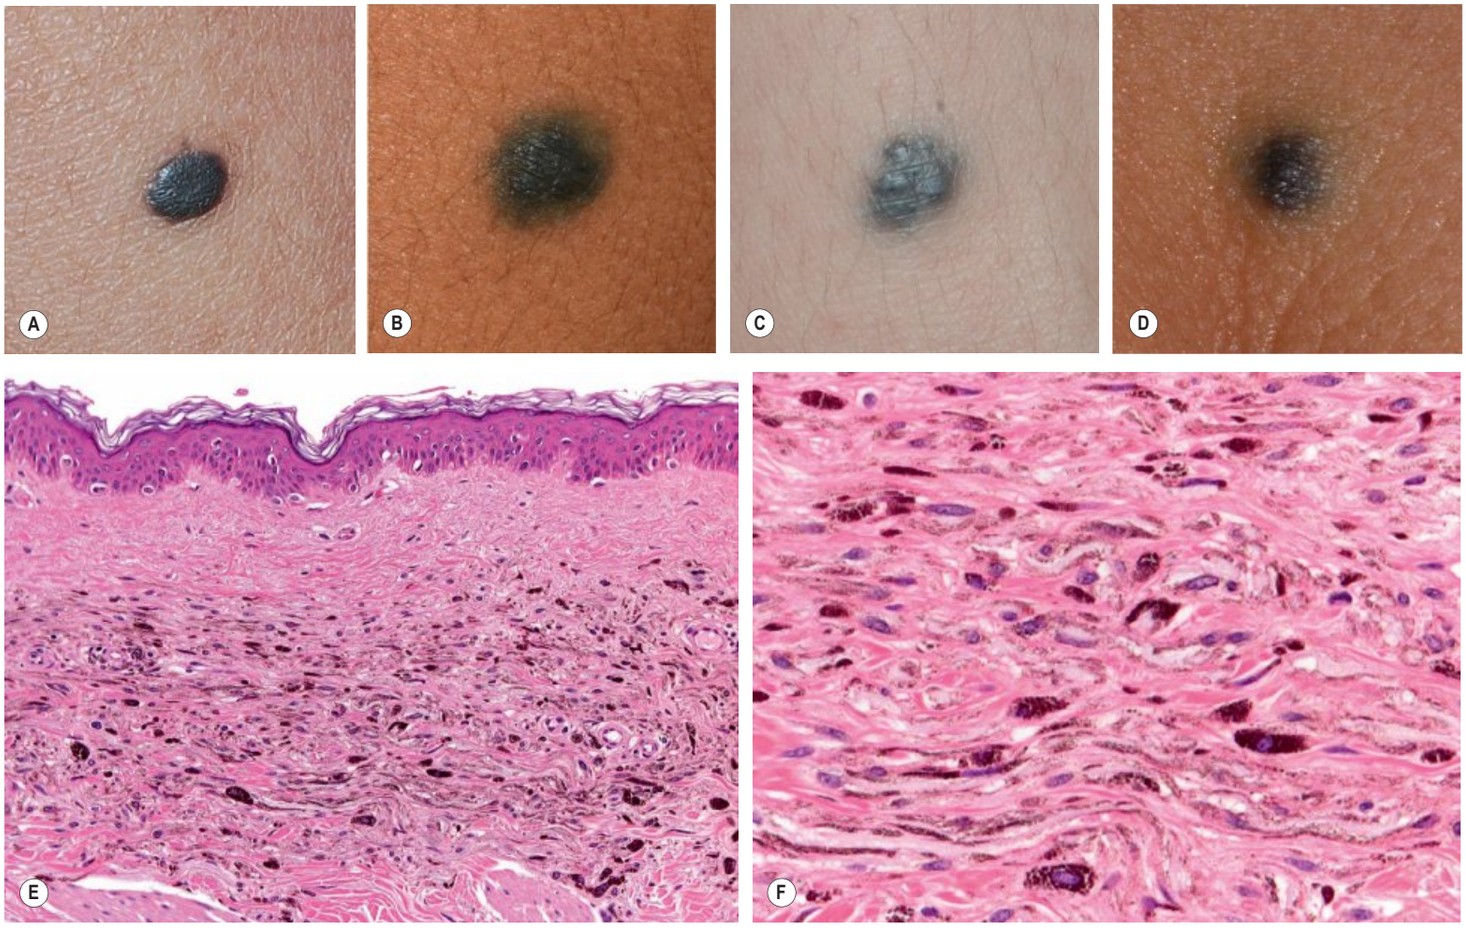

Fig. 112.10 Common blue nevi – clinical and histopathologic features. A Well-circumscribed, dark blue flat papule. **B** Dark blue–black papule in a patient with more darkly pigmented skin. **C** Blue papule with an irregular, micropapular surface. **D** Congenital blue–black papule superior to the gluteal cleft. **E, F** Heavily pigmented, spindle-shaped melanocytes as well as melanophages within the dermis; the melanocytes are denser than in dermal melanocytosis or nevus of Ota. *A–D, Courtesy Julie V. Schaffer, MD; E, F, Courtesy Lorenzo Cerroni, MD.*

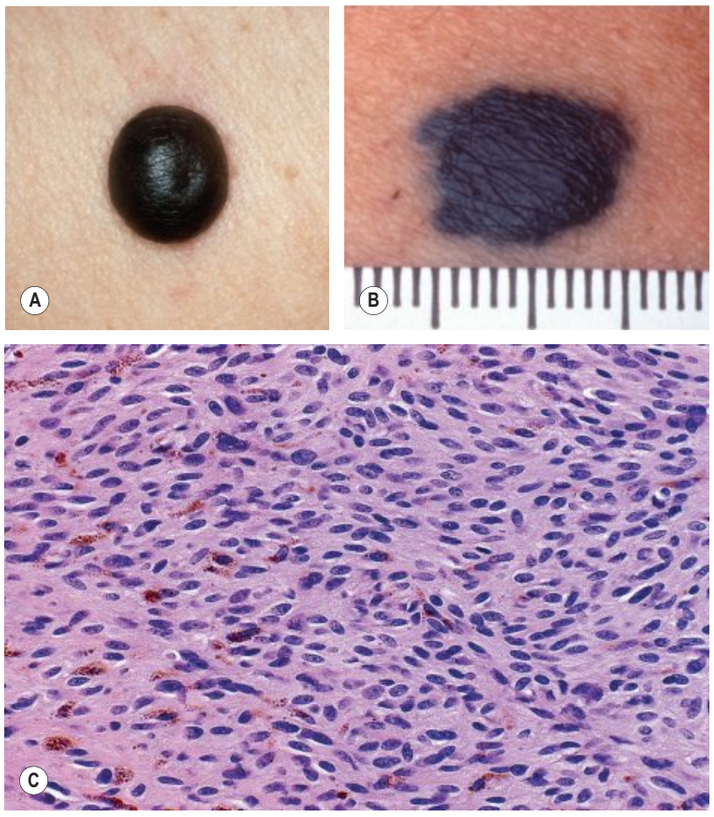

Fig. 112.11 Cellular blue nevi – clinical and histopathologic features. A A black nodule. **B** A firm blue plaque is a common presentation. **C** Plump spindled melanocytes devoid of melanin pigment and arranged within bundles are present within the dermis. Scattered melanin-containing melanophages are also present. *A, C, Courtesy Lorenzo Cerroni, MD; B, Courtesy Jean L. Bolognia, MD.*

Melanoma arising from blue nevus (MBN) refers to a melanoma arising within a pre-existing blue nevus, nearly always the cellular type. Classically, a rapidly growing, large (>2 cm) nodule arises on the scalp (followed by the face and trunk) in an adult who is usually >45 years of age. MBNs are often aggressive, with frequent metastasis to regional lymph nodes and the liver. In addition to the *GNAQ* or *GNA11* mutations in blue nevi, MBN often show additional genomic aberrations in *BAP1* or *SF3B1*[23].

Differential Diagnosis

The clinical differential diagnosis of a common blue nevus includes traumatic tattoo, vascular lesions including venous lake and angiokeratoma, combined nevus, sclerosing hemangioma, primary or metastatic melanoma, pigmented spindle cell nevus, atypical nevus, pigmented dermatofibroma, papular pigmented basal cell carcinoma, and glomus tumor. Cellular blue nevi also need to be distinguished from nevus of Ota, when on the face, as well as cutaneous neurocristic hamartoma, a complex proliferation of nevus cells, Schwann cells, and pigmented dendritic and spindled cells. Histologically, an atypical cellular blue nevus needs to be distinguished from MBN. Occasionally, a cutaneous melanoma metastasis may resemble a blue nevus.

Treatment

Blue nevi that are <1 cm in diameter, clinically stable, located in a typical anatomic site, and have no atypical features do not require removal. Histologic evaluation should be considered for lesions that appear *de novo*, are multinodular or plaque-like, or have undergone change. Atypical cellular blue nevi should be resected completely in order to prevent recurrence and because of the risk for malignant transformation or metastases. The approach to typical cellular blue nevi varies, but if observation is difficult (e.g. lesions on the scalp), excision can be considered.

PIGMENTED EPITHELIOID MELANOCYTOMA

Synonyms: ■ Epithelioid blue nevus ■ PRKAR1A-inactivated melanocytoma ■ Animal-type melanoma

Key features

- Rare tumor that usually presents as a slowly growing pigmented papulonodule
- Characterized by inactivation of *PRKAR1A*

Epidemiology and Pathogenesis

The term pigmented epithelioid melanocytoma (PEM) encompasses tumors previously referred to as epithelioid blue nevus and "animal-type", "melanophagic", or "pigment synthesizing" melanoma. PEMs are rare tumors that occur in both sexes with diverse ethnic backgrounds. The majority of PEMs have a loss of PRKAR1A immunoreactivity or inactivating mutations in *PRKAR1A*. The latter lead to activation of protein kinase A catalytic subunits (PRKACA, PRKABA) and induce melanocyte proliferation, differentiation, and pigmentation. Inactivation of PRKAR1A is usually combined with kinase fusions or mutations in genes (e.g. *BRAF*, *NRAS*, *NF1*, *CYSLTR2*, *GNAQ*, *GNA11*) involved in other melanocytic tumors (see Table 112.3)[24].

Clinical Features and Pathology

PEM presents as a slowly growing pigmented papule or nodule. It usually arises in the second or third decade, with the extremities being the most common site. Although PEMs were first described as a feature of Carney complex (see Table 112.2), they also may occur sporadically[25,26]. Histologically, a PEM is composed of pigmented epithelioid melanocytes with large vesicular nuclei. These cells are often admixed with heavily pigmented spindled and dendritic melanocytes as well as melanophages. Cytologic atypia and dermal mitoses may be present. PEMs frequently metastasize to regional lymph nodes but rarely spread extranodally and are almost never fatal.

The clinical appearance of a PEM is similar to a cellular blue nevus. Histologically, it needs to be differentiated from primary or metastatic melanoma as well as tumoral melanosis due to complete or almost complete regression of melanoma.

COMMON ACQUIRED MELANOCYTIC NEVI

Synonyms: ■ Nevocellular nevus ■ "Mole"

Key features

- A junctional nevus is a brown to black macule with melanocytic complexes at the dermoepidermal junction
- An intradermal nevus is a skin-colored to light pink or brown papule with complexes of melanocytes in the dermis
- A compound nevus is a brown papule with combined histologic features of junctional and intradermal nevi

Epidemiology

The prevalence of melanocytic nevi depends on age, ethnicity, genetic, and environmental factors. In early childhood, only a few nevi are present, but their number then increases and reaches a peak in the third decade of life; thereafter, nevi disappear with age[27]. There is a period of particularly rapid development of nevi at puberty. A study in Scotland noted that, in the first decade of life, girls had an average of three nevi and boys two nevi. For the peak age interval of 20 to 29 years, women and men had mean nevus counts of 33 and 22, respectively. In the seventh decade of life, women had a mean of 6 nevi and men 4 nevi, reflecting a progressive decline.

White individuals generally have greater numbers of nevi than populations with more darkly pigmented skin, e.g. African-Americans and Asians. In White individuals, the number of nevi is highest in those with skin phototype II. Additionally, melanocytic nevi (includes lentigines) on the palms and soles, nail beds, and conjunctivae are more prevalent in Africans and Asians. The mean acral "nevus" count for Africans in Uganda was 11, versus 2 to 8 for African-Americans.

Genetic factors also play a role in the prevalence of nevi: increased numbers of nevi have been shown to cluster in families, especially those with familial melanoma. Although an autosomal dominant mode of inheritance has been postulated for clinically atypical nevi in hereditary melanoma families, the pattern of inheritance may be more complex. Environmental factors such as sun exposure influence the development of melanocytic nevi as exemplified by the nevus counts of the outer versus inner arm or the back versus buttocks. However, genetic factors seem to directly determine an individual's potential for developing melanocytic nevi, and the final expression of this potential is influenced by solar exposure. In addition, individuals appear to inherit different propensities for nevogenesis[27], e.g. there is a higher correlation of nevus counts in monozygotic twins (r = 0.94) as compared to dizygotic twins (r = 0.60)[28].

Pathogenesis

The majority of melanocytic nevi arise from an activation of oncogenes that allows a clonal proliferation of affected melanocytes. In common acquired nevi, the initiating oncogenic event is usually an activating mutation in *BRAF* (80%) or *NRAS* (5%). Factors leading to the onset of melanocytic nevi are poorly understood but include the genetic influences alluded to earlier and environmental agents, principally UV exposure (Table 112.5). In genome-wide association studies (GWAS), a correlation was found between the number of melanocytic nevi and certain single nucleotide polymorphisms (SNPs) located near the *MTAP*, *PLA2G6*, *IRF4*, and *KITLG* genes.

Clinical Features

Melanocytic nevi are well-circumscribed, round to ovoid lesions, generally measuring from 2 to 6 mm in diameter. In general, they are symmetric and have a homogeneous appearance. While some common nevi may display slight asymmetry, the borders are usually regular and well-defined. *Junctional* nevi are macular lesions with a uniform, medium-to-dark brown color and slight accentuation of skin markings visible with side-lighting (Fig. 112.12A). The dermoscopic features of a junctional nevus include a uniform pigment network thinning out towards the periphery (see Table 0.15) (Fig. P2). *Compound* nevi show variable degrees of elevation and in general somewhat lighter shades of brown than do junctional nevi (Fig. 112.12C). Dermoscopically, compound nevi are characterized by a globular architecture with multiple round to ovoid globules sometimes forming a cobblestone pattern (see Table 0.15). *Intradermal* nevi are usually more elevated and show lighter shades of brown or even skin-colored tones compared to compound nevi (Fig. 112.12E). These nevi can also be pink in color. The dermoscopic features of an intradermal nevus predominantly consist of focal globules or globular-like structures. In addition, pale to whitish structureless areas and fine linear or comma vessels may be present (Fig. P3). In addition to clinical and dermoscopic overlap amongst all three types of nevi, intradermal nevi (and to a lesser degree compound nevi) may be papillomatous with pseudo-horn cysts.

Nevi, especially acquired "congenital-appearing" nevi, contain hairs that are coarse and dark compared to those in the surrounding skin. Nevi of the palms and soles are often macular or only slightly raised, have regular and well-defined borders, and show uniform or linear brown coloration (see below). Melanocytic nevi of the nail matrix usually present as uniformly pigmented, brown longitudinal bands (melanonychia striata, longitudinal melanonychia) with regular and distinct margins (Fig. 112.13; see Ch. 71).

Melanocytic nevi associated with epidermolysis bullosa

Distinctive melanocytic nevi termed "epidermolysis bullosa (EB) nevi" or "EB nevi" may develop at the sites of antecedent bullae or erosions primarily in patients with forms of EB that are recessively inherited (see Ch. 32)[29]. These nevi can have a strikingly large size (up to 3 cm) as well as asymmetry, border irregularity, dark color, and satellitosis. Their development may be related to repetitive disruption of the basement membrane zone with the promotion of proliferation or dispersion of melanocytes into the blister cavity with their subsequent proliferation in its floor. Although there are no reports of cutaneous melanoma developing at the sites of EB nevi, melanoma can occasionally arise within the setting of EB; thus longitudinal observation is warranted.

TRIGGERS FOR THE DEVELOPMENT AND/OR GROWTH OF MELANOCYTIC NEVI
Exposure to ultraviolet light
• Sun exposure leading to multiple or severe sunburns*
• Intermittent intense sun exposure (e.g. on sunny holidays)
• Chronic moderate sun exposure (e.g. residence at lower latitudes)
• Neonatal phototherapy
Blistering processes (other than severe sunburns)
• Toxic epidermal necrolysis/Stevens–Johnson syndrome*
• Epidermolysis bullosa – junctional (particularly generalized atrophic benign) > recessive dystrophic > recessive simplex*
• Bullae secondary to sulfur mustard (mustard gas) exposure*
Scarring/fibrosing processes
• Genital lichen sclerosus†
Systemic immunosuppression
• Chemotherapy, particularly for childhood hematologic malignancies and capecitabine*,†,‡
• Allogeneic bone marrow transplantation‡
• Solid organ transplantation, particularly renal and with the use of azathioprine*,‡
• HIV infection/AIDS*
• Chronic myelogenous leukemia*
• TNF inhibitor therapy*,‡
• Cyclosporine, azathioprine*
Increased hormone levels
• Pregnancy*,¶
• Growth hormone (increased size, not number, of nevi)
• Addison disease*
• Thyroid hormone*
• α-Melanocyte stimulating hormone analogue (afamelanotide)*
Other
• Sorafenib, vemurafenib, sunitinib, encorafenib, radotinib, regorafenib, nilotinib*
• Rituximab
• Atopic dermatitis in children (conflicting results in different studies)
• Postoperative fever*
• Seizures or electroencephalographic abnormalities*
*Eruptive nevi have been reported.
†An increased number of atypical nevi may also be seen.
‡Nevi have a predilection for the palms and soles.
¶Relative immunosuppression may also play a role; an increase in the size or number of nevi has not been clearly demonstrated for pregnant women in general, with the exception of areas that enlarge such as the abdomen. Melanoma may grow at an accelerated pace during pregnancy.

Table 112.5 Triggers for the development and/or growth of melanocytic nevi. TNF, tumor necrosis factor. *Adapted from Schaffer JV, Bolognia JL. The biology of melanocytic nevi. In: Nordlund JJ, Boissy RE, Hearing VJ, et al. (eds). The Pigmentary System: Physiology and Pathophysiology, 2nd edn. Oxford: Blackwell Publishing, 2006:1092–125.*

Melanocytic nevi associated with lichen sclerosus

Occasionally, melanocytic nevi develop within areas of genital lichen sclerosus[30]. The lesions are often dark brown to black in color, irregular in outline, and can measure ≥6 mm. As a result, the possibility of melanoma is frequently considered clinically, and histologic distinction is not always easy.

Pathology

Melanocytic nevi contain intraepidermal and/or dermal nests of melanocytes (Fig. 112.12B,D,F). The cells within the junctional nests have round, ovoid, or fusiform shapes and are arranged in cohesive nests. These melanocytes often contain melanin or occasionally may be

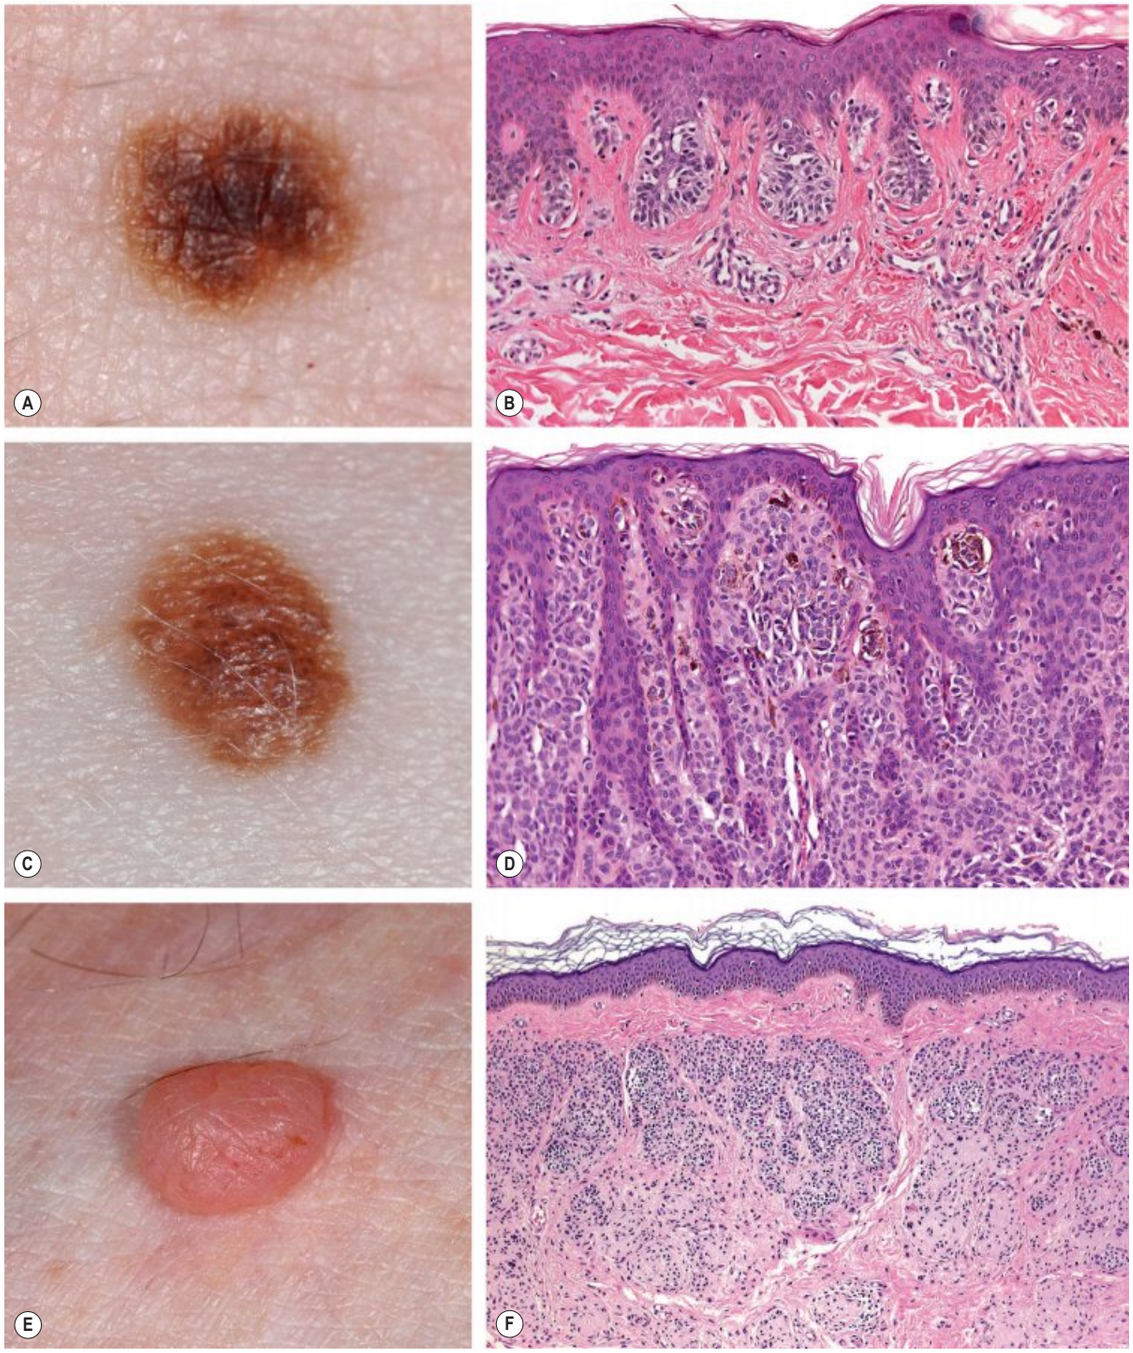

Fig. 112.12 Common acquired melanocytic nevi – clinical and histopathologic features. **A, B** Junctional nevus – dark brown macule with lighter brown rim and regular nests of small, uniform melanocytes at the dermal–epidermal junction. **C, D** Compound nevus – light to medium brown papule and both junctional and dermal nests of melanocytes. **E, F** Intradermal nevus – soft light pink papule and nests of melanocytes within the dermis. *B, D, F, Courtesy Lorenzo Cerroni, MD.*

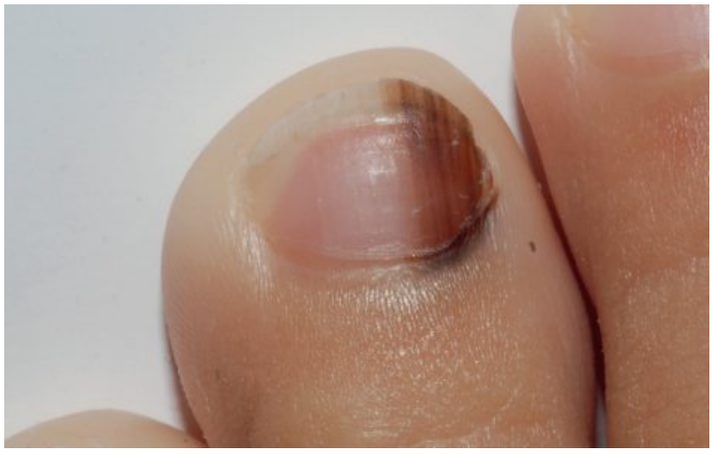

Fig. 112.13 Longitudinal melanonychia due to a benign melanocytic nevus of the nail matrix. Note the pseudo-Hutchinson sign. *Courtesy Julie V. Schaffer, MD.*

non-pigmented. In the superficial dermis, the melanocytes usually have epithelioid cell characteristics and contain amphophilic cytoplasm and, frequently, granular melanin. The nuclei have uniform chromatin with a slightly clumped texture. Deeper in the dermis, the melanocytes have less cytoplasm and appear smaller. There may be a further transition to cells separated by fine connective tissue and assuming a spindled configuration, similar to fibroblasts or Schwann cells.

EB nevi are best considered as exaggerated variants of recurrent/persistent melanocytic nevi (see below). They usually exhibit asymmetry and considerable variation in the overall architecture, including the junctional nests. Pagetoid melanocytosis and cytologic atypia may be present, as well as fibroplasia, a lymphocytic infiltrate, and melanophages.

In *melanocytic nevi associated with lichen sclerosus* (LS), the features of a genital nevus are superimposed on the changes of LS, which can vary from subtle to obvious. Irregular and confluent junctional nests are often accompanied by cytologic atypia. The changes of LS may suggest regression, and if the inflammatory component is significant, it may hinder assessment of the nevus cells. Findings that favor a genital nevus (rather than melanoma) include: a diameter <5 mm; relative symmetry;

sharp circumscription; nests located predominantly at the dermal–epidermal junction which predominate over melanocytes arranged as solitary units; low-grade cytologic atypia of melanocytes; a conventional dermal nevus component; absence of significant dermal mitoses; and limitation of the nevus to the area of LS.

Differential Diagnosis

The differential diagnosis of melanocytic nevi includes the full spectrum of pigmented and skin-colored lesions (see Ch. 0). Raised nevi, potentially confused with seborrheic keratoses, are less likely to have a verrucoid surface and pseudo-horn cysts and do not have a cerebriform surface when examined by dermoscopy. Dermatofibromas are usually differentiated from nevi by their very firm consistency, "dimpling" with lateral compression, preference for the lower extremities, and central white patch by dermoscopy. Both neurofibromas and fibroepithelial polyps may be indistinguishable from skin-colored or slightly pigmented, pedunculated intradermal nevi. In general, typical melanocytic nevi are distinguishable from atypical nevi and melanoma by smaller size, overall symmetry and orderly appearance, homogeneous coloration, and regular, well-defined borders. Furthermore, red, blue, gray, and black colors are not usually seen in common acquired nevi and should alert one to a potentially atypical lesion.

Treatment

Indications for removing melanocytic nevi include a changing lesion (e.g. enlarging, new color) and an atypical clinical appearance suspicious for melanoma. Nevi are also removed when they are bothersome (e.g. site of repeated trauma) or for cosmetic concerns. Even though the total number of melanocytic nevi correlates with the risk of melanoma (see Fig. 113.5), there is no reason to remove nevi on a routine basis.

GENITAL NEVUS AND NEVI OF SPECIAL SITES

Key features

- Benign melanocytic nevi that occur in "special" anatomic sites; the latter include the genitalia as well as the scalp, ear, nipple, umbilicus, and acral and flexural sites (e.g. axilla)
- Atypical clinical and histologic features make a reliable distinction from melanoma difficult and may lead to higher excision rates

Clinical Features

Melanocytic nevi occurring in genital sites, especially the vulva, often have distinctive clinical and histopathologic features compared to nevi from non-genital sites. Similar nevi may also occur in other locations such as the scrotum and perineum as well as the scalp, ear, nipple, umbilicus, and acral and flexural sites (e.g. axilla). These special-site nevi appear to be uncommon, perhaps accounting for <10% of nevi removed, but data could be biased by selection factors. Compared to common acquired nevi, nevi of special sites are often larger in size, may have irregular borders, and often have a complex mahogany color, i.e. an admixture of tan, brown, and red[31]. However, it is important to remember that melanoma can also arise in these sites, especially in middle-aged to older adults.

Pathology

In general, nevi of special sites have architectural features that differ from those of common acquired nevi and overlap with those of dysplastic nevi and melanoma. These atypical features include asymmetry, irregular arrangement of junctional melanocytic nests (including along the lateral aspects of the rete ridges), bridging of nests, discohesive melanocytes within nests, lentiginous proliferation, follicular involvement, pagetoid spread, dermal lamellar fibroplasia, and cytologic atypia[32].

Differential Diagnosis

The differential diagnosis includes primarily melanoma, Spitz nevus, and nevi associated with genital LS (see above). Vulvar melanoma tends to occur in older women (average age ~65 years) and is quite rare in young patients.

ACRAL NEVUS

Synonyms: ■ Melanocytic nevus of acral skin ■ Melanocytic acral nevus with intraepidermal ascent of cells (MANIAC)

Key features

- Benign melanocytic neoplasm of the non-hair-bearing skin of the hands and feet
- Histologically, about one-third of acral nevi demonstrate intraepidermal upward migration of melanocytes and other architectural changes that can resemble melanoma

Epidemiology and Pathogenesis

Acral nevi are common, occurring in up to one-third of the population. Their incidence peaks in the third and fourth decades of life. They are more common in individuals with darker skin phototypes. As in common acquired nevi, acral nevi have mutations in *BRAF* or *NRAS* in a mutually exclusive pattern.

Clinical Features

Acral nevi are usually macular or only slightly elevated. They may display a uniform brown or dark brown color, but often have linear striations. The characteristic dermoscopic features of acral nevi are due to the unique anatomy of acral skin. Both the palms and soles have parallel ridges (mountains) and furrows (valleys), with the intraepidermal eccrine ducts passing through the ridges (Fig. 112.14). In acral nevi, the nests of nevus cells are situated around the furrows. The three major dermoscopic patterns seen in acral nevi are the parallel furrow (Fig. 112.15), the lattice-like (Fig. P4), and the fibrillar pattern (Table 112.6)[33].

Pathology

Acral nevi are usually relatively small (<5–6 mm), well-circumscribed, symmetric compound nevi. Occasionally, the junctional nests are somewhat enlarged, but they usually have a fairly uniform round or oval shape and are similar in size and spacing. Lentiginous melanocytic

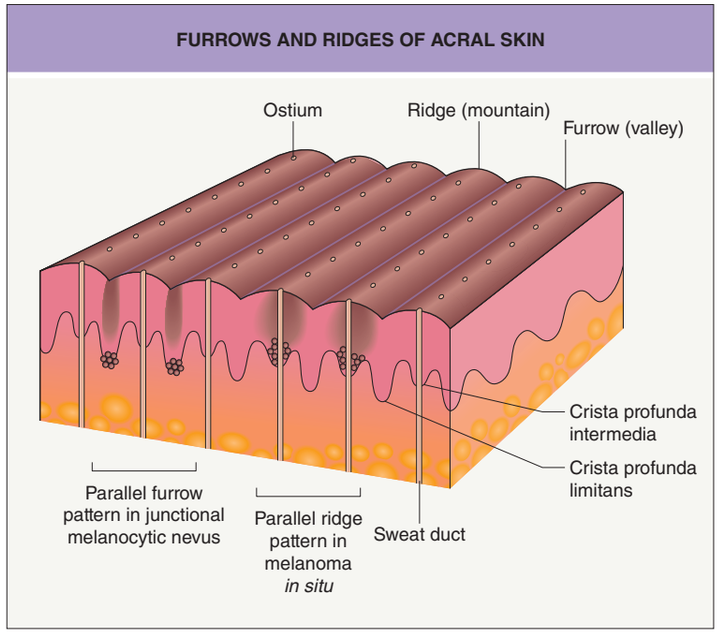

Fig. 112.14 Furrows and ridges of acral skin.

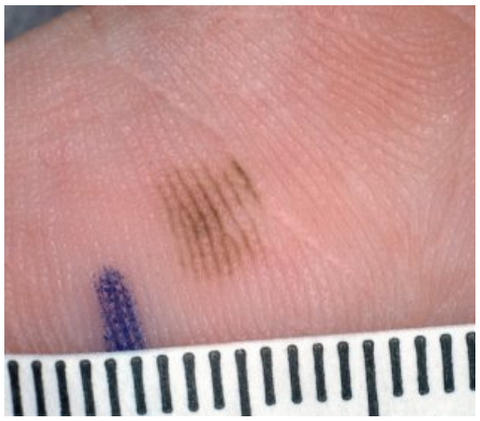

Fig. 112.15 Acral melanocytic nevus. The parallel furrow pattern is evident with a small focus of the lattice pattern. The ostia of the eccrine ducts within the epidermal ridges can also be seen, especially at the site of blue ink. *Courtesy Jean L. Bolognia, MD.*

ACRAL NEVI – COMMON DERMOSCOPIC PATTERNS	
Pattern	**Dermoscopy features**
Parallel furrow (most common)	Parallel rows of linear pigmentation along furrows/valleys (sulci of the surface skin markings; see Fig. 112.14 & 112.15)
Lattice-like	Parallel furrows plus lines of pigmentation crossing the parallel lines (see Fig. P4)
Fibrillar	Densely packed, fine parallel lines of pigmentation, often set in a direction that crosses the skin markings

Table 112.6 Acral nevi – common dermoscopic patterns.

proliferation and some degree of upward migration of melanocytes are features commonly observed in acral nevi. One should be cautious in over-interpreting the latter changes unless prominent architectural disorder and cytologic atypia are also present. The dermal component of acral nevi is often characterized by round nests of melanocytes[33].

SPITZ NEVUS AND ATYPICAL SPITZ TUMOR

Synonyms for Spitz nevus: ■ Epithelioid cell nevus ■ Spindle cell nevus ■ Spindle and epithelioid cell nevus ■ Spitz's juvenile melanoma ■ Benign juvenile melanoma

Key features

- Pink, red, or pigmented papule or nodule, usually in children or young adults
- Composed of epithelioid and/or spindled melanocytes with a regular architecture
- Often harbor tyrosine kinase fusions (e.g. involving *ALK*, *ROS1*, *NTRK1/2/3*, *BRAF*) or activating *HRAS* mutations

Epidemiology

The prevalence of Spitz nevus in the general population has not been accurately documented[34]. However, of the melanocytic lesions that have been surgically excised, ~1% exhibit the histologic characteristics of Spitz nevus. In data from Australia, it has been estimated that Spitz nevus accounts for 1.4 cases per 100 000 population, as compared with an annual incidence of 25.4 melanomas per 100 000 population. The vast majority of Spitz nevi are acquired, with congenital Spitz nevi being exceedingly rare. Spitz nevi occur in all age groups, but are uncommon beyond 40 to 50 years of age. In one series, 36% of the individuals with Spitz nevi were under the age of 10 years, 33% were between the ages of 10 and 20 years, and 31% were older than 20 years of age[34]. There is no sex predilection and Spitz nevi occur in all skin phototypes.

Pathogenesis

Spitz nevi are clonal proliferations of melanocytes, and most Spitz nevi are caused by structural genomic rearrangements that lead to gene fusions, activating either receptor tyrosine kinases (*ROS1*, *ALK*, *NTRK1/2/3*, *MET*, *MERTK*, *RET*) or kinases in the MAPK pathway (*BRAF*, *RAF1*, *MAP3K8*) (see Table 112.3). These kinase fusions can then activate various oncogenic pathways, including the MAPK signaling pathway. In addition, a subset of Spitz nevi harbors activating mutations in *HRAS* that are often accompanied by copy number gains of the mutant *HRAS* allele[35].

Widespread eruptive Spitz nevi have been associated with HIV infection, Addison disease, chemotherapy, pregnancy, puberty, and trauma, many of the same triggers as for common acquired nevi (see Table 112.5). The eruption of Spitz nevi during pregnancy and puberty suggests a possible role for hormonal activation.

Clinical Features

Spitz nevi vary in size from 2 mm to >10 mm, with an average diameter of ~8 mm[34]. Typically, they are well-circumscribed, dome-shaped papules or nodules that vary in color from pink to tan to dark brown or black (Fig. 112.16). Generally, the color is homogeneous and the margins are well defined. The surface topography may be smooth or, in some instances, verrucous. Relatively flat, polypoid, and pedunculated morphologies have also been described. Occasional lesions may have erosions and scale-crust while others may be firm due to sclerosis and resemble dermatofibromas (i.e. desmoplastic)[36]. Telangiectasia is a frequent finding. While Spitz nevi may develop anywhere on the body, they are frequently observed on the lower extremities as well as in the head and neck region, particularly in children. In most instances, there is a history of recent onset, but a small percentage of Spitz nevi have been present for many years.

Multiple Spitz nevi may occur in an agminated (grouped) or disseminated pattern[37]. *Disseminated Spitz nevi* can number in the hundreds, erupt suddenly, and involve the entire integument except for the palms, soles, and mucous membranes. The papules tend to be polymorphous, affect adults, and spontaneously regress over several years. To date, no case reports of malignant degeneration of grouped or disseminated Spitz nevi have been published, although disseminated Spitz nevi have been associated with seizures.

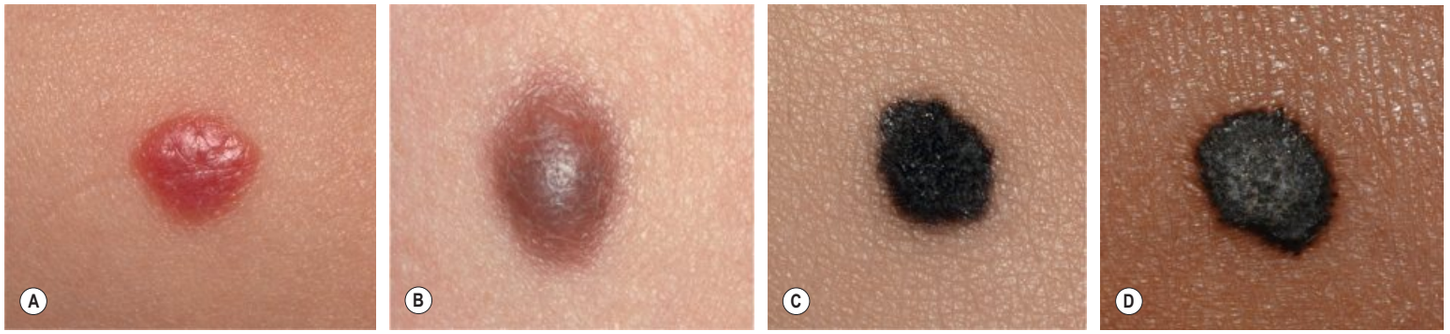

Fig. 112.16 Spitz nevi. A Red, symmetric, dome-shaped papule on the thigh of a child. **B** Medium-brown, symmetric, dome-shaped papule with a thinner rim in an adolescent. **C** Darkly pigmented Spitz nevus in a child with a flatter surface. **D** Sometimes there is a verrucous surface. *A, C, D, Courtesy Julie V. Schaffer, MD; B, Courtesy Lorenzo Cerroni, MD.*

Fig. 112.17 Agminated Spitz nevi. The grouped papules have arisen on normally pigmented skin.

Agminated (grouped) Spitz nevi are characterized by varying numbers of individual, raised nevi occurring in a localized or segmental distribution and arising in otherwise clinically normal skin (Fig. 112.17). Some confusion has arisen in the literature as lesions arising within a CALM-like tan background have been referred to as agminated Spitz nevi; however, these lesions would be better termed Spitz nevi within a nevus spilus (speckled lentiginous nevus). Spindle and epithelioid cell proliferations can also develop within large/giant congenital nevi.

Atypical Spitz tumor (Spitz melanocytoma) refers to a melanocytic neoplasm that morphologically and genetically lies between Spitz nevus and Spitz melanoma. Atypical Spitz tumors have one or more atypical features that deviate from conventional Spitz nevi[38]; these include: large size (>5–10 mm in diameter); asymmetry; deep involvement of the dermis or subcutis; ulceration; easily found dermal mitoses (>2–3 mitoses/mm^2), especially deep; significant pagetoid spread; prominent confluence and high cellular density of melanocytes in the dermis; and lack of maturation. Genetically, atypical Spitz tumors harbor the same genetic alterations as Spitz nevi (i.e. kinase fusions) and additional genomic aberrations such as inactivation of the tumor suppressor gene *CDKN2A*.

Spitz melanoma are rare lesions and the diagnosis is best established by integrating clinical, histologic, and molecular criteria (see Ch. 113)[39]. Compared to atypical Spitz tumors, Spitz melanomas exhibit even greater asymmetry, poor circumscription, and higher degrees of nuclear atypia with numerous mitoses.

Pathology

Spitz nevi are usually symmetric, sharply circumscribed, and composed of large epithelioid and/or spindled melanocytes. The melanocytes usually extend from the epidermis into the reticular dermis in an inverted-wedge configuration. The closely apposed nests of cells within a uniformly hyperplastic epidermis often contribute to a so-called "raining-down" appearance (Fig. 112.18). Both mononuclear and multinucleated giant epithelioid cells are frequently observed. These cells extend into the dermis as nests, fascicles, or single cells. In general, there is orderly infiltration of the dermal collagen by melanocytic complexes with so-called maturation, i.e. gradual diminution of nuclear and cellular sizes as well as the size of nests.

The individual cells usually have abundant cytoplasm that stains slightly bluish or pink and nuclei with open chromatin patterns. Rather uniform nucleoli are usually also noted. Intraepidermal eosinophilic globules (Kamino bodies) are commonly found in Spitz nevi, but may occasionally be encountered in other melanocytic tumors including cutaneous melanoma. Kamino bodies represent altered components of the basement membrane, including collagen types IV and VII.

In Spitz nevi, some histopathologic patterns are associated with particular genetic features. For example, a plexiform pattern typically corresponds to the molecular presence of *ALK* fusions and to positivity for ALK by immunohistochemistry[40].

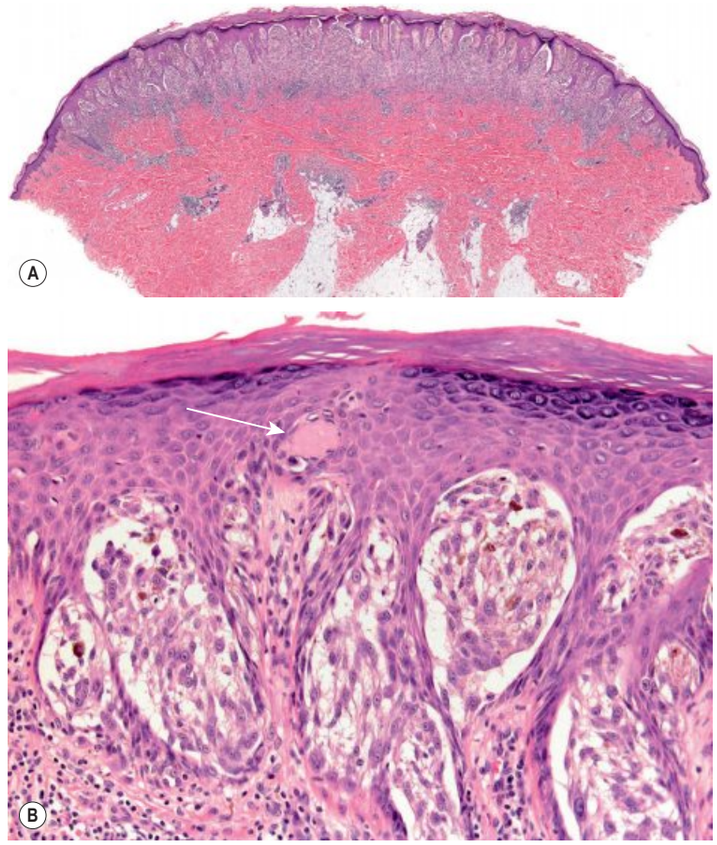

Fig. 112.18 Spitz nevus – histopathologic features. A Dome-shaped with sharply demarcated and symmetric proliferation of spindled and epithelioid melanocytes at the dermal–epidermal junction and within the papillary dermis; there is also regular epidermal hyperplasia. **B** Nests of cohesive spindled and epithelioid melanocytes with clefts between the nests and the hyperplastic epidermis. Note a "Kamino body" (arrow). *Courtesy Lorenzo Cerroni, MD.*

Differential Diagnosis

The clinical differential diagnosis of Spitz nevi is wide and includes other melanocytic nevi, particularly intradermal nevi, hemangiomas, pyogenic granulomas, verrucae, mollusca contagiosa, juvenile and adult xanthogranulomas, dermatofibromas, mastocytomas, and adnexal tumors. The fundamental diagnostic problem is the histologic differentiation of Spitz nevus from cutaneous melanoma, which is one of the most difficult problems in pathology. A number of clinical and histopathologic parameters are summarized in Table 112.7. Spitz nevi are differentiated from BAP1-inactivated melanocytic tumors by immunohistochemical positivity for BAP1 (see below).

Treatment

Because of the frequent diagnostic difficulty in classifying these lesions, histologic evaluation of the entire lesion is recommended. Recurrence rates from 5% to 15% have been observed when lesions are incompletely excised. Some authors recommend complete excision with tumor-free margins for all Spitz nevi, whereas others reserve this recommendation for lesions with atypical features (clinically or histologically) or for Spitz nevi in adults. For highly atypical or histologically ambiguous variants, a margin of ~1 cm is recommended. It is also advisable that patients with atypical lesions have periodic evaluations every 6 to 12 months. Sentinel lymph node biopsy, although controversial, may be considered on a case-by-case basis for clearly atypical lesions with a Breslow depth ≥1 mm. However, there is mounting evidence that sentinel lymph node involvement by Spitz tumors is not necessarily analogous to conventional metastatic melanoma[38], as almost all of the cases studied to date have not shown progression of disease beyond the sentinel lymph nodes.

Whole-genome sequencing followed by targeted therapy has also been employed. In a patient with unresectable "agminated" Spitz nevi and GOPC-ROS1 fusion, the oral tyrosine kinase inhibitor crizotinib led to improvement.

COMPARISON OF SPITZ NEVUS AND MELANOMA		
Parameter	**Spitz nevus**	**Melanoma**
Clinical features		
Age	Young age, especially prepubertal, favors a benign process	Exceedingly rare in pre-pubertal children; outnumber Spitz nevi in patients >30 years of age
Anatomic site	May occur anywhere, but favors the lower extremities and particularly in children the head and neck region	Most often on the trunk (back) in men and distal lower extremities in women; favors intermittently sun-exposed skin, but may occur anywhere
Size	Often <5–6 mm, usually <10 mm	Often >6 mm, but early lesions may be smaller; large size favors melanoma
Symmetry	Usually symmetric	Increasing asymmetry favors melanoma
Histopathologic features		
Architecture	Dome-shaped, plaque-like, wedge-shaped in dermis, plexiform	Heterogeneous and complex (with exceptions)
Circumscription	Usually well demarcated with peripheral junctional nests	Often poorly demarcated ending in single-cell patterns
Epidermal features	Regular hyperplasia; intraepidermal eosinophilic globules common, numerous, and large-sized	Irregular epidermal pattern; intraepidermal eosinophilic globules uncommon, few in number, and small-sized
Maturation	Overall reduction in cellular density with depth; orderly dispersion and regular spacing of nests and cells among collagen bundles with depth; nests become progressively smaller, finally resulting in single melanocytes at the base of lesion; cells and nuclei also diminish in size with depth; maturation may be absent in a subset of Spitz nevi	Little or no maturation; confluence of melanocytes is not lost with depth; irregular spacing and disorderly arrangements of cells
Pagetoid spread	Less frequent than in melanoma; orderly; often confined to the epidermis over the central part of the lesion; nested patterns may be more frequent than single cells	Common; disorderly; the melanoma cells often reach the granular layer; higher cellular density
Zonation	Uniformity of cytologic features across horizontal strata of lesion	Heterogeneity of features
Mitotic figures in dermal component	Limited in number, superficial, usually not atypical	Greater in number, deeply located, atypical
Cytologic features	Abundant ground-glass or opaque cytoplasm; polyangular, rhomboidal; occasional dendrites	Variable amount of cytoplasm; often granular or "dusty" and abundant in epithelioid cells; scant cytoplasm in spindled cells
Nuclear features	Enlarged nuclei; uniform dispersed chromatin pattern; nucleoli may be prominent but usually uniform; reniform, multilobulated, multinucleate and giant bizarre forms occur	Pleomorphism; often high nuclear to cytoplasmic ratios; hyperchromatism; prominent variable nucleoli commonly multiple; thickened nuclear membranes
Genetic features		
	Translocations (fusions) of receptor tyrosine kinases (*ROS1*, *ALK*, *NTRK1/2/3*, *MET*, *MERTK*, *RET*) or kinases of the MAPK pathway (*BRAF*, *RAF1*, *MAP3K8*) *HRAS* activating mutations (often seen in desmoplastic Spitz tumors)	Oncogenic mutations in *BRAF* (~ 35%–50%), *NRAS* (~10%–25%), *NF1* (~10%) *TERT* promoter mutations Inactivation of *CDKN2A*, *PTEN*, *TP53*

Table 112.7 Comparison of Spitz nevus and melanoma.

PIGMENTED SPINDLE CELL NEVUS

Synonyms: ■ Pigmented spindle cell tumor of Reed ■ Pigmented variant of Spitz nevus

Key features

- Dark brown to black thin papule, usually <6 mm in diameter
- A spindle cell variant of Spitz nevus with heavily pigmented spindle-shaped melanocytes in the epidermis ± the superficial dermis

Epidemiology and Pathogenesis

Pigmented spindle cell nevi are classified by some authors as a subtype of Spitz nevi and in this case account for <20% of Spitz nevi[41]. A few have been noted at birth; however, the mean age at diagnosis is 25 years (the age range in one series was 3 to 66 years). Women are affected more often than men. Pigmented spindle cell nevi are most commonly located on the extremities (70% of cases in one study), with the thigh being the most frequent site. About 20% of pigmented spindle cell nevi are found on the trunk, and ~10% occur in the head and neck region.

Pigmented spindle cell nevi are initiated by activating kinase fusions, most commonly involving *NTRK3* which encodes neurotrophic receptor tyrosine kinase 3. In one study, genomic fusions involving *NTRK3* were found in 80% of cases; other less common fusions involved *MERTK*, *ROS1*, and *RET*[42].

Clinical Features

The pigmented spindle cell nevus is usually a relatively flat or slightly raised, well-circumscribed lesion with an average diameter of 3 mm (range 1.5 to 10 mm). The color is usually dark brown or black and homogeneous. The most common dermoscopic patterns include the following: a dark structureless area almost to the periphery of the lesion, a central dark structureless area with symmetric pseudopods or radial streaming (starburst pattern), and/or a peripheral globular pattern (see Fig. 0.37). Irregularity of pigmentation is rare but may be found in atypical variants of pigmented spindle cell nevi. There is often a history of recent development or change. In one study, lesions had been present on average for about 6 months, although some were of longstanding duration.

Congenital forms of pigmented spindle cell nevi, although unusual, have been recognized. The occurrence of atypical varieties of pigmented spindle cell nevi and the presence of remnants of pigmented spindle cell nevi in association with cutaneous melanoma are circumstantial evidence that pigmented spindle cell nevi can undergo rare

transformation to cutaneous melanoma. In a long-term (mean 8.8 years) follow-up of 15 patients with excised pigmented spindle cell nevi, there was no evidence of recurrence. In our experience, these lesions have almost never recurred. Thus, unless a lesion has been incompletely excised, recurrence strongly suggests an atypical process, possibly cutaneous melanoma.

Pathology

Pigmented spindle cell nevi display a well-circumscribed and orderly appearance (Fig. 112.19). Lesions are usually only slightly raised with nevus cells confined to the epidermis, although they may involve the papillary dermis. The lesion is well circumscribed and is typified by fascicles of uniform, slender spindle cells that are closely aggregated (Fig. 112.19, inset). The cells usually contain fine, granular melanin and their nuclei have delicate chromatin and small inconspicuous nucleoli. There may be clefting around the intraepidermal fascicles. Numerous melanophages are usually present in the papillary dermis. Upward migration of nevus cells throughout the epidermis is sometimes noted, but usually these cells are confined to the lower half of the epidermis. Atypical variants exhibit prominent single-cell hyperplasia extending peripherally along the basal layer of the epidermis and in a pagetoid pattern throughout the epidermis. Cytologic atypia may also be present to a varying degree in these atypical variants.

Differential Diagnosis

The clinical differential diagnosis of pigmented spindle cell nevi includes early melanoma, atypical nevus, blue nevus, angiokeratoma, and pigmented basal cell carcinoma. In general, the borders of pigmented spindle cell nevi are regular and well-defined. The color is also homogeneous in most instances. However, atypical forms of pigmented spindle cell nevi may have irregular borders and variation in color. Although spindle cell nevi have a characteristic dermoscopic pattern, histopathologic examination is required for diagnosis. It must be emphasized, however, that the clinicopathologic presentation of typical pigmented spindle cell nevi is distinctive. Its history is that of a recently developed or changing, small, well-circumscribed, black lesion on the thigh of a young woman (usually in her 20 s). These lesions are often conspicuous because of the dearth of pigmented lesions elsewhere on the body.

Treatment

The proper treatment of pigmented spindle cell nevi is complete excision with clear margins. The reason for this recommendation is to prevent recurrence, since the pathology of recurring lesions may be alarming and difficult to distinguish from melanoma. For pigmented spindle cell nevi with atypical features, wider surgical margins are advised. For example, we advocate resection margins of 5 to 10 mm for markedly atypical forms of pigmented spindle cell nevus because histopathologic distinction from melanoma may be exceedingly difficult. Periodic follow-up, i.e. every 6 to 12 months, is also strongly advised for patients with atypical variants of pigmented spindle cell nevus.

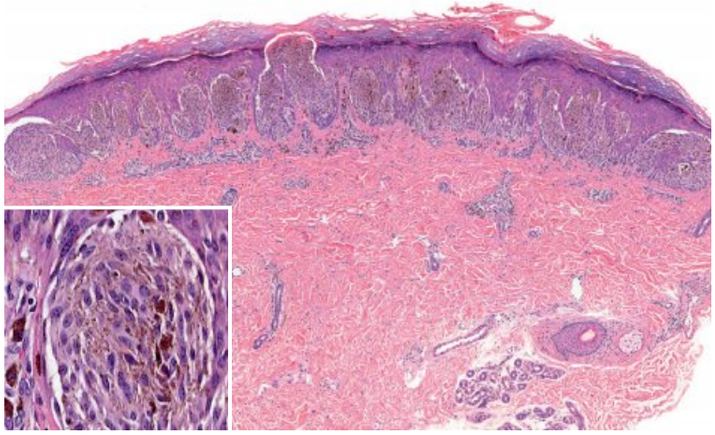

Fig. 112.19 Pigmented spindle cell nevus – histopathologic features. A predominantly junctional melanocytic proliferation that is characterized by well-defined margins, symmetry, and an overall plate-like configuration. Several nests have a vertical configuration and some may show "perforation" of the epidermis. Inset: the melanocytes are spindle-shaped and heavily pigmented. *Courtesy Lorenzo Cerroni, MD.*

WNT-ACTIVATED DEEP PENETRATING/ PLEXIFORM NEVUS

Synonyms: ■ Deep penetrating nevus/melanocytoma ■ Plexiform spindle cell nevus/melanocytoma

Key features

- Well-circumscribed, symmetric, darkly pigmented papule measuring 5–10 mm in diameter
- Due to concomitant activation of the WNT signaling pathway (typically due to a *CTNNB1* mutation) and the MAPK pathway (typically due to a *BRAF* mutation)
- Histologically characterized by spindled and/or epithelioid melanocytes extending into the deep reticular dermis and arranged in a wedge-shaped or plexiform pattern

Epidemiology and Pathogenesis

WNT-activated deep penetrating/plexiform nevi are rare tumors that occur in all age groups, with a mean age of 30 years and a slight predominance in women[43]. Most lesions arise from common acquired nevi due to an additional mutation that activates the WNT signaling pathway. In more than 90% of cases, these mutations affect a critical domain of *CTNNB1*, which encodes β-catenin. In rare cases, this pathway is activated by loss-of-function mutations in *APC*. The additional MAPK pathway activation is due to mutations in *BRAF* or rarely mutations in *MAP2K1* or *HRAS*, or *BRAF* fusions. WNT pathway activation leads to an increase in pigmentation, cell volume, and nuclear cyclin D1 levels, thereby altering the phenotype of a *BRAF*-mutated common acquired nevus into a WNT-activated deep penetrating/plexiform nevus[44].

Clinical Features

These nevi occur most commonly in the head and neck region, followed by the extremities and trunk. They are typically symmetric, well-circumscribed, darkly pigmented papules with a diameter that is <10 mm[45].

Pathology

WNT-activated deep penetrating/plexiform nevi are predominantly dermal melanocytic neoplasms. In most lesions, a junctional component and variably large areas of a conventional nevus are present, i.e. the histopathologic features of a "combined" nevus. Nests of enlarged epithelioid to spindle-shaped pigmented melanocytes are admixed with melanophages. The *deep penetrating subtype* is often wedge-shaped with bulbous extension into the deep reticular dermis or subcutis, with melanocytes extending along adnexal and neurovascular structures. In the *plexiform spindle cell subtype*, the melanocytes are located more superficially and are arranged in a fascicular-plexiform pattern. By immunohistochemistry, nuclear positivity for β-catenin or LEF1, which is also involved in WNT signaling, may help establish the diagnosis (cytoplasmic positivity is not specific)[45].

Differential Diagnosis

The clinical differential diagnosis includes melanoma and other types of melanocytic nevi, especially blue nevi, combined nevi, pigmented Spitz nevi, and pigmented epithelioid melanocytomas. However, the fundamental diagnostic issue is histologic differentiation from melanoma. Compared to melanomas, these nevi usually occur in younger patients, are smaller, have a regular, symmetric, and plexiform architecture,

and display monomorphous cells with low-grade atypia and a mitotic rate of ≤2 mitoses/mm[2,45]. True bona fide melanomas derived from a WNT-activated deep penetrating/plexiform melanocytoma appear to be extremely rare.

Treatment

These nevi usually exhibit a benign clinical behavior. However, atypical lesions may spread to regional lymph nodes and eventually have an unfavorable clinical outcome[43]. Consequently, some authors recommend complete excision, whereas others reserve this recommendation for lesions with clinically or histologically atypical features. In the case of partial biopsies, patient age, size of the lesion, and clinical and histopathologic features can be considered, but it is important to note that histopathologic differentiation from melanoma may be very difficult or even impossible when the entire lesion is not examined.

BAP1-INACTIVATED MELANOCYTIC NEVUS

Synonyms: ■ BAP1-inactivated melanocytic tumor ■ BAP1-inactivated melanocytoma ■ BAPoma ■ Melanocytic BAP1-mutated atypical intradermal tumor (MBAIT) ■ Wiesner nevus

Key features

- Skin-colored to reddish-brown, dome-shaped, 5–10 mm papule
- Caused by a bi-allelic inactivation of the *BAP1* tumor suppressor gene, usually in combination with a *BRAF* mutation
- Histologically characterized by an epithelioid cell morphology

Epidemiology and Pathogenesis

BAP1-inactivated melanocytic nevi are rare tumors, but their exact prevalence is unknown. They can occur sporadically or in association with the *BAP1* tumor predisposition syndrome (BAP1-TPDS), which is a rare autosomal dominant tumor syndrome due to germline *BAP1* mutations[46].

These nevi usually arise from a bi-allelic inactivation of *BAP1* in a conventional nevus, which usually has a *BRAF* mutation, or less commonly a *NRAS* mutation or *RAF1* fusion. The *BAP1* inactivation results in an epithelioid cell morphology of the clonally expanding melanocytes[47]. In sporadic tumors, bi-allelic *BAP1* inactivation often occurs through a loss-of-function mutation in one *BAP1* allele and a chromosomal deletion in the remaining wild-type *BAP1* allele. In patients with BAP1-TPDS, bi-allelic BAP1 loss is due to inactivation of the remaining wild-type *BAP1* allele.

Clinical Features

BAP1-inactivated melanocytic nevi can occur anywhere on the skin, but are more commonly observed in chronically sun-exposed sites. They usually present as inconspicuous, skin-colored to reddish-brown, dome-shaped papules measuring 5–10 mm in diameter (Fig. 112.20). Some lesions have small brown areas at their periphery, representing remnants of a conventional nevus. By dermoscopy, they usually appear as: (1) structureless pink-to-tan lesions, sometimes with irregular eccentric dots/globules or peripheral vessels; (2) a network with raised structureless pink-to-tan areas; or (3) a globular pattern[48].

Solitary BAP1-inactivated melanocytic nevi occur sporadically and are usually not associated with an increased cancer risk. In contrast, multiple BAP1-inactivated melanocytic nevi are associated with the BAP1-TPDS. Genetic testing for *BAP1* germline mutations should be considered in patients with multiple such nevi or with a family history of BAP1-TPDS-associated cancers, most commonly uveal or cutaneous melanoma, mesothelioma, and renal cell carcinoma[46].

Pathology

BAP1-inactivated melanocytic nevi are predominantly intradermal melanocytic proliferations with occasional junctional involvement. The majority have remnants of an adjacent conventional nevus (e.g. small nevoid cells) plus larger epithelioid cells (Fig. 112.21A–C), i.e. features of a "combined" nevus. The minority have no remnants of a conventional nevus.

Fig. 112.20 BAP1-inactivated melanocytic nevus. Reddish-brown, elevated, slightly asymmetric papule on the upper arm.

The characteristic cells are large, epithelioid melanocytes with well-defined cytoplasmic borders, large amounts of eosinophilic cytoplasm, and vesicular nuclei with prominent nucleoli. The BAP1-inactivated melanocytes reside within the dermis and are typically not pigmented. They can show varying degrees of nuclear size, including nuclear pleomorphism with dispersed chromatin patterns and prominent nucleoli. The mitotic activity is low, and tumor-infiltrating lymphocytes are frequently present.

In the epithelioid cells, bi-allelic *BAP1* inactivation typically leads to complete loss of nuclear BAP1 expression by immunohistochemistry, and this is a good surrogate for demonstration of *BAP1* inactivation at a molecular level. In combined cases, BAP1 immunoreactivity is retained within the nevoid compartment (Fig. 112.21D)[49].

Differential Diagnosis

The differential diagnosis includes intradermal nevi, neurofibromas, and fibroepithelial polyps. However, the notable diagnostic issue is the histologic differentiation from spitzoid lesions and melanoma. In some cases with spitzoid cytomorphology, BAP1-inactivated melanocytic nevi may resemble a Spitz nevus; however, Kamino bodies are absent and typically there is a lack of the wedge-shaped silhouette of Spitz nevi as well as lack of expression of BAP1. Combined BAP1-inactivated melanocytic nevi may be confused with melanoma arising in a nevus. Helpful clues are recognition of the typical epithelioid melanocytes and loss of BAP1 expression by immunohistochemistry in the absence of malignant features. However, because BAP1-inactivated melanoma, sometimes in association with a pre-existing melanocytic nevus, may occasionally be observed, BAP1 inactivation *per se* is not a criterion for benignity.

Treatment

BAP1-inactivated melanocytic nevi typically have an indolent clinical course[50]. However, the increased incidence of BAP1-inactivated cutaneous melanomas in patients with multiple BAP1-inactivated melanocytic nevi indicates an increased risk of progression to melanoma. In the setting of a partial biopsy, histopathologic features, patient age, and size of the residual lesion should be considered when making recommendations regarding re-excision.

Cancer screening criteria for uveal and cutaneous melanoma, mesothelioma, renal cell carcinoma, and cholangiocarcinoma have been proposed for carriers of *BAP1* germline pathogenic variants. Of note, BAP1-inactivated melanocytic nevi often precede the onset of other tumors[46].

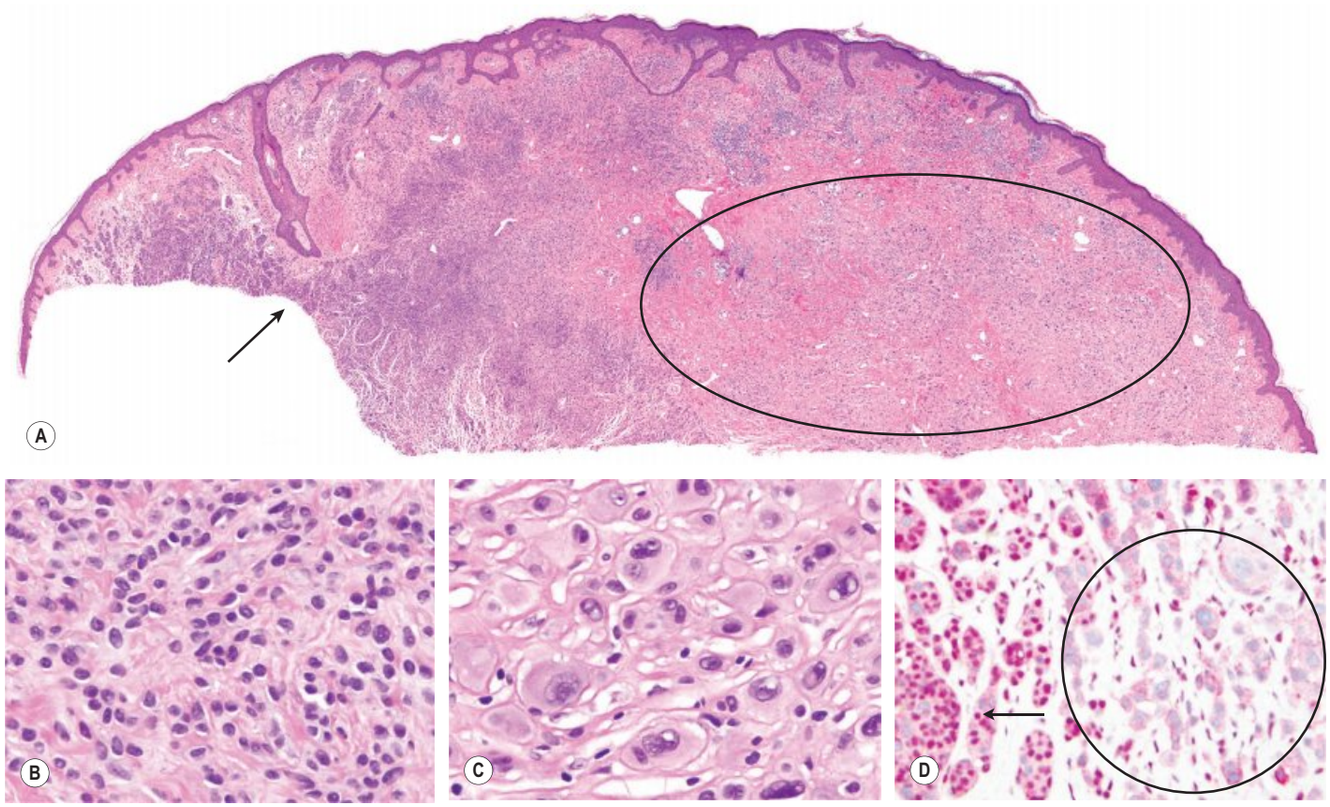

Fig. 112.21 Combined BAP1-inactivated melanocytic nevus. A The conventional nevus (left; arrow) consists of small oval melanocytes, whereas the BAP1-inactivated nevus (right; oval) consists of large, nonpigmented epithelioid melanocytes. **B** Higher magnification of the small oval melanocytes of the conventional nevus. **C** Higher magnification of the large, non-pigmented epithelioid melanocytes with large pleomorphic nuclei, vesicular chromatin, abundant cytoplasm, distinct cell borders, and a sparse infiltrate of lymphocytes. **D** BAP1 immunohistochemistry shows nuclear immunoreactivity in the conventional nevus component (left; arrow) and loss of nuclear immunoreactivity in the BAP1-inactivated component (right; circle).

ATYPICAL (DYSPLASTIC) MELANOCYTIC NEVUS

Synonyms: ■ Nevus with architectural disorder and cytologic atypia ■ Atypical nevus ■ Clark's nevus ■ Atypical mole ■ "Dysplastic" melanocytic nevus ■ B-K mole ■ The mole of FAMM (familial atypical mole and melanoma) syndrome

Key features

- A controversial clinical term for nevi that have atypical morphologic features such as asymmetry, irregular borders, and color variation
- Also a controversial pathologic term used for nevi with atypical architectural features and cytologic atypia
- The diagnostic threshold for melanoma versus atypical nevus remains a gray area due to a lack of consensus concerning precise differentiating criteria

History

Since the description of atypical or "dysplastic" melanocytic nevi in melanoma-prone families more than 40 years ago, and subsequently in individuals outside such kindreds, these lesions have remained a controversial topic[51–53]. The controversy arose primarily because no consensus could be reached regarding the nature of these lesions and it was not possible to formulate precise, commonly accepted diagnostic criteria. This relates both to criteria for individual lesions (what are the essential morphologic criteria required for diagnosis?) and for the so-called "dysplastic nevus syndrome" (how many clinically atypical melanocytic nevi are needed?). A particular problem, dating back to the original studies of atypical ("dysplastic") melanocytic nevi in hereditary kindreds, has been the tendency to consider the histopathologic diagnosis of atypical melanocytic nevi as the gold standard. However, it has been shown that the histopathologic criteria ascribed to atypical melanocytic nevi lack specificity and the correlation between *clinically* atypical melanocytic nevi and *histopathologically* atypical melanocytic nevi is poor. Thus, the term atypical melanocytic nevus does not describe a distinct clinicopathologic entity, but rather encompasses a heterogeneous group of nevi including:

- nevi with atypical *clinical* features, which have been termed simply "atypical nevi"; in general, these atypical nevi can clinically simulate melanoma; this group of nevi includes not only atypical ("dysplastic") nevi, but also some congenital and combined melanocytic nevi, Spitz nevi, and pigmented spindle cell nevi
- nevi with abnormal *histopathologic* features
- nevi with *both* abnormal clinical and histopathologic features

Many studies have found that, irrespective of histology, melanoma risk correlates with both: (1) the number of ordinary nevi (e.g. >50 or >100; see Fig. 113.6); and (2) the presence and number of clinically atypical nevi, as defined by several features including size (e.g. >5, 6, or 10 mm), irregular or ill-defined borders, and variation in color (Tables 112.8 & 112.9; see Fig. 113.7)[54–58]. Despite the seemingly logical conclusion that *histopathologically* atypical nevi should be associated with an increased risk of melanoma, thus far relatively limited data have shown such a relationship[59]. Currently, the assessment of a patient's melanoma risk is based almost exclusively

MELANOCYTIC NEVUS PHENOTYPES		
	Common pattern	**Atypical pattern**
Number	None to few (<25) nevi	Many (>50) nevi
Size	<5 mm	Variable: small to large, often several >5 mm
Color	Uniform, homogeneous color	Some to many melanocytic nevi with irregular or haphazard color, erythema within the nevus
Borders	Well circumscribed	Irregular or ill-defined borders

Table 112.8 Melanocytic nevus phenotypes.

MELANOMA RISK ASSOCIATED WITH CLINICALLY ATYPICAL MELANOCYTIC NEVI: COMPARISON OF OCCURRENCE IN MELANOMA PATIENTS VERSUS CONTROLS					
Study	**Country**	**Definition**	**Melanoma patients (%)**	**Controls (%)**	**Relative risk**
Roush et al. & Nordlund et al.	Australia	>5 mm, irregular border, and haphazard pigmentation	34	7	7.7
MacKie et al.	Scotland	>5 mm and either irregular pigmentation or inflammation	38	20	2.1–4.5*
Holly et al.	US	At least 3 of 6 criteria: ill-defined border, irregular border, irregular pigmentation, >5 mm, erythema, accentuated skin margins	55	17	3.8–6.3†
Halpern et al.	US	>4 mm, macular component, variegation of color, and irregular or indistinct border	39	7	8.8
Garbe et al.	Germany	At least 3 of 5 criteria: >5 mm, irregular margins, ill-defined border, color variation, macular and papular components	45	5	7

*Relative risk for one or two atypical nevi, 2.1; for three or more atypical nevi, 4.5.
†Relative risk for one to five atypical nevi, 3.8; for six or more atypical nevi, 6.3.

Table 112.9 Melanoma risk associated with clinically atypical melanocytic nevi: comparison of occurrence in melanoma patients versus controls[54–58]. A more recent study found statistically significant adjusted odds ratios of 2.57, 2.59, and 3.08 for multicomponent dermoscopic features, size >8mm, and anterior truncal location, respectively[58a].

on a total body skin examination that assesses the total number of nevi and number of atypical melanocytic nevi, plus risk factors, in particular a personal and/or family history of melanoma and degree of photodamage (see Ch. 113).

Epidemiology

Estimates of the incidence of atypical melanocytic nevi cover a wide range, as would be expected given the lack of consensus regarding definitions. Most estimates are in the 10% range for the general population but up to 40% in patients with melanoma. Atypical melanocytic nevi may be single or multiple. In the general population, atypical nevi may arise in a "sporadic" fashion, i.e. without a history of familial melanoma, versus in the context of a family history of atypical moles and/or melanoma. In both clinical settings, there is agreement that these nevi indicate some increase in melanoma risk.

Sporadic atypical melanocytic nevi may occur at any time, while persons with a family history of atypical melanocytic nevi and/or melanoma usually manifest their atypical lesions by the end of the second decade. In contrast to common acquired nevi that tend to appear in increasing numbers around puberty, atypical melanocytic nevi may appear, even in an eruptive fashion, as late as the sixth decade. Histologic contiguity of atypical melanocytic nevi to melanomas was frequently observed in several studies[60], but the development of melanoma in association with an individual atypical melanocytic nevus in the sporadic setting seems to be an uncommon event and not more frequent than the development of melanoma in other types of melanocytic nevi. One study estimated that the annual transformation rate of any single melanocytic nevus into melanoma ranged from ≤1 in 200 000 (≤0.0005%) to ≤1 in 33 000 (≤0.003%)[60a].

Pathogenesis

The pathogenesis of atypical nevi is not well understood. As in common acquired nevi, the driver mutation is frequently a *BRAF* V600E mutation, and less frequently an oncogenic *BRAF* non-V600E or *NRAS* mutation. In addition, mutations in the *TERT* promoter or loss of the tumor suppressor *CDKN2A* may be present. Atypical nevi appear to have a higher mutation rate than common acquired nevi or congenital melanocytic nevi, but a lower mutation rate than melanoma[53].

Clinical Features

Atypical nevi occupy an intermediate position on a continuum with common nevi at one end and cutaneous melanoma at the other end, and, as a result, they overlap with both. No single feature is diagnostic of atypical melanocytic nevi; rather, a constellation of clinical and dermoscopic findings is required for their recognition (Figs. 112.22 & see Fig. P9). Some authors recommend the following criteria: a macular component plus at least three of the following features: size >5 mm, color variegation, ill-defined border, uneven peripheral contour, and erythema[61]. By

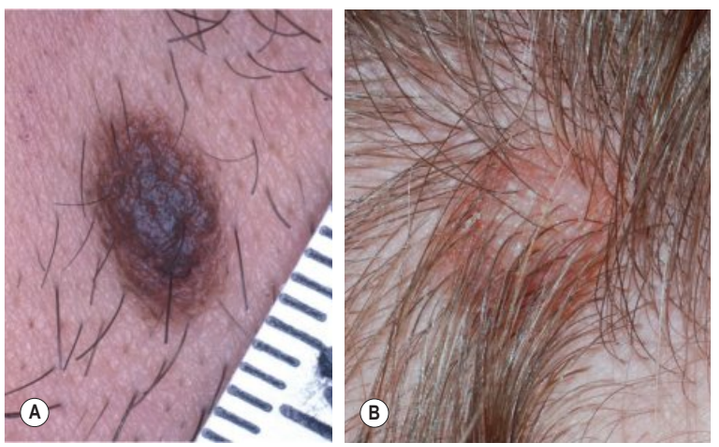

Fig. 112.22 Atypical melanocytic nevi. A Although this "fried egg" nevus is at least 7 mm in size, it is symmetric and does not need to be excised. **B** "Eclipse" nevi, characterized by a tan center and brown rim, are commonly found on the scalp of children who go on to develop numerous melanocytic nevi. The associated dermoscopic patterns are those seen in benign melanocytic nevi. *A, Courtesy Jean L. Bolognia, MD; B, Courtesy Julie V. Schaffer, MD.*

definition, these lesions have a flat component representing junctional proliferation, and there is often a central raised portion that represents a dermal component resulting in the resemblance to a "fried egg" or a "head with shoulders". The more clinical abnormalities present, the greater the likelihood that the lesion will prove to be histologically atypical.

The following gross morphologic features are commonly seen in atypical melanocytic nevi:

- *Asymmetry*: atypical melanocytic nevi often lack mirror-image symmetry.
- *Size*: atypical melanocytic nevi can be of any size, but generally range from 5 to 15 mm in diameter.
- *Borders*: atypical melanocytic nevi often have irregular and ill-defined borders, but not typically the notched or scalloped borders of melanoma.
- *Coloration*: atypical melanocytic nevi commonly have irregular pigmentation with two or three shades of brown, e.g. tan, brown, and dark brown (Fig. 112.23A). They may also have pink, gray, brown–black, or skin-colored areas. However, some atypical melanocytic nevi present with fairly uniform coloration and an erythematous appearance.

Atypical melanocytic nevi appear most commonly on the trunk, especially the back, but are also found on the scalp. Their numbers may range from one or two to hundreds (Fig. 112.23B). When multiple large lesions are present, their prominence is noteworthy, and while there may be variability, patients often have a "signature" nevus, clinically and histologically. Localized patterns such as linear tracts, clusters, or figurate arrays may also be seen in patients with numerous nevi.

Fig. 112.23 Atypical melanocytic nevi. **A** There is asymmetry as well as several shades of brown, simulating the clinical features seen in cutaneous melanoma. **B** In addition to multiple atypical nevi, patients can have numerous banal nevi.

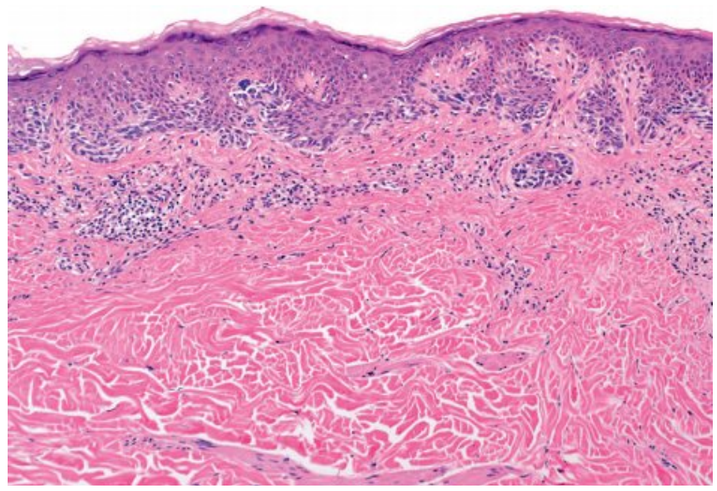

Fig. 112.24 Atypical melanocytic nevus – histopathologic features. Note confluent nests of melanocytes at the dermal–epidermal junction with so-called "bridging" of rete ridges (confluence of melanocytic nests parallel to the epidermis bringing together two or more rete ridges) as well as scattered solitary melanocytes in the lower portion of the epidermis. *Courtesy Lorenzo Cerroni, MD.*

The overwhelming majority of atypical melanocytic nevi are clinically stable. However, there is evidence that some lesions eventuate in cutaneous melanoma. Progressive abnormalities in DNA content, cytogenetic alterations, and increased expression of melanocyte-associated antigens by immunohistochemistry have been correlated with progressive degrees of histologic atypia[60]. Although findings suggest a progression of atypical melanocytic nevi toward melanoma, atypical melanocytic nevi are not inevitable precursors to melanoma, and their presence can be viewed as a phenotypic marker of "an entire skin at risk".

Pathology

Prototypic atypical melanocytic nevi are characterized by several architectural features. Compared to ordinary nevi, these nevi are often larger (commonly >5 mm in diameter), poorly circumscribed, slightly asymmetric, relatively flat (especially at the periphery of the lesion), and often show heterogeneity. In atypical melanocytic nevi, the junctional component frequently extends beyond the dermal component (the "shoulder" phenomenon).

Of particular importance is architectural disorder of the intraepidermal component, which occurs in two patterns that are often present simultaneously to a varying degree (Fig. 112.24). The *first* is lentiginous melanocytic proliferation that is almost always associated with elongated epidermal rete ridges. In general, the basilar melanocytes are concentrated in the lowermost portions of the rete ridges, and the frequency of basilar melanocytes varies greatly, e.g. from one melanocyte per one to two keratinocytes to the melanocytes replacing the basilar keratinocytes and resulting in a confluent, clustered, or multilayered cellular appearance.

The *second* pattern consists of melanocytic nests that are irregularly disposed along and between the rete ridges, as compared to ordinary nevi. These nests vary in size and shape, are often elongated, commonly have their long axes oriented along the dermal–epidermal junction, and contain variable numbers of cells. Colliding nests of melanocytes frequently fuse or "bridge". Discohesion of cells within these nests is also common; this feature contrasts with the cohesive appearance of junctional nests of melanocytes in ordinary nevi. Atypical nevi often have a higher density of melanocytes in the intraepidermal component than do ordinary nevi.

Atypical melanocytic nevi often exhibit cytologic atypia. The latter is discontinuous and variable, from only a small percentage of melanocytes demonstrating nuclear atypia to most cells being atypical. Cytologic atypia often correlates with the degree of architectural abnormality. Pleomorphism of the nuclei (i.e. variation in size, shape, and staining properties) is the most characteristic attribute of the nuclear changes in atypical melanocytic nevi. However, nuclear enlargement and hyperchromatism also occur. The cells are frequently typified by a perinuclear clear space resulting from cytoplasmic shrinkage, which is an artifact of tissue processing. Criteria for grading the degree of cytologic atypia and even architectural abnormality have been proposed, but there is neither consensus regarding using a grading system nor how to define different grades of atypia.

The dermal component of atypical melanocytic nevi may be composed of typical nevus cells, as in any acquired nevus, or of cells that may exhibit atypia. In addition to the abnormal architectural disorder and cytologic atypia, atypical melanocytic nevi usually exhibit changes related to host response. Two forms of collagenous change occur in the papillary dermis and a mixture of the two patterns is not uncommon. The most common pattern, termed *concentric fibrosis*, is a condensation of collagen around the epidermal rete. A less common pattern, termed *lamellar fibroplasia*, consists of finely layered or laminated collagen beneath the rete tips with fibroblasts arranged in a linear array along the laminated collagen fibers. Both patterns can also be observed in melanoma. Lymphocytic infiltrates, usually distributed in a perivascular fashion and less commonly in a band-like pattern, are also frequently observed. Finally, atypical melanocytic nevi usually have prominent vascularity throughout the papillary dermis, which is due to dilation and hypertrophy of existing vascular channels, rather than angiogenesis.

Differential Diagnosis

The differential diagnosis of pigmented lesions with a similar size includes both melanocytic and keratinocytic lesions. Lichen planus-like keratoses, pigmented seborrheic keratoses, solar lentigines, pigmented actinic keratoses, pigmented Bowen disease, and basal cell carcinomas may exhibit pink, tan, brown, or dark brown colors. Among melanocytic proliferations, the principal diagnostic considerations are common acquired nevi, small congenital nevi, and cutaneous melanoma. The atypical melanocytic nevus is characterized by haphazard, irregular coloration, including hues of pink, tan, brown and even black, and irregularity in shape (features it shares with melanoma). The other non-melanoma lesions either show symmetry and/or uniformity of coloration or, when irregularly colored, show orderly gradations or patterns of pigmentation.

Dermoscopy plays an important role in the evaluation of atypical melanocytic nevi (Fig. P5). Although atypical melanocytic nevi can clinically resemble melanoma, many of these lesions fall into one of the benign dermoscopic melanocytic patterns (see Fig. P9). Features employed to evaluate a melanocytic nevus include colors, symmetry, and organization. Benign melanocytic lesions tend to have few colors and are symmetric with regard to the distribution of colors and structures. When these structures are symmetrically distributed and there are fewer than three colors (light brown, dark brown, and black) noted, they create a pattern seen in many benign lesions. The most common benign patterns are reticular, globular, and homogeneous (see Fig. 0.37). In addition, there are the subset patterns of reticular–homogeneous, reticular–globular, and globular–homogeneous (see Fig. P9)[62]. Finally, another subset of atypical melanocytic nevi is characterized by uncertain melanocytic dermoscopic patterns. Just as the clinical and histologic features of atypical melanocytic nevi are a continuum, so too are the features with dermoscopy. These lesions should either be excised or serially monitored.

The histopathological differential diagnosis of atypical (dysplastic) melanocytic nevi from melanoma may be very difficult and may be influenced by the threshold of a given dermatopathologist for the diagnosis of early melanoma. For example, some cases classified as "dysplastic nevus with severe architectural and morphologic atypia" in one center may be diagnosed as "melanoma *in situ*" by another. Immunohistochemical stains may be helpful, and strong positivity for PRAME (*pr*eferential expressed *a*ntigen of *me*lanoma) in the majority of neoplastic cells is a strong criterion for the histopathologic diagnosis of melanoma. In addition, atypical nevi located on chronic sun-damaged skin and/or the face should be judged with caution, as the likelihood of melanoma is significant in these settings.

Treatment

As within any area of medicine, the physician is first obliged to do no harm. Such an approach is particularly important in patients with atypical melanocytic nevi with avoidance of overly aggressive procedures, surgery, and follow-up. Common sense should prevail at all times and consideration should be given to whether the intervention has an impact on potentially reducing melanoma mortality. Treatment depends upon several factors including: (1) whether the patient presents with one or a few nevi versus numerous nevi; (2) whether the patient has a personal history of melanoma; and (3) whether there exists a familial setting of atypical melanocytic nevi and/or melanoma. The risk of melanoma is probably continuous and increases with the number of nevi, clinical atypia of nevi, and personal and familial occurrence of atypical nevi and melanoma.

Regardless of the risk group, any pigmented lesion suspicious for melanoma and any significantly changing lesion should, in the authors' opinion, be excised completely with free margins. Some authors have advocated "deep" shave excision (saucerization) for superficial lesions, which is acceptable as long as the lesion is removed entirely, including its base. As opposed to partial punch biopsy, which should be discouraged, the latter allows for assessment of the overall architecture of the lesion and leads to less sampling error.

A helpful rule of thumb in following patients with many atypical melanocytic nevi is to search for lesions that clearly stand out as different from the patient's other (baseline) nevi ("ugly duckling"); such lesions should be examined carefully. It should be kept in mind that new nevi will continue to develop and nevi may enlarge and change with time, especially in young individuals. One must use common sense in assessing this normal evolution of nevi and not be overly aggressive in removing such nevi. An acceptable practice is to follow such patients on a regular schedule with a total body skin examination plus dermoscopy, baseline photography, and/or digital dermoscopy, as preferred by the clinician. Computerized assessment and comparison of clinical photographs is increasingly being employed. The frequency of follow-up examinations is individualized and is based on the previously mentioned risk factors, i.e. numbers and clinical atypia of nevi, lesion stability, and personal and family history of melanoma.

For any melanocytic lesion, it is important to know if the lesion has been adequately sampled and if the lesion was considered to be clinically atypical. If lesions are "severely" atypical, re-excision is recommended because of frequent overlap with, and difficult distinction from, melanoma *in situ*. For atypical melanocytic nevi with lesser degrees of atypia, the answer regarding whether to re-excise is controversial. In general, if lesions are "mildly" atypical, no re-excision is recommended, as long as no significant residuum of the nevus is clinically apparent. If lesions are "moderately" atypical, the decision to re-excise is particularly difficult. Studies show that dermatologists tend to re-excise moderately atypical lesions if a biopsy margin is positive[63]. Despite this propensity for re-excision, available data do not necessarily support re-excision of moderately atypical nevi. Independent retrospective studies examining the utility of re-excision of moderately atypical nevi conclude that re-excision of these nevi rarely results in a change in diagnosis[64]. In a study of 1809 mildly and moderately atypical nevi, 765 were found to have positive margins and of these 495 underwent re-excision. Of the 495 re-excisions, only a single case resulted in a clinically significant change[65]. Therefore, the current data may not support a blanket recommendation to re-excise all moderately atypical nevi even if there are positive margins.

Unfortunately, the discussion of whether or not to re-excise dysplastic nevi is greatly confounded by the lack of a uniform grading system amongst pathologists. Often this leaves dermatologists erring on the side of caution when it comes to this clinical decision. Therefore, even when no residual lesion is clinically obvious, re-excision might be considered, depending upon a number of factors: the initial degree of concern clinically, the size of the nevus (versus the size of the biopsy), the color (more inclined with amelanotic lesions as assessing residuum is more difficult), the site (easy or difficult to visualize by the patient), the patient's ability and interest in following the site, and the patient's prior personal and family history of melanoma.

In general, follow-up of patients with multiple atypical nevi, especially in the context of a personal or family history of melanoma, should be every 3 to 12 months, depending on the clinical situation. One should consider documentation of nevi by body charts and clinical photography as judged appropriate, with periodic updating. Individual photographs of the most atypical or difficult-to-follow nevi are particularly helpful. Additional tools such as dermoscopy and/or digital imaging devices may be useful diagnostic aids. Finally, individuals presenting with atypical melanocytic nevi should have a family history taken for the presence of atypical melanocytic nevi and/or melanoma. First-degree blood relatives should be examined both for documentation and to assess and potentially diminish their own risks of developing melanoma.

CONGENITAL MELANOCYTIC NEVUS

Synonyms:

- Congenital nevomelanocytic nevus
- Large or giant congenital melanocytic nevus: • Bathing trunk nevus • Garment nevus

Key features

- Small congenital nevi are <1.5 cm in diameter (in adults)
- Medium-sized congenital nevi are between 1.5 and 20 cm in diameter (in adults)
- Large (>20 to 40 cm in adults) and giant congenital nevi (>40 cm in adults) have a higher risk for developing melanoma than do ordinary nevi
- Neurocutaneous melanosis may occur in patients with multiple medium-sized congenital nevi and those with large/giant congenital nevi, especially when in a posterior axial location and accompanied by satellite lesions

Introduction

Congenital melanocytic nevi are benign proliferations of melanocytes that are present at birth and may be intraepidermal, dermal, or both[66,67]. Lesions indistinguishable from congenital nevi may appear up to 2 years after birth and are therefore referred to as *tardive congenital nevus*. Finally, histopathologic features of congenital nevi may be observed in melanocytic tumors acquired during childhood or adolescence, with dermatopathologists often referring to them as melanocytic nevi with a congenital pattern.

Some congenital melanocytic nevi may be just a few millimeters in size and appear clinically indistinguishable from common acquired nevi. In general, congenital melanocytic nevi are classified as small (<1.5 cm), intermediate- or medium-sized (1.5 to 20 cm), large (>20 to 40 cm), and giant (>40 cm), based upon their size in adults[68]. Given the eventual size, a congenital nevus ≥9 cm on the scalp or ≥6 cm on the trunk in a newborn is assigned to the large/giant category; with extensive involvement (e.g. the entire trunk), assignment to the giant category is self-evident. Some authors base the distinction between small, intermediate, and large/giant congenital nevi on their ease of removal. In this scheme, small congenital nevi generally may be removed by simple excision, medium-sized nevi often require staged excisions for closure, and large/giant nevi often cannot be removed or require multiple staged excisions and/or tissue expanders for removal.

Patients with ≥3 small or medium-sized congenital melanocytic nevi or a giant congenital melanocytic nevus may have associated neurocutaneous melanosis (see below).

Epidemiology

The prevalence of congenital melanocytic nevi varies widely depending on the study, ranging from 0.5% to 30%[67], but in our experience occur in ~1% of newborns. Most lesions are 3 to 4 cm in diameter. Large/giant congenital nevi are rare, with an estimated incidence of 0.005% (1 in 20 000). Patients with large/giant nevi often have multiple smaller (satellite) nevi, with greater numbers correlating with an increased risk of neurocutaneous melanosis (see below). Familial aggregation of congenital nevi has occasionally been reported.

Pathogenesis

The majority of congenital melanocytic nevi have oncogenic *NRAS* mutations. *BRAF* mutations are detected in up to 7% of cases while *KRAS* mutations and kinase fusions are rare[69]. Individual melanocytes begin to appear in fetal skin before 40 days' gestation. Given the observation of congenital divided nevi of the eyelid and the fact that the eyelids open during the sixth month of gestation, it appears that congenital melanocytic nevi can develop prior to the sixth month of gestation. Patients with a large/giant congenital nevus and/or multiple satellite lesions should be thought of as having a systemic disease (Fig. 112.25), as nevus cells can be found in sites beyond the skin and central nervous system (CNS), such as the retroperitoneum.

Fig. 112.25 Congenital melanocytic nevi associated with neurocutaneous melanosis. A Multiple medium-sized nevi. The patient had 25–30 such lesions. This presentation is most commonly associated with neurocutaneous melanosis. **B** Giant congenital nevus in an axial location with numerous satellite nevi, some of which have hypertrichosis. This patient died of intractable ascites due to the migration of melanocytes from the brain to the peritoneal cavity via his VP shunt. In the perianal region, the nevus was softer and somewhat "spongy" due to neurotization. *Courtesy Jean L. Bolognia, MD.*

Clinical Features

Small and medium-sized congenital nevi are usually round or oval, fairly symmetric, slightly raised, and tan in color (Fig. P6). They may or may not have associated hypertrichosis (Fig. 112.26), and perifollicular hypo- or hyperpigmentation may be seen. Some congenital melanocytic nevi have rugose or pebbly surfaces (see Fig. 112.26A,B). Lesions that are initially minimally elevated often become thicker and darker in color and may develop a verrucous appearance.

After an initial darkening during the first year of life, some congenital melanocytic nevi may become lighter in color with aging, including satellite lesions. In addition, congenital nevi can develop the halo phenomenon (see below), and occasionally, congenital nevi completely regress, even without forming a halo. As hamartomas, congenital nevi can exhibit asymmetry and color variation, develop papules and nodules (e.g. proliferative nodules), and change over time (see Fig. 112.26); however, histologic examination of any concerning areas is recommended (Table 112.10). Areas within congenital nevi can also undergo neurotization and develop compressible, boggy plaques or nodules (Fig. 112.27).

The dermoscopic structures seen in congenital nevi include the following: globules, diffuse background pigmentation (structureless), milia-like cysts, hypertrichosis, hyphae-like structures, and perifollicular pigment changes. The most common dermoscopic patterns are reticular, globular, reticular–globular (see Fig. P6), diffuse brown pigmentation, and multicomponent. The multicomponent pattern is often difficult to distinguish from melanoma and requires either monitoring or biopsy.

Varying numbers of satellite lesions often accompany large/giant congenital melanocytic nevi (see Fig. 112.25B). Such lesions typically resemble small or medium-sized congenital melanocytic nevi. Of note, some patients present with multiple medium-sized congenital nevi in the absence of a large congenital nevus (see Fig. 112.25A), and these individuals are at greatest risk for neurocutaneous melanosis (up to 70% in one study).

Neurocutaneous melanosis (melanocytosis)

In neurocutaneous melanosis, there can be diffuse involvement of the leptomeninges that cover the brain and/or the spinal cord. In addition, intraparenchymal melanosis or solid tumors within the brain parenchyma may be observed. The melanocytes can be benign or malignant and can result in obstruction (with hydrocephalus) or a mass effect. In addition, a variety of intracranial and intraspinal anomalies (e.g. Dandy–Walker malformation, extensive arachnoid cysts) can be seen in association with neurocutaneous melanosis[66,67].

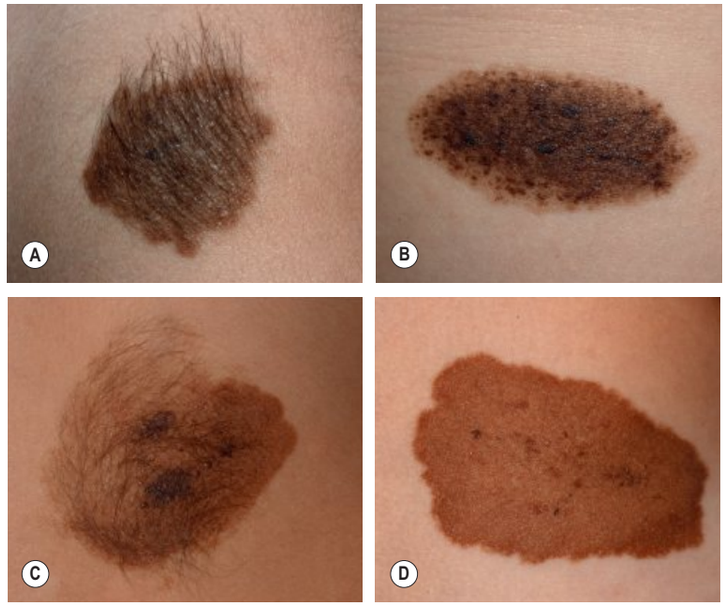

Fig. 112.26 Medium-sized congenital melanocytic nevi. A Hypertrichosis and slight heterogeneity in pigmentation. **B, C** More marked heterogeneity in pigmentation, topography, and hypertrichosis, reflecting the hamartomatous nature of congenital nevi. **D** Hyperpigmented papules of varying sizes and color. *Courtesy Julie V. Schaffer, MD.*

MANAGEMENT OF CHILDREN WITH GIANT CONGENITAL MELANOCYTIC NEVI
Surgical excision versus long-term clinical examination
• Consider surgical excision of the nevus (staged and/or with tissue expanders), typically in children at least 6 months of age in order to avoid the period of highest general anesthesia risk • If not excised or partial excision, lifelong examination of the nevus (including palpation) every 6 to 12 months plus baseline photography • Histologic examination of enlarging firm papulonodules and new areas of induration or ulceration*
MRI of head and spine for the detection of neurocutaneous melanosis† (NCM) and other CNS abnormalities‡

• Risk factors for NCM
  • multiple satellite lesions (≥20)¶
  • giant/"garment" nevus (>40 cm projected adult size)
  • posterior axial location (in some but not all studies)
• If no risk factors and no neurologic symptoms, MRI not necessary
• If at least one risk factor but asymptomatic, MRI should be considered prior to 4–6 months of age for highest sensitivity
• In asymptomatic patients with intermediate risk (e.g. <10–20 satellites, 20–40 cm nevus as an adult), MRI can be considered on a case-by-case basis
• Patients with symptomatic NCM should have MRI performed
• See Fig. 112.28 for recommendations regarding further evaluation

*Ulceration at birth or during the first week of life in areas prone to trauma may be due to immaturity of the skin but should heal over a few weeks. †Also referred to as neurocutaneous melanocytosis. ‡Need to check renal function given association with genitourinary malformations. ¶Highest risk of NCM in those with multiple satellite nevi but no giant congenital nevus. Some authors consider MRI if ≥3 congenital nevi whereas others do so if ≥2 congenital nevi (see Fig. 112.28)

Table 112.10 Management of children with giant congenital melanocytic nevi (GCMN). CNS, central nervous system; MRI, magnetic resonance imaging.

Based upon MRI screening of at-risk infants (Fig. 112.28), preferably done during the first 6 months of life, ~80% of infants have no abnormalities, ~15%–20% have intraparenchymal melanosis, and <10% have other abnormalities (e.g. diffuse leptomeningeal involvement, masses)[70]. This latter group has a poor prognosis with associated seizures and neurodevelopmental delay as well as the highest risk for developing CNS melanoma. However, MRI cannot always predict or exclude the possibility of future symptoms[66,67].

Fig. 112.27 Several areas of "neurotization" within a giant congenital nevus. The edges of the boggy plaques or nodules are demarcated by arrowheads. This phenomenon should not be confused with how cells of acquired nevi can display a neuroid differentiation within conventional intradermal nevi, sometimes characterized by Schwann cell-like features.

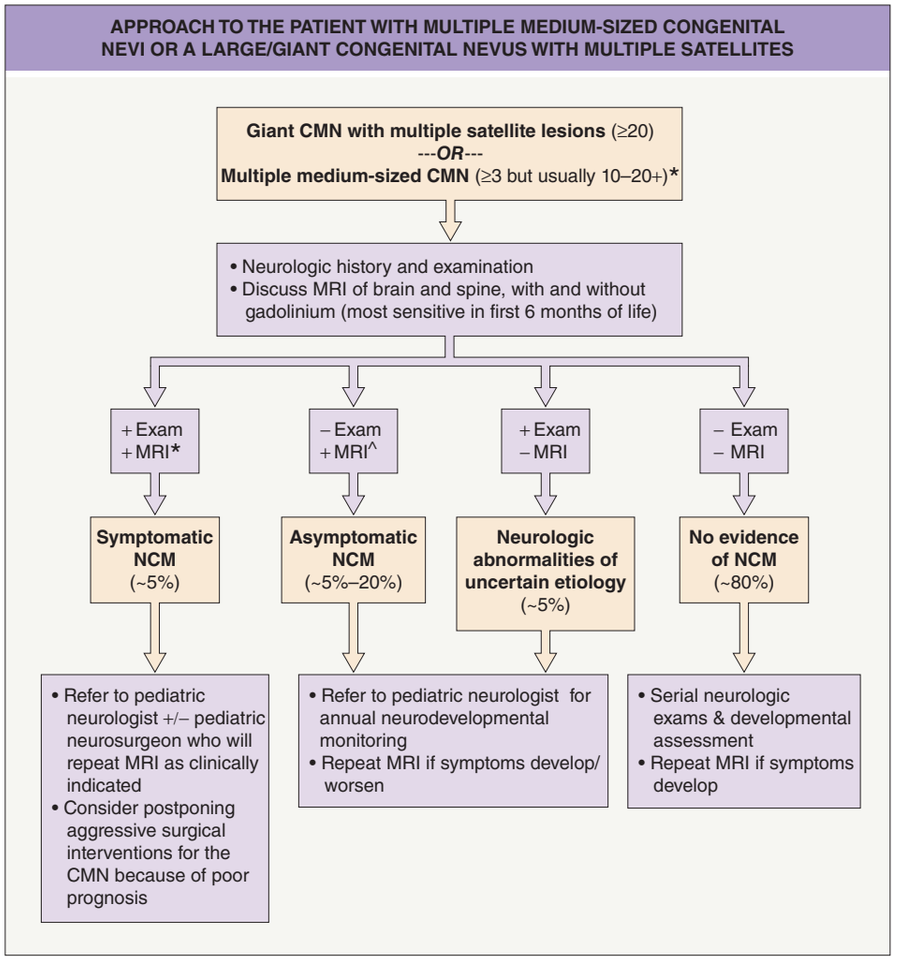

Fig. 112.28 Approach to the patient with multiple medium-sized congenital nevi or a large/giant congenital nevus with multiple satellites. *A relatively high percentage of these patients have NCM; some authors use the criterion of ≥2 CMN. **Diffuse leptomeningeal involvement and masses. ^Usually intraparenchymal melanosis. CMN, congenital melanocytic nevus; NCM, neurocutaneous melanosis.

As noted previously, neurocutaneous melanosis occurs primarily in patients with ≥3 small or medium-sized congenital melanocytic nevi or a giant congenital melanocytic nevus with satellitosis. In one series of 33 patients with neurocutaneous melanosis associated with giant congenital melanocytic nevi, all nevi had a posterior axial location (involving the head, neck, back, and/or buttocks); 31 of 33 patients had satellite nevi. In another study, 80% had posterior axis involvement and 55% had more than 20 satellite nevi. Of note, neurocutaneous melanosis can also be seen in patients with nevus of Ota and phakomatosis pigmentovascularis.

Melanoma arising in congenital nevi

Although all sizes of congenital melanocytic nevi may be associated with melanoma, historical estimates of melanoma risk have been exaggerated because of referral and selection bias and misdiagnosis. The risk of melanoma increases with the size of the nevus, with most studies reporting an incidence rate of melanoma in small/medium congenital melanocytic nevi of <1%. For example, a prospective study of 230 medium-sized congenital melanocytic nevi in 227 patients, followed on average for 6.7 years, failed to document the development of a single case of melanoma. Similarly, in a longitudinal cohort study of 265 patients with medium-sized congenital melanocytic nevi, none developed melanoma.

On the other hand, several studies have noted substantial melanoma risk linked to large or giant congenital melanocytic nevi. In a prospective study of 92 patients with large/giant congenital melanocytic nevi, three patients developed melanoma in extracutaneous sites (brain, CNS, retroperitoneum) during follow-up averaging 5.4 years. The authors calculated the cumulative 5-year life-table risk for melanoma to be 4.5% and the standardized morbidity ratio to be 239, leading to the recommendation for continuous surveillance[71]. A comprehensive review of 14 studies that examined the development of melanoma in patients with congenital melanocytic nevi reported an overall risk of melanoma of 0.7% (in those with congenital melanocytic nevi of all types), with a risk of 2.5% and 3.1% in large and giant nevi, respectively[72].

When a cutaneous melanoma develops in a relatively small congenital melanocytic nevus, it appears most commonly at the dermal–epidermal junction in a pattern similar to that of other conventional melanomas. However, cutaneous melanomas arising in larger congenital melanocytic nevi can develop within the dermis, subcutaneous fat, or even deeper, as a distinct nodule[73]. Rarely, other malignant tumors may arise in these lesions, including rhabdomyosarcomas, malignant peripheral nerve sheath tumors, fibrosarcomas, leiomyosarcomas, osteogenic sarcomas, and liposarcomas.

Leptomeningeal melanomas can arise in patients with neurocutaneous melanosis and most commonly involve the frontal and temporal lobes. As expected, these melanomas have a poor prognosis.

Abnormalities associated with congenital nevi

Patients with large/giant congenital nevi can also have urinary tract anomalies, obstruction of orifices by the nevus (e.g. perianal), and infiltration of lymph nodes and the mother's placenta by nevus cells.

Pathology

In contrast to common acquired nevi, which are confined to the papillary and upper reticular dermis, congenital nevi may have infiltration of the lower reticular dermis, subcutaneous fat, fascia, and even deeper (Fig. 112.29). It is characteristic to observe melanocytes in a single-cell array throughout the middle or lower reticular dermis and even extending into the septa of the subcutis. Melanocytes often surround (cuffing) and/or infiltrate blood vessels, adnexal structures such as hair follicles, sebaceous glands and sweat glands, and cutaneous muscles and nerves. There is often maturation and diminished cellularity with increasing depth within the dermis. Uncommonly, congenital melanocytic nevi may show striking neural differentiation suggesting a peripheral nerve sheath tumor such as a neurofibroma or schwannoma. Structures resembling Meissner corpuscles, Verocay bodies, or neuroid tubules may be observed.

In some patients, nodular proliferations can arise within congenital nevi ("proliferating nodules"), particularly those that are medium-sized, large, or giant. These nodules can be very difficult to distinguish from melanoma arising in a congenital nevus, both clinically and histopathologically. Proliferating nodules usually arise during the first few years of life or are present at birth. They tend to blend well with the remaining nevus and have only slight atypia and occasional mitoses. When analyzed by array comparative genomic hybridization (aCGH), proliferating nodules contain gains and losses of entire chromosomes, in contrast to melanomas that contain several gains and losses, but only of portions of chromosomes.

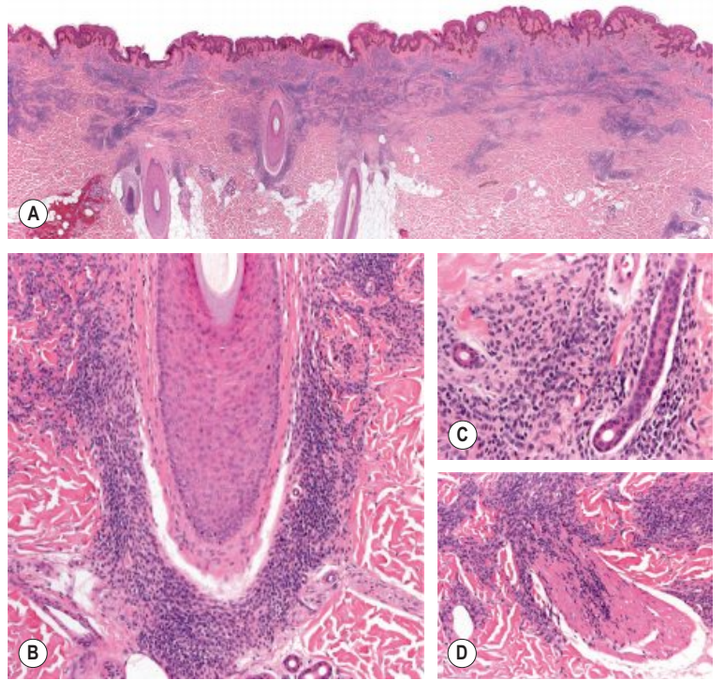

Fig. 112.29 Congenital melanocytic nevus – histopathologic features. **A** Scanning view with complexes of nevus cells extending into the deep reticular dermis and down adnexal structures. Melanocytes surround a hair follicle (**B**), extend along eccrine sweat ducts (**C**), and surround and infiltrate an arrector pili muscle (**D**). *Courtesy Lorenzo Cerroni, MD.*

Differential Diagnosis

The differential diagnosis of small congenital nevi includes congenital smooth muscle hamartoma, neurofibroma, atypical nevus, and melanoma. For medium-sized congenital nevi, an additional entity to consider is Becker melanosis, including those with an associated smooth muscle hamartoma. Large/giant congenital melanocytic nevi are occasionally misdiagnosed as plexiform neurofibromas, as the latter can have both hyperpigmentation and hypertrichosis. Of course, the possibility of melanoma exists for any clinically atypical area (e.g. darkening, nodularity) within a congenital nevus. The differences between melanoma and a proliferating nodule are outlined in the Pathology section.

Treatment

The treatment of congenital melanocytic nevi is primarily related to two factors: their cosmetically disfiguring appearance and their increased risk for progression to melanoma. The decision to remove a congenital nevus is individualized and based on melanoma risk, age, anatomic location (especially proximity to vital structures), presence or absence of neurocutaneous melanosis, anticipated cosmetic outcome, and complexity of removal. In the absence of a cosmetic concern, the routine excision of uniform-appearing small and medium-sized congenital nevi no longer seems justified due to the low melanoma risk. An acceptable alternative to surgical excision is baseline photography, education, and yearly examination.

The treatment of large/giant congenital nevi is more problematic, since melanoma risk is present from birth. If such large/giant nevi are to be excised, most authorities recommend delaying the procedure for

at least 6 months so as to decrease the risk from general anesthesia (see Table 112.10). Since the prognosis of patients with *symptomatic* neurocutaneous melanosis is poor, excisions of large/giant congenital melanocytic nevi should be delayed. In neonates with either large/giant congenital melanocytic nevi with multiple satellite nevi (especially if ≥20) or multiple medium-sized congenital nevi, MRI is routinely performed to detect neurocutaneous melanosis. For patients with asymptomatic neurocutaneous melanosis, individualized care is indicated (see Fig. 112.28).

In the past, dermabrasion was sometimes performed, resulting in a more lightly pigmented and less elevated congenital nevus. Repeat curettage performed in the first few weeks of life (when there is a cleavage plane in the upper dermis) has led to similar results. Scarring and prolonged healing in the case of large lesions are the drawbacks. Lasers (e.g. Q-switched ruby, Q-switched alexandrite) have also been used to treat congenital nevi, but recurrence of pigmentation is an issue as is persistence of nevus cells[74].

Suspected proliferating nodules should be evaluated histologically. As mentioned previously, when melanoma supervenes in a large congenital nevus, it may involve the dermal or subcutaneous component and be difficult to detect early. Cutaneous melanoma arising in the smaller types of congenital melanocytic nevi usually begins in the epidermis and can be detected more readily.

As with Spitz nevi, whole-genome sequencing followed by targeted therapy has been tried for large/giant congenital nevi. There is at least one report of a MEK inhibitor leading to a decrease in size and thickness.

NEVUS SPILUS

Synonyms: ■ Speckled lentiginous nevus ■ Zosteriform lentiginous nevus (based upon distribution pattern)

Key features

- Tan patch containing a variable number of more darkly pigmented macules and papules, which range from lentigines to junctional and compound nevi to Spitz and blue nevi
- Occasionally, atypical nevi and small and medium-sized congenital nevi are seen within a larger nevus spilus

Epidemiology

The prevalence of nevus spilus varies from 0.2% to 3%, and it has no sex or ethnic predilection. Lesions are usually present at birth or appear within the first few years of life. Therefore, nevus spilus is classified as a type of congenital melanocytic nevus[75].

Pathogenesis

A nevus spilus often has an oval shape, but it may have a block-like configuration or follow the lines of Blaschko (see Ch. 62). Nevi in the latter patterns are sometimes referred to as zosteriform speckled lentiginous nevi and their configuration suggests a molecular event affecting melanoblasts during embryogenesis. Melanocytes in both the background café-au-lait patch and the smaller nevi contain a mosaic of activating *HRAS* mutations[76]. In theory, these secondary genomic alterations contribute to the development of the nevi. As an example, in a nevus spilus in which Spitz nevi developed, amplification of *HRAS* was identified in the Spitz nevi.

Clinical Features

Nevus spilus usually occurs on the trunk and extremities. The tan macular area typically ranges from 1 to 4 cm in diameter (Fig. 112.30A,B), but can be >20 cm and involve an entire extremity or half the trunk

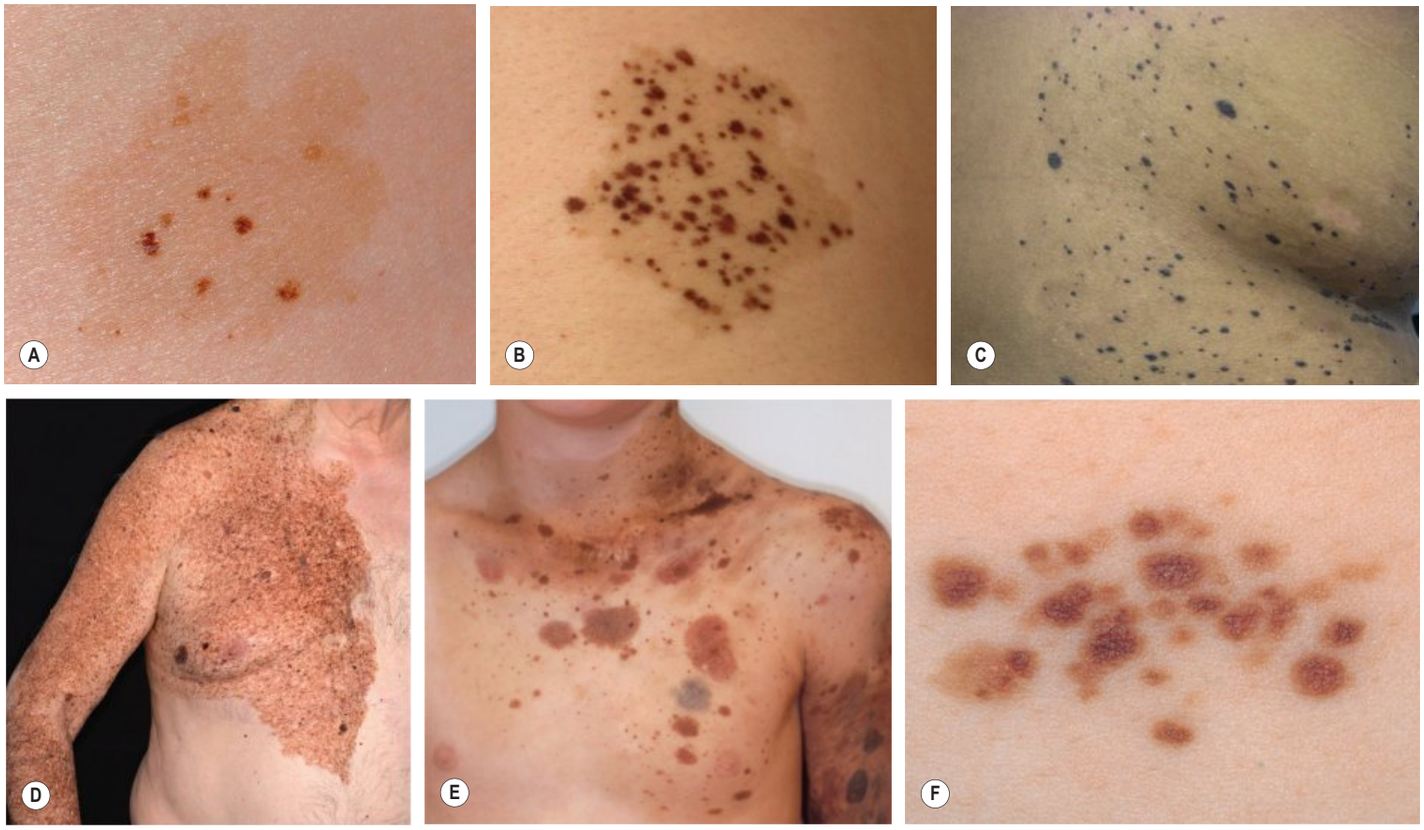

Fig. 112.30 Nevus spilus (speckled lentiginous nevus) – range of presentations and comparison to agminated nevi. A, B A few versus numerous medium to dark brown macules and papules superimposed upon a tan patch. **C** Larger lesion of the lateral trunk with dark brown to black nevi of varying sizes; sometimes the tan background is subtle and not initially recognized. **D** Zosteriform variant with more extensive involvement of the chest and arm. **E** The "speckles" can be larger and resemble small and medium-sized congenital nevi. The larger lesions were present at birth while the smaller nevi have appeared over time. **F** Agminated melanocytic nevi – grouped brown macules and papules in the absence of background hyperpigmentation (see also Fig. 112.17). *B, C, E, F, Courtesy Jean L. Bolognia, MD; D, Courtesy Luis Requena, MD.*

(Fig. 112.30C,D)[75]. Although the darker speckles are usually macules or papules that are 1–6 mm in diameter, larger lesions that resemble small and medium-sized congenital nevi are occasionally seen (Fig. 112.30E).

At birth, only a subtle lightly pigmented CALM-like patch may be seen. Over time, there is usually an increase in "speckling". Cutaneous melanoma may arise within a nevus spilus, and on occasion melanocytic dysplasia has been noted in the nevus spilus adjacent to the site of melanoma development. As with conventional congenital melanocytic nevi, the risk of melanoma may be related to size, but it may also be related to the type of "speckles".

Nevus spilus maculosus, characterized by macular speckles, is seen in patients with phacomatosis spilorosea (phakomatosis spilorosea: phakomatosis pigmentovascularis type III; see Ch. 104) whereas the papular variant favors those with phakomatosis pigmentokeratotica. The latter patients also have organoid nevi, which combine features of epidermal nevi and sebaceous nevi. Patients with speckled lentiginous nevi may have ipsilateral dysesthesia, muscular weakness, or hyperhidrosis, a combination referred to as the "speckled lentiginous nevus syndrome".

Pathology

The tan patch of nevus spilus is characterized by elongated epidermal rete ridges plus lentiginous melanocytic hyperplasia. In the hyperpigmented macular foci, either lentiginous melanocytic hyperplasia or a junctional nevus is present, whereas the papular foci represent compound, dermal, blue, Spitz, and/or atypical nevi. Histopathologic features characteristic of congenital melanocytic nevi can also be seen.

Differential Diagnosis

The major entities in the differential diagnosis are agminated melanocytic nevi and partial unilateral lentiginosis (Fig. 112.30F). However, neither has an associated tan patch as a background, and agminated nevi have less variation in the types of nevi present. Sometimes Wood's lamp examination is required to make the distinction.

Treatment

Nevus spilus is a benign melanocytic neoplasm. Patients with larger lesions or nevi with atypical features should undergo longitudinal evaluation, as there are reports of cutaneous melanoma developing within a nevus spilus. Individual pigmented lesions with atypical features or a suspicious change should be evaluated histologically.

HALO NEVUS

Synonym: ■ Sutton nevus

Key features

- Circumferential depigmentation (white halo) around a nevus
- Most common on the trunk in teenagers with an increased number of nevi
- Inflammatory infiltrate within the nevus

Epidemiology

The prevalence of halo nevi in the general population is ~1%. Halo nevi generally develop in individuals under the age of 20 years, with a mean age at presentation of ~15 years. There is no sex predilection, but patients who develop halo nevi have a higher number of melanocytic nevi. Approximately 20% of individuals with halo nevi have vitiligo and their nevi are less often associated with atypical features[77].

Pathogenesis

Development of a halo of depigmentation is thought to be an immunologic reaction against nevus cells. The inflammatory infiltrate usually consists predominantly of T cells, especially cytotoxic $CD8^+$ T cells[78]. Although the basis for nevus cell destruction in halo nevi is poorly understood, both humoral and cellular immunologic factors have been implicated. Individuals with regressing halo nevi have antibodies directed against melanoma cells and lymphocytes isolated from patients with halo nevi are cytotoxic to melanoma cells *in vitro*. Transcriptome analysis of halo nevi did reveal immune mechanisms similar to vitiligo[79].

Clinical Features

Halo nevi are most commonly observed in teenagers and young adults, and they are often initially noted in the summer. This is likely because tanning leads to greater contrast with the halo. The trunk is the most common location and 25%–50% of affected individuals have two or more halo nevi. Numerous eruptive halo nevi is a rare phenomenon. In older adults, a distinction is made between persistent halo nevi versus new-onset halo nevi (see below).

Halo nevi are characterized by a central melanocytic nevus component that may be relatively flat or raised and dark brown to pink in color. The nevus may exhibit surface scale or crusting. Surrounding the central nevus is a well-circumscribed annulus of hypo- or depigmented skin (Fig. 112.31A,B). Erythema occasionally precedes the development of the depigmented halo, which is thought to appear over a period of weeks to months. In typical halo nevi, the central nevus often measures 3–6 mm in diameter, has smooth and well-defined borders, and has a homogeneous color (stage I). By dermoscopy, globular and/or homogeneous patterns that typify benign nevi in children and young adults are usually observed[80]. The white halo is often symmetric with a uniform width that may vary from a few millimeters up to several centimeters (uncommon), but it can be asymmetric (Fig. 112.31C). A Wood's lamp can enhance or discern the halo and allow for assessment of the number of halo nevi. Dermoscopically, the halo is white and structureless (Fig. P7). The development of circumscribed poliosis involving scalp hairs, eyebrows, or eyelashes can be a clue to the presence of a halo nevus in these locations.

After the development of a halo nevus, its subsequent course is variable. Usually the nevus regresses over months to years, leaving a

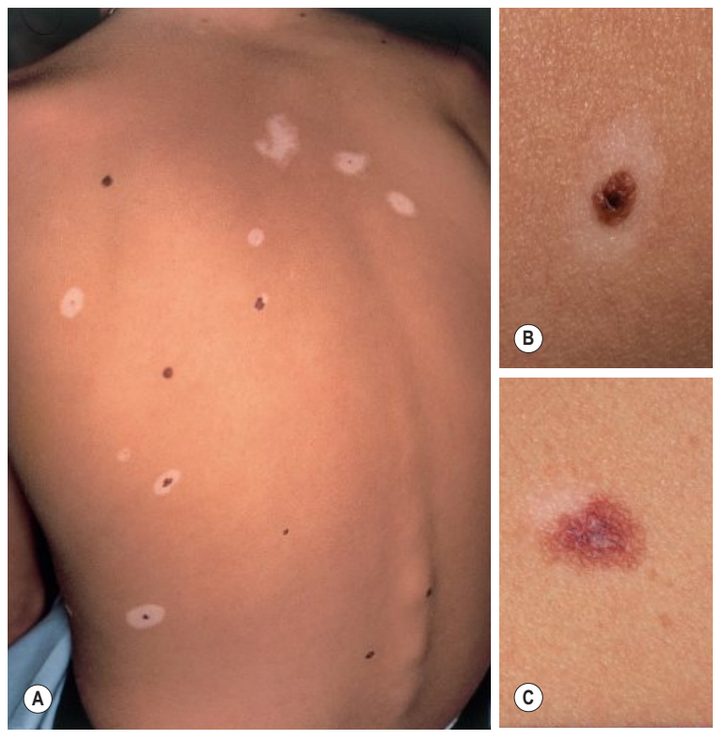

Fig. 112.31 Halo melanocytic nevi. A Stage I (central brown nevus), II (central pink nevus), III (depigmented macule), and early IV (partially repigmented skin) halo nevi are present. Multiple halo nevi are seen most commonly in children and young adults with numerous nevi. **B** Two-tone compound nevus surrounded by an oval ring of hypopigmentation. **C** A benign compound nevus with an asymmetric halo. *B, Courtesy Edward Cowen, MD; C, Courtesy Jean L. Bolognia, MD.*

white macule (stage III). The central nevus may first become irregular or pink in color (stage II). Complete repigmentation of the skin is seen in the majority of patients, but the process may take years to decades (stage IV). Rarely, the central nevus persists and the halo repigments.

In most patients, halo nevi occur as an isolated phenomenon in the setting of multiple melanocytic nevi. However, a relationship to vitiligo, melanoma, and atypical nevi has been well documented. Multiple halo nevi may be a sign of an ocular or cutaneous melanoma elsewhere, especially in older adults whose lesions are of recent onset. Occasionally, halo nevi appear following immunotherapy for melanoma or administration of other medications, e.g. imatinib, tocilizumab.

Pathology

The halo nevus may be junctional, compound, or dermal. In the fully evolved stages, the central nevus is associated with a well-circumscribed, dense infiltrate of lymphocytes and histiocytes, which occupies the papillary dermis and penetrates the nests of nevus cells. The lymphohistiocytic infiltrate can be so prominent that the nevus cells are difficult to distinguish from surrounding cells without special stains. Degenerating nevus cells can sometimes be identified in this zone.

Differential Diagnosis

Common acquired melanocytic nevi with halo phenomenon must be distinguished from: (1) other melanocytic proliferations with halos, such as congenital melanocytic nevi, atypical nevi, blue nevi, Spitz nevi, primary melanomas, or melanoma metastases; and (2) non-melanocytic lesions with halos, such as dermatofibromas, seborrheic keratoses, flat warts, mollusca contagiosa, basal cell carcinomas, lichen planus, psoriasis, or sarcoidosis. When a solitary halo lesion develops, especially in an older adult, the possibility of melanoma needs to be considered and a biopsy performed if there are atypical features. However, in adolescents, halo nevi are exceedingly more common than halo primary melanomas.

Treatment

Halo nevi are benign melanocytic lesions and the approach to patients with halo nevi is individualized and depends upon the clinical setting. All persons with halo nevi should be questioned regarding a personal or family history of cutaneous melanoma, atypical nevi, and vitiligo. Each halo nevus should be inspected carefully for features of an atypical melanocytic nevus or melanoma. The patient also should undergo a comprehensive skin examination for evidence of other halo nevi, atypical nevi, melanoma, or vitiligo. If no atypical features are observed, the patient should be followed with periodic skin examinations. Clinically atypical halo nevi should be examined histologically. Individuals beyond 40 years of age with new-onset halo nevi should be examined carefully for melanoma (ocular, mucosal, and cutaneous). A possible association with other malignancies has been noted for post-adolescent patients with eruptive halo nevi[81].

COMBINED NEVUS

Synonyms: ■ Biphasic melanocytic nevus ■ Biphenotypic nevus ■ Melanocytic nevus with phenotypic heterogeneity ■ Clonal nevus ■ Inverted type A nevus

Key features

- A benign melanocytic neoplasm with two or more phenotypically distinct tumor cell populations
- Usually <6 mm in diameter with variegated pigmentation

Introduction and Epidemiology

Combined melanocytic nevus refers to the simultaneous presence of at least two distinct nevus components in a single melanocytic neoplasm[82]. While any combination of conventional nevus, blue nevus, or Spitz nevus may potentially be observed, a common combination is a conventional compound nevus plus a blue nevus. Of note, some lesions diagnosed as combined nevi in the past are nowadays classified differently, e.g. as BAP1-inactivated tumors, WNT-activated deep penetrating/plexiform nevi, pigmented epithelioid melanocytomas.

The exact incidence of combined nevi is unknown, but has been estimated to be <1% of all melanocytic nevi sampled for histopathologic examination. Combined nevi can develop at any age, but typically present in young adults, with a mean age of ~30 years. There is no sex predilection[83].

Clinical Features

Combined nevi may arise at any site, but they have a predilection for the head and neck region, especially those with a blue nevus component. The clinical features reflect the types of nevi that are present. A smooth, blue–gray to blue–brown to blue–black papule or nodule is a common presentation, as is a discrete dark brown to black focus within an otherwise uniformly tan or brown common acquired nevus (Fig. 112.32). A papule or nodule may also arise within any type of melanocytic nevus including atypical and congenital nevi.

Pathology

The histologic features also vary depending on the types of nevi present. Most often, a banal compound or intradermal nevus is either admixed with a dermal population of pigmented epithelioid or spindled melanocytes or it overlies a more discrete pigmented spindle and epithelioid component (Fig. 112.33). Cytologic atypia and mitotic activity are rare[83].

Differential Diagnosis and Treatment

Both clinically and histologically, the presence of two or more components in a melanocytic lesion raises the possibility of melanoma, including melanoma arising within a nevus. If the lesion is sufficiently suspicious, a biopsy that includes the entire tumor should be performed. The clinical differential diagnosis also includes blue nevus, pigmented Spitz nevus, pigmented spindle cell nevus, pigmented basal cell carcinoma, benign vascular tumor, the hemosiderotic variant of dermatofibroma, and melanoma metastasis. Immunohistochemistry can assist in excluding other types of combined melanocytic neoplasms, e.g. BAP1 for BAP1-inactivated tumors, β-catenin and LEF1 for WNT-activated deep penetrating/plexiform nevi, PRKAR1A for pigmented epithelioid melanocytomas.

Fig. 112.32 One variant of combined melanocytic nevus. Dark brown to black papule within an otherwise uniformly pigmented light brown nevus. The differential diagnosis includes the possibility of a melanoma developing in a nevus. Some clinicians refer to nevi with this clinical appearance and the histologic features seen in Fig. 112.33 as clonal nevi. *Courtesy Lorenzo Cerroni, MD.*

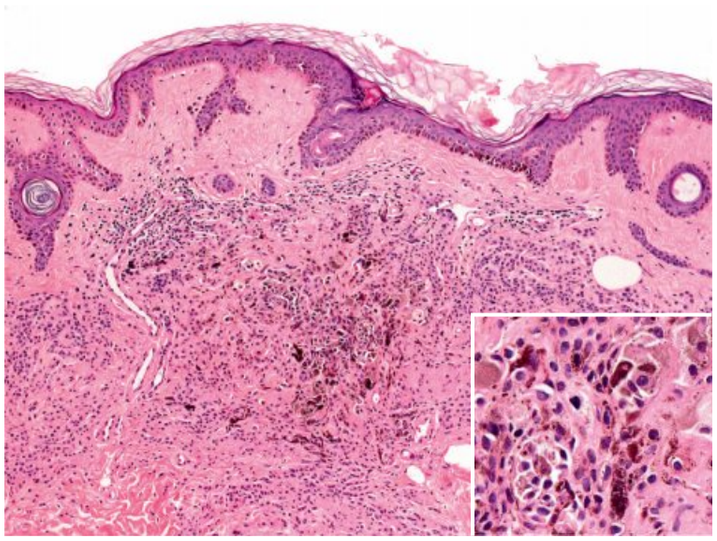

Fig. 112.33 Combined nevus – histopathologic features. Within this intradermal nevus is a focal collection of pigmented epithelioid dermal melanocytes and melanophages. The cells are benign in appearance (inset). Close examination of the focal collection of pigmented cells is recommended to exclude the possibility of melanoma. *Courtesy Lorenzo Cerroni, MD.*

RECURRENT MELANOCYTIC NEVUS

Synonyms: ■ Persistent melanocytic nevus ■ Pseudomelanoma

Key features

- A benign melanocytic nevus that recurs after incomplete removal, including following excisional or laser surgery
- Overlying scar tissue, heavily pigmented melanocytes proliferate within the epidermis, often with upward migration, and may resemble melanoma histologically

Epidemiology

Recurrent nevi are most often observed in women aged 20–30 years, reflecting the greater number of nevi removed from women and a higher prevalence in younger patients. Recurrent nevi are most commonly observed on the trunk, followed by the head and neck region. Most recurrences occur after shave excisions and are evident within 6 months of the surgical procedure[84]. When the recurrence develops >12 months after the original procedure and/or extends beyond the scar, the original biopsy should be re-evaluated and if unavailable, repeat histologic examination performed.

Pathogenesis

The recurrence of melanocytic nevi reflects migration of residual nevus cells into the epidermis, followed by proliferation. These residual cells originate from the underlying dermal component or periphery of the original incompletely excised nevus. Hence, the alternative term persistent nevus. Trophic factors stimulating melanocyte migration, melanocyte proliferation, or both, may be related to mechanisms of wound healing or scar formation.

Clinical Features

Recurrent nevi are characterized by circumscribed hyperpigmentation within a scar. The scar is usually secondary to a surgical procedure, but can follow attempted laser removal, application of chemical irritants, or significant trauma (Fig. 112.34A). Most recurrent nevi are macular and measure 2 to 5 mm in diameter. They can be circular, especially when perifollicular, or irregular in outline (Fig. P8) and most have a

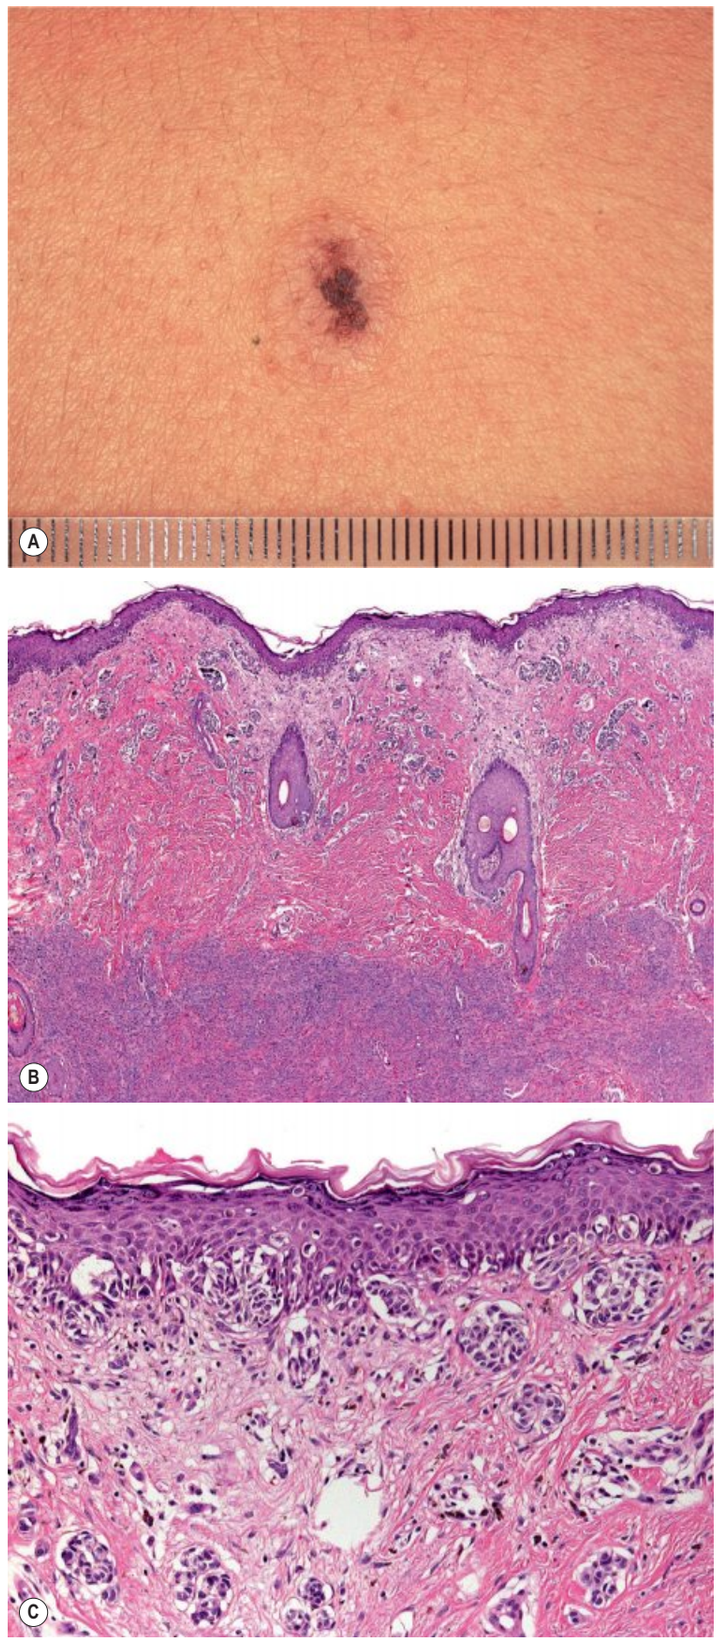

Fig. 112.34 Recurrent melanocytic nevus – clinical and histopathologic features. A Irregular dark brown pigmentation within the center of a circular scar; the pigmentation reflects the proliferation of melanocytes within the epidermis. Note that there is no extension of the recurrence beyond the scar itself, one of the signs that favors observation rather than repeat biopsy. **B** Histologically, an irregular junctional and superficial dermal melanocytic proliferation overlies a dermal scar and more deeply located residual dermal nevus. **C** At higher magnification, both junctional nests of melanocytes and single melanocytes are noted along the flattened dermal–epidermal junction as well as focally in suprabasal layers. The melanocytes are enlarged polygonal cells and show some low-grade nuclear pleomorphism. *A, Courtesy Jean L. Bolognia, MD; B, C, Courtesy Lorenzo Cerroni, MD.*

single shade of brown. However, recurrences following shave excision of darker brown compound melanocytic nevi can be black in color. When the recurrent nevus has varied pigmentation or extends beyond the associated scar, the possibility of an atypical nevus or melanoma should be considered. The dermoscopic features of recurrent/persistent nevi are sometimes difficult to distinguish from melanoma.

Most recurrent nevi are stable for years after development and then may fade. No increased melanoma risk has been associated with recurrent nevi. Clinical features that point to the need for a repeat biopsy include progressive enlargement, extension beyond the confines of the surgical scar, and a longer time interval before recurrence (>12 months)[85].

Pathology

Corresponding to the clinical features, one frequently observes intraepidermal melanocytic proliferation confined to the area above a dermal scar (Fig. 112.34B,C). The epidermis exhibits effacement of the rete pattern and variable lentiginous or nested proliferation of melanocytes. The presence of intraepidermal melanocytes extending beyond the dermal scar is suspicious for melanoma. Often, the cells contain abundant melanin and have relatively uniform, small nuclei. Occasionally, low-to-moderate grade cytologic atypia may be noted, but mitotic activity is rare. Upward migration of epidermal melanocytes may occur.

Frequently, there are residual dermal nevus cells beneath the superficial dermal scar and cytologically they resemble the junctional component (see Fig. 112.34B). Staining for PRAME is negative. In general, re-evaluation of the original biopsy, if one had been performed, is considered part of the histopathologic assessment of recurrent melanocytic tumors.

Differential Diagnosis

The differential diagnosis of recurrent nevi includes the lentiginous melanocytic proliferations and pigmented streaks due to basilar hyperpigmentation that can both develop in surgical excision scars (including those for melanoma). Additional entities to consider are traumatized nevi, recurrent atypical melanocytic nevi, and recurrent melanoma. In general, a recurrent melanocytic nevus is confined to the area of the surgical scar, appears within 6 months of surgery, and exhibits a bland histologic picture. Recurrent atypical nevi may have more disordered intraepidermal melanocytic proliferation (even a pagetoid pattern) and greater cytologic atypia than conventional recurrent nevi. Clinical features suggesting melanoma include irregular pigmentation, progressive enlargement, extension beyond the confines of the surgical scar, and a longer time interval before recurrence (>12 months). Strong PRAME-positivity of most melanocytes is considered very suspicious for melanoma.

Treatment

Establishing the etiology of the scar (see above) is integral to the diagnosis. Review of the previous biopsy specimen is mandatory if any atypicality is noted histologically or if the lesion arises >12 months after the attempt at removal. It is also a preferred practice for all recurrent nevi. Clinical features that point to the need for a repeat biopsy are outlined above and histopathologic findings guide the need for further re-excision.

Key features

- Melanoma represents a malignant tumor that arises from melanocytes and is responsible for the majority of skin cancer deaths
- The incidence rates of melanoma have increased over the past four decades by five- to seven-fold, whereas mortality rates began to stabilize in the early 1990s and more recently have declined due to effective therapies for advanced disease
- Dermoscopy has led to an improvement in diagnostic accuracy as have bedside imaging technologies and molecular tests, performed both before and after skin biopsy
- Early-stage melanomas are usually curable by surgical excision
- A greater understanding of molecular pathophysiology has translated into improved melanoma risk assessment, diagnosis, prognostication, and targeted therapies
- For metastatic melanoma, the advent of oral therapies that target mutant signaling pathways (e.g. BRAF and MEK inhibitors) and immunotherapies that act as checkpoint inhibitors (e.g. anti-CTLA-4, -PD-1, and -PD-L1 antibodies) has resulted in improved overall survival

INTRODUCTION

Melanoma is a malignant tumor that arises from melanocytes and is most commonly cutaneous in origin. It can also arise on mucosal surfaces (e.g. oral, conjunctival, vaginal) and within the uveal tract of the eye as well as the leptomeninges.

Rising incidence rates of cutaneous melanoma have been observed worldwide over the past four decades in White populations. While mortality rates increased slightly in the US and Europe during the 1970s and 1980s, a stabilization of mortality rates has been observed in a number of countries since the 1990s. The latter is due primarily to increased early detection of thinner cutaneous melanomas that have a lower likelihood of metastasis. Melanoma is also one of the most common forms of cancer in young adults. It therefore represents a significant public health concern in this age group, especially with respect to potential years of life lost. After decades of minimal progress, the recent introduction of effective targeted and immune therapies has led to a significant decline in mortality rates in patients with advanced disease.

MOLECULAR PATHOGENESIS

Cancer usually develops through a stepwise evolutionary process, with tumor progression involving both genetic instability and selective growth of cells with advantageous mutations. Additional contributing factors include genetic predisposition, mutagenic environmental events, and antitumor host response. As discussed in Chapter 107, the hallmarks of cancer can be acquired by the activation of oncogenes or the inactivation of tumor suppressor genes via point mutations, genomic rearrangements (e.g. deletions, inversions, duplications, fusions, and translocations), and epigenetic mechanisms such as microRNA expression and promoter methylation. Genome-wide analysis of genetic aberrations has revolutionized our understanding of the complex interplay of signaling pathways[1].

In melanoma, initiating oncogenic events frequently affect genes involved in the mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K) signaling pathways (Fig. 113.1). While these alterations may initially result in senescence, secondary genetic alterations can then result in progression into a malignant tumor[2]. The constitutive activation of MAPK or PI3K signaling that commonly occurs can be due to mutations in several kinase genes or fusions that disrupt the regulatory domain of a kinase gene, as well as copy number alterations. Other mechanisms include: upregulation of telomerase genes which results in unlimited replicative potential; changes in chromatin remodeling that lead to increased gene expression; and disruption of cell cycle regulation via mutations in genes that encode cyclin D1, p16/p14^{ARF}, or p53[3]. Table 113.1 lists some of the key primary and secondary driver mutations identified in melanomas[2].

Melanomas from different anatomic sites with varying degrees of UV radiation (UVR) damage differ in their characteristic driver mutations (see Table 113.1). Recognition of several distinct mechanisms of melanoma pathogenesis has inspired the current taxonomy of melanocytic neoplasia reflected in the 2018 WHO Classification of Skin Tumours, which integrates site of origin (epithelium- versus non-epithelium-associated) and role of cumulative sun damage (CSD; high-, low-, or non-CSD-related), along with mole phenotype (high vs low nevus count) and frequency of BRAF, NRAS, and other relevant mutations[2,4–6].

Advances in our understanding of the molecular basis of melanoma have paved the way for the era of targeted therapy. For example, discovery of the *BRAF* V600E mutation, which substitutes a glutamic acid (E) for valine (V) at codon 600, leading to activation of the MAPK pathway, has led to the use of BRAF inhibitors for *BRAF*-mutant melanomas. These agents are combined with MEK inhibitors, which act downstream of BRAF in the MAPK pathway, for improved efficacy and tolerability. For melanomas lacking the typical point mutations in *BRAF*, *NRAS*, or *NF1* (so-called "pan-negative" melanomas), identification of MAPK-activating kinase gene fusions in a subset of these melanomas

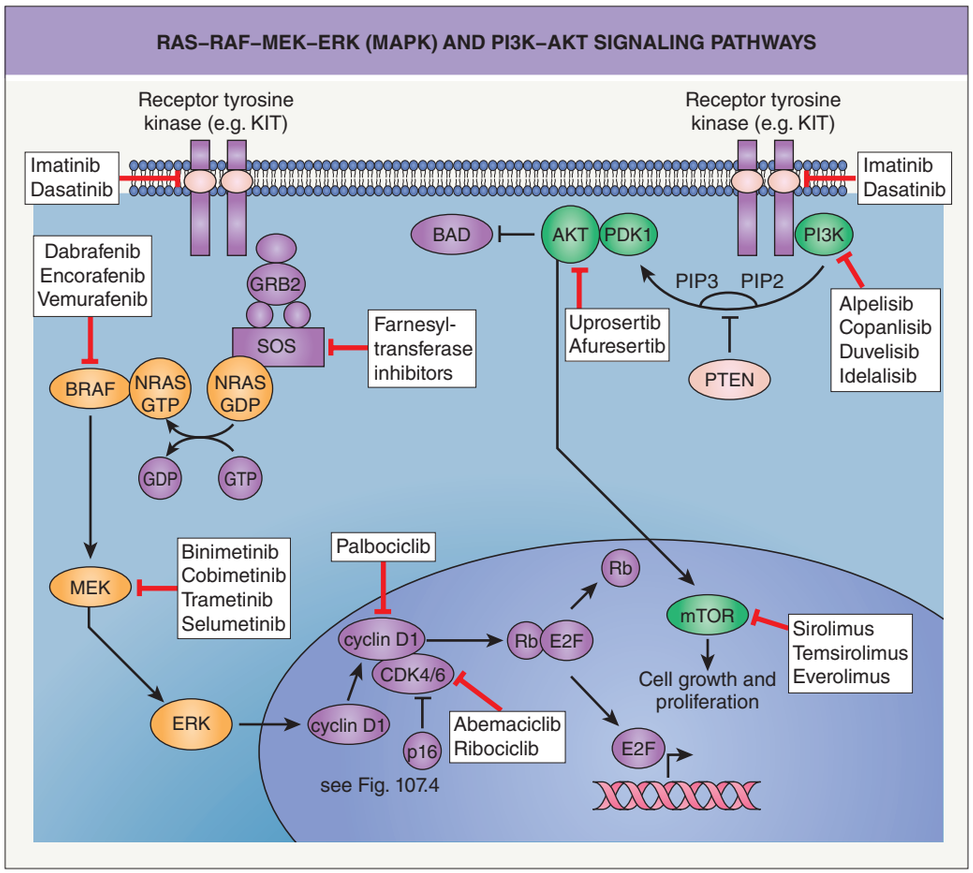

Fig. 113.1 RAS–RAF–MEK–ERK (MAPK) and PI3K–AKT signaling pathways. The *m*itogen-*a*ctivated *p*rotein *k*inase (MAPK) pathway (orange color), also referred to as the MAP kinase pathway, is physiologically activated by growth factor binding to receptor tyrosine kinases. The stimulus is relayed to the nucleus via the GTPase activity of NRAS and the kinase activity of BRAF, MEK, and ERK. Within the nucleus, this results in increased transcription of genes involved in cell growth, proliferation, and migration. The central role of this pathway in melanocytic neoplasia is highlighted by the fact that either *NRAS* or *BRAF* is mutated in up to 80% of all cutaneous melanomas and melanocytic nevi. The PI3K–AKT pathway is another important regulator of cell survival, growth, and apoptosis (green color). A key inhibitor of this pathway is PTEN and inactivation of the gene that encodes PTEN via mutations, deletions, or promoter methylation also occurs in cutaneous melanomas. As a result, there is increased activity of the PI3K–AKT signaling pathway. Examples of farnesyltransferase inhibitors are tipifarnib and lonafarnib. BAD, BCL-2 associated agonist of cell death; CDK, cyclin-dependent kinase; E2F, transcription factor that controls transcription of cyclins; ERK, extracellular signal-regulated kinase; GDP, guanosine-5-diphosphate; GRB2, growth factor receptor-bound protein 2, an adaptor protein that contains one Src homology 2 (SH2) domain and two SH3 domains; GTP, guanosine-5-triphosphate; MEK, MAPK kinase; mTOR, mammalian target of rapamycin (aka sirolimus); p16, protein product of *CDKN2A*; PDK1, phosphoinositide-dependent kinase-1; PI3K, phosphatidylinositol 3-kinase; PIP2, phosphatidylinositol 4,5-bisphosphate; PIP3, phosphatidylinositol 3,4,5-triphosphate; PTEN, phosphatase and tensin homolog; Rb, retinoblastoma protein; SOS, son of sevenless.

may permit their treatment with other kinase inhibitors. For example, melanomas harboring *NTRK* fusions can be treated with larotrectinib, a selective TRK inhibitor approved for TRK fusion-positive tumors[7].

HOST IMMUNE RESPONSE TO MELANOMA

Melanoma is a highly immunogenic tumor, making it ideal for immune-based therapeutic approaches (Fig. 113.2). Multiple melanoma antigens, recognized by autologous T cells or antibodies, have been described including: (1) mutant tumor antigens (e.g. mutant p16 [CDKN2A]); (2) shared tumor-specific antigens of the cancer/testis family (e.g. MAGE-1, MAGE-3, NY-ESO-1); and (3) cell type-specific differentiation antigens (e.g. tyrosinase, PMEL17/gp100, MART-1/Melan-A). These proteins are processed and presented on the melanoma cell surface as MHC/peptide complexes. $CD8^+$ cytotoxic T cells recognize these antigens via their T cell receptors (TCRs) and, if appropriately activated by costimulatory signals, are able to kill tumor cells. $CD4^+$ T helper cells and antibodies also play a critical role.

Activation of melanoma-specific $CD8^+$ T cells is dependent on the migration of tumor antigen-loaded dendritic cells to a draining lymph node. Here, melanoma antigens are presented to $CD8^+$ T cells in the presence of a costimulatory signal; the latter consists of the binding of B7 on the antigen-presenting cell to CD28 on the T cell (see Ch. 4). Cytotoxic T lymphocyte-associated antigen-4 (CTLA-4) is an inhibitory homolog of CD28 that is upregulated following T cell activation and acts as natural inhibitor of T cell activation by removing the costimulatory signal. Programmed cell death protein 1 (PD-1) is another inhibitory receptor in the CD28 family (see Fig. 128.9). The interaction of PD-1 with its ligands PD-L1 and PD-L2 promotes apoptosis of tumor antigen-specific T cells and reduces apoptosis in regulatory T cells.

Immunotherapy based upon CTLA-4, PD-1, and PD-L1 blockade was first introduced for the treatment of melanoma (see below), beginning with ipilimumab, an anti-CTLA-4 antibody. This was followed by the approval of anti-PD-1 antibodies (nivolumab, pembrolizumab) as first-line monotherapy for metastatic and locally advanced melanoma. Combining anti-CTLA-4 and anti-PD-1 antibodies leads to greater efficacy, but a significant increase in immune-related adverse events (irAEs). Of note, vitiligo is a melanocyte-targeted irAE that occurs in 2%–25% of patients and its development correlates with improved progression-free survival[8].

Insights into mechanisms of melanoma-specific host immune responses and immune escape have clearly led to improved immunotherapy in the form of checkpoint inhibitors and hopefully will result in other more effective therapies, including vaccines. However, overcoming the range of immune escape mechanisms still remains a challenge (Table 113.2).

EPIDEMIOLOGY

Cutaneous melanoma develops primarily in individuals with lightly pigmented skin. While melanoma is relatively uncommon amongst more darkly pigmented individuals of African, Asian, or Hispanic origin, its incidence has been slowly rising in some of these populations[9].

In 2015, over 350 000 new cases of melanoma were diagnosed worldwide, corresponding to an age-standardized incidence rate of 5 per 100 000 individuals, and nearly 60 000 deaths were attributable to melanoma. Globally, Australia, New Zealand, North America, and Europe bear the greatest burden of disease, with the highest incidence rates in Australia/New Zealand (~54/100 000) and Northern Europe (~25–26/100 000)[10]. Based upon the Surveillance Epidemiology and End Results (SEER) database, an estimated 99 780 men and women in the US are expected to be diagnosed with invasive cutaneous melanoma in 2022, with a projected 7650 melanoma-associated deaths[11].

Over the past several decades, the incidence rates of cutaneous melanoma have increased significantly (Fig. 113.3A)[12]. Whereas the annual increase in melanoma incidence varies depending upon the population, in general it has been estimated to be between 3% and 7%. These estimates predict a doubling of rates every 10–20 years, making cutaneous melanoma the most rapidly increasing cancer in White populations. However, an increase in skin screening, biopsy rates, and histopathologic diagnosis likely also contribute to this rise[13]. The trend of increasing incidence rates is predicted to continue for at least the next decade, although several countries have begun to observe stabilizing or declining rates in recent years[14].

Since 2006, the overall incidence of melanoma in the US has risen at a slower rate of ~1% per year. Although melanoma incidence rates have

GENETIC MUTATIONS IN MELANOMAS			
Gene	**Genomic alteration(s)**	**Molecular effect**	**Clinical significance**
BRAF	Point mutation, kinase fusion	Constitutive kinase activity, leading to activation of MAPK pathway	• 50%–60% of cutaneous melanomas, including 70% of non-CSD melanomas (*BRAF* V600E most common) • V600K and non-V600E mutations seen in high-CSD melanomas • Also in acquired melanocytic nevi and atypical (dysplastic) nevi
NRAS	Point mutation	Constitutive kinase activity, leading to activation of MAPK and PI3K pathways	• 15%–20% of melanomas, including high-CSD (most common mutation), low-CSD, acral lentiginous, and mucosal melanomas • Also in majority of large/giant congenital melanocytic nevi and melanoma arising in congenital nevi
KIT	Point mutation, amplification	Constitutive activation or increased expression of RTK, leading to MAPK pathway activation	• 15%–40% of acral lentiginous, mucosal, and high-CSD melanomas
GNAQ, GNA11	Point mutation	Constitutive G protein activity, leading to activation of downstream protein kinase C and MAPK pathways	• 80%–90% of uveal melanomas • Also in blue nevi and melanomas arising within blue nevi
NF1	Deletion	Loss of NF1 tumor suppressor function, leading to activation of MAPK and PI3K pathways	• 25% of desmoplastic melanomas • 30% of high-CSD melanomas
HRAS	Point mutation	Constitutive kinase activity, leading to activation of MAPK pathway	• Spitz melanomas
NTRK1/3	Kinase fusion	Constitutive activation of RTK, leading to increased activation of MAPK and PI3K pathways	• Spitz melanomas • Subset of BRAF/NRAS/NF1-negative melanomas
CDKN2A	Deletion	Loss of p16 tumor suppressor function, leading to increased Rb phosphorylation, E2F transcription factor activation, and expression of cell cycle progression genes	• *Most common germline mutation* in familial melanoma • Accounts for ~2% of cutaneous melanomas • Also in atypical (dysplastic) nevi, atypical Spitz tumors
CCND1	Amplification	Increased phosphorylation of Rb, leading to activation of transcription factor E2F and expression of cell cycle progression genes	• *Melanoma susceptibility gene* • Copy number gains common in high-CSD and acral lentiginous melanomas
CDK4	Amplification	Same as *CCND1*	• *Melanoma susceptibility gene*
BAP1	Deletion	Loss of BAP1 deubiquitinase function, leading to altered histone modifications and deregulated gene expression	• *Melanoma susceptibility gene* (BAP1 tumor syndrome) • Nearly 50% of uveal melanomas
TERT	Promoter mutation, amplification	Increased telomerase enzyme activity, leading to telomere elongation and impaired cell senescence	• *Melanoma susceptibility gene* • Amplifications commonly present in acral lentiginous melanomas
MITF	Point mutation, amplification	Alteration of transcription factor function, leading to dysregulation of melanin biosynthesis and upregulation of *CDK4*, *CDKN2A*, and *BCL2* transcription	• *E318K germline mutation* associated with lightly pigmented skin, elevated melanocytic nevus count, and increased melanoma risk, including amelanotic melanoma
POT1	Point mutation	Increased telomerase enzyme activity, activation of DNA damage	• *Germline mutations* associated with an increased risk of cutaneous melanoma
PTEN	Point mutation, deletion	Loss of PTEN tumor suppressor function, leading to increased activation of PI3K pathway	• *Germline mutations* (e.g. Cowden syndrome) associated with increased risk of cutaneous melanoma

Table 113.1 Genetic mutations in melanomas. Germline mutations in BRAC2 may be associated with a slightly increased risk of melanoma. The genes in the darker shade can be inherited as melanoma susceptibility genes. See Figs. 65.4, 67.22, and Fig. 113.1 for sites of activity of protein products. CSD, cumulative sun damage; MAPK, mitogen-activated protein kinase; PI3K, phosphatidylinositol-3 kinase; Rb, retinoblastoma; RTK, receptor tyrosine kinase. From references 2, 4, 26, and 30.

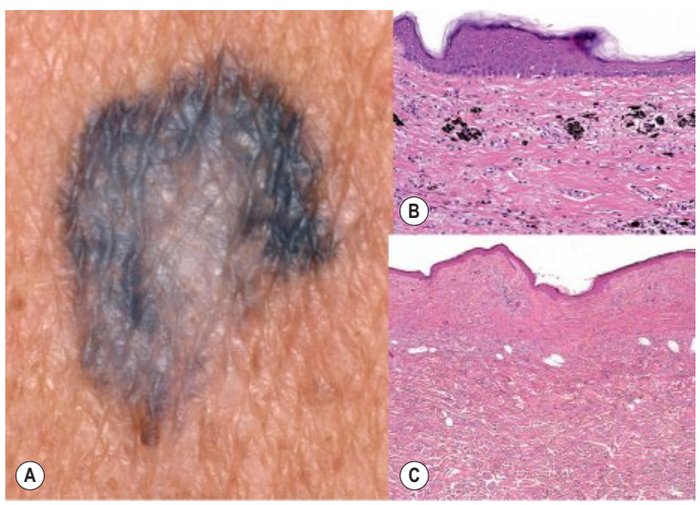

Fig. 113.2 Completely regressed cutaneous melanoma. A, B The gray-black arciform area had only melanophages in the upper dermis; although there were no remaining cells of melanoma, the patient already had nodal metastases. **C** The central hypopigmented area had fibrosis with sparse inflammation. Complexes of a pre-existing melanocytic nevus were present focally below the zone of regression. *Courtesy, Department of Dermatology, Medical University of Graz.*

ESCAPE MECHANISMS OF MALIGNANT TUMORS, INCLUDING MELANOMA
Loss of tumor-specific antigens
Loss of MHC class I molecules
Secretion of immuno-inhibitory cytokines (e.g. IL-10, TGF-β)
Upregulation of inhibitory costimulatory molecules and ligands on tumor or immune cells (e.g. CTLA-4, PD-L1, PD-1)

Table 113.2 Escape mechanisms of malignant tumors, including melanoma. IL, interleukin; MHC, major histocompatibility complex; TGF, transforming growth factor.

decreased in younger populations, they have significantly increased among older individuals, specifically non-Hispanic White men >55 years of age and White women >45 years of age[15]. Invasive melanomas, particularly thick melanomas, have also increased significantly over the past two decades among Hispanics in regions of high UVR exposure (e.g. California, Florida)[16].

Despite the continued increase in melanoma incidence worldwide, melanoma mortality has generally stabilized and in some countries declined in recent years. After increasing during the 1980s in most European countries as well as in North America (Fig. 113.3B),

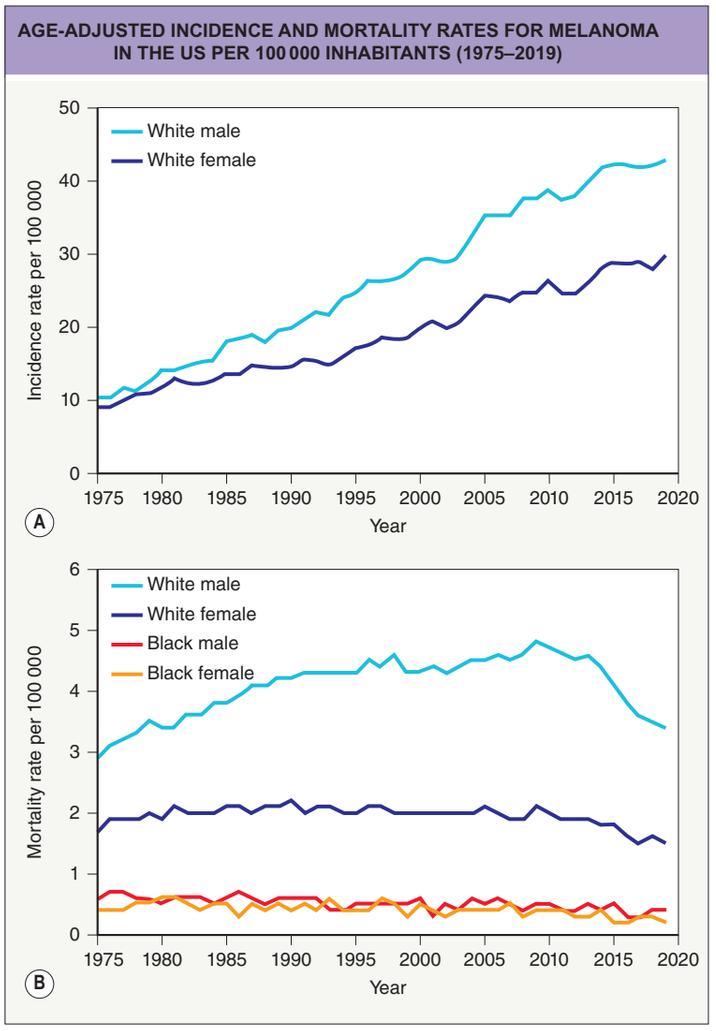

Fig. 113.3 Age-adjusted incidence rates and mortality rates for melanoma in the US per 100 000 inhabitants (1975–2019). A, B While the incidence of melanoma has increased significantly in White men and women over the past four decades, there has been a modest increase in mortality, primarily in middle-aged to older White men and individuals of lower socioeconomic status, across all racial and ethnic groups[12]. *Data from https://seer.cancer.gov/statistics-network/explorer.*

RISK FACTORS FOR THE DEVELOPMENT OF CUTANEOUS MELANOMA
Epidemiologic factors
• Male sex • >60 years of age
Genetic factors
• Family history of cutaneous melanoma, pancreatic cancer, astrocytoma, uveal melanoma, and/or mesothelioma • Lightly pigmented skin (Fitzpatrick I–II phototypes) • Tendency to burn, inability to tan • Red hair color and blue eyes (pheomelanin-predominant) • Personal history of melanoma • DNA repair defects (e.g. xeroderma pigmentosum) • Predisposing germline mutations or polymorphisms (e.g. *CDKN2A, CDK4, BAP1, TERT, MITF*)
Environmental factors
• Intense intermittent sun exposure • Multiple and/or blistering sunburns, including during childhood • Chronic sun exposure • Residence in equatorial latitudes • Tanning bed use, especially under the age of 35 years • Iatrogenic or acquired immunosuppression (e.g. solid organ transplant recipients, HIV infection)
Phenotypic expressions of gene/environment interactions

• Melanocytic nevi and solar lentigines:
  • Increased total number of acquired melanocytic nevi (MN)
  • >100 MN, relative risk ~8- to 10-fold increased
  • Atypical melanocytic nevi (AMN)
  • 5 AMN, relative risk ~4- to 6-fold increased
  • Actinic keratosis or keratinocyte carcinoma
  • Multiple solar lentigines (SL)
  • Multiple SL, relative risk ~3- to 4-fold increased

Table 113.3 Risk factors for the development of cutaneous melanoma.

Australia, and New Zealand, mortality rates from melanoma peaked in the early 1990s. Subsequently, trends have been less uniform, with mortality rates still rising in several European countries but stabilizing or decreasing in others as well as in Australia and the US. Worldwide, there has been a widening sex disparity over the past three decades, with male death rates continuing to rise in contrast to stable or decreasing female death rates. Several countries have also observed increasing mortality rates among older adults, but stable or decreasing rates among younger adults[17]. Similar trends have been noted in the US, where mortality rates for non-Hispanic White individuals have decreased in women and younger age groups but continue to increase in men over age 65 years[18]. However, with the advent of effective therapies, notable reductions in mortality have been observed since 2013 in non-Hispanic White individuals, including older men[19]. Melanoma survival among non-White populations continues to significantly lag behind White populations[20], and in several countries lower socioeconomic status has also been associated with higher mortality rates.

Vertical tumor thickness (Breslow depth) is the most important prognostic factor in primary cutaneous melanoma. Tumor thickness at initial diagnosis is somewhat age-dependent[21], with the percentage of thick melanomas increasing significantly with age, reaching 20% by age 80 years in both sexes. In the US, populations with the greatest mortality rates – older men, non-White individuals, and those in lower socioeconomic groups – have experienced a disproportionate increase in the incidence of thicker, more advanced melanomas at diagnosis[22,23].

Over the past several decades, a progressive reduction in mean tumor thickness has occurred as a result of more effective detection of melanoma at an earlier stage[24]. In Germany, for example, there has been a trend towards diagnosing thinner melanomas since the 1980s, with the median tumor thickness decreasing from 1.81 mm (1980s) to 0.53 mm (2000). The percentages of *in situ* and thin (T1; ≤1 mm) melanomas also increased[24]. Diagnosing thinner tumors should translate into stable or decreasing mortality rates, despite the rise in incidence rates. However, US data indicate that incidence rates among all tumor thickness categories have significantly increased over the past few decades (although most prominently for thin melanomas), suggesting that enhanced detection of thin melanomas cannot entirely account for the continued rise in overall melanoma incidence[22,23].

RISK FACTORS FOR CUTANEOUS MELANOMA

Recognition of risk factors for the development of melanoma is important from a public health and a clinical care perspective (Table 113.3)[25]. Identification of high-risk cohorts improves the efficiency and efficacy of public health efforts. Individual risk assessment influences clinical decision-making, including the threshold for performing a biopsy, prevention counseling, and surveillance. Risk factors may be divided into three categories: (1) genetic factors; (2) phenotypic manifestations of gene–environment interactions; and (3) environmental factors.

Genetic Risk Factors

Germline genetic mutations and polymorphisms can predispose individuals to melanoma, but detection of inherited genetic susceptibility is relatively uncommon. Approximately 5%–10% of melanomas develop in individuals with a family history of melanoma, though it is not necessarily due to transmission of a single genetic mutation[26,27]. The genes involved range from the rare high-penetrance genes responsible for some familial clustering of melanoma (e.g. *CDKN2A*) to the more common pigmentation genes responsible for the relative propensity of light-skinned individuals to develop melanoma (e.g. *MC1R*).

The major high-penetrance susceptibility gene locus associated with familial melanoma is *CDKN2A*. Approximately 2% of cutaneous melanomas can be specifically attributed to pathogenic germline mutations in *CDKN2A*[28]. This locus encodes two distinct protein products, p16 and $p14^{ARF}$, with the latter via an alternative reading frame, hence the designation ARF. p16 and $p14^{ARF}$ exert regulatory effects on cell cycle progression through the retinoblastoma protein (Rb) and p53 pathways, respectively (see Fig. 107.4). Germline *CDKN2A* mutations have been observed in 20%–40% of familial melanoma kindreds, ranging from 5% to 70% depending on the population studied[27,29] (Fig. 113.4). The penetrance of *CDKN2A* mutations is modified by germline variants of other genes, including *MC1R*. In some families, carriers of germline *CDKN2A* mutations are also at increased risk of developing pancreatic cancer[29].

Less common high-risk melanoma susceptibility genes have been identified, including the cell cycle regulator *CDK4*, the BRCA1-associated protein 1 gene (*BAP1*; see below), and telomere maintenance genes such as *TERT* and *POT1* (see Fig. 113.4). There is increasing recognition that germline mutations in these loci may not only confer an increased risk of cutaneous melanoma but also an increased risk of other internal malignancies, with melanoma possibly considered a "sentinel" cancer[30]. Although the full spectrum of potential malignancies remains to be fully characterized for some of these mutations, greater understanding of these melanoma-cancer complexes will impact future management and cancer surveillance of affected individuals.

Various pigmentation genes confer a low to moderate level of melanoma susceptibility. Specific germline variants of the melanocortin 1 receptor gene (*MC1R*) have been found to correlate with melanoma risk above and beyond clinically apparent skin phenotype (see Ch. 65). A strong association between *MC1R* as a susceptibility gene and the risk of developing *BRAF*-mutant melanomas has also been observed. While the risk of developing any cutaneous melanoma lies between 1.5- and 3-fold for individuals with *MC1R* variants, the risk of developing *BRAF*-mutant melanomas was as high as 17-fold for those with two *MC1R* germline variants[31]. In addition to *MC1R*, single nucleotide polymorphisms in the tyrosinase gene (*TYR*), tyrosinase-related protein 1 gene (*TYRP1*), and *SLC45A2* are significantly associated with melanoma risk (see Ch. 65). A rare functional variant in the gene that encodes microphthalmia-associated transcription factor (*MITF*), p.E318K, has also been associated with a light-skin phenotype and predisposes to cutaneous melanoma as well as renal cell carcinoma[32].

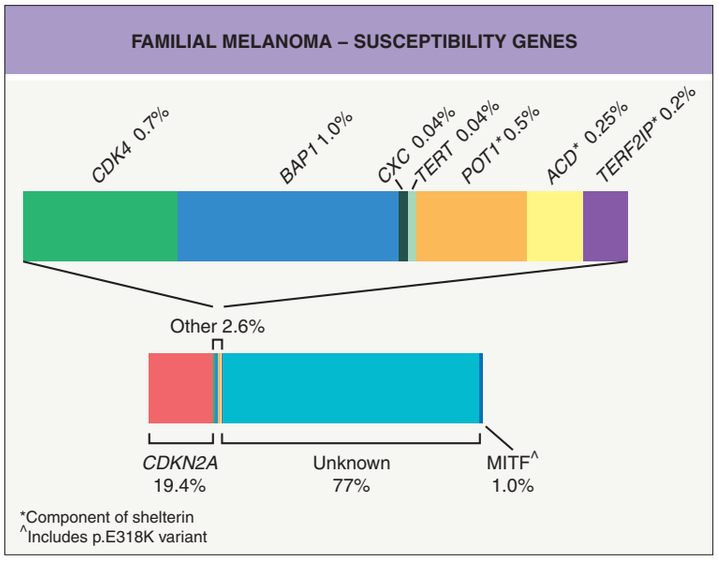

Fig. 113.4 Familial melanoma – susceptibility genes. Germline *CDKN2A* mutations are observed in 20%–40% of familial melanoma kindreds. Note the significant percentage of families for whom the genetic basis is unknown, a point that should be discussed with patients contemplating genetic screening. Patients with mutations in *CDKN2A* (p16), *CDKN2A* ($p14^{ARF}$), and *MITF* can also develop pancreatic carcinoma, neural tumors, and renal cell carcinoma, respectively, while those with *BAP1* mutations can develop uveal melanoma, mesothelioma, renal cell carcinoma, cholangiocarcinoma, meningioma, and basal cell carcinoma (at an early age). *POT1* mutations are associated with chronic lymphocytic leukemia, gliomas, and cardiac angiosarcomas. Screening recommendations are based upon the detected genetic mutation. ACD, adrenocortical dysplasia protein homolog; BAP1, BRCA1 associated protein 1; CDK4, cyclin-dependent kinase 4; CXC, CXC motif chemokine; MITF, microphthalmia-associated transcription factor; POT1, protection of telomeres 1; TERF2IP, telomeric repeat binding factor 2 interacting protein; TERT, telomerase reverse transcriptase (mutations in promoter). *Adapted from Potrony M, Badenas C, Agulilaera P, et al. Update in genetic susceptibility in melanoma. Ann Transl Med 2015;3:210.*

BAP1 tumor syndrome

Among the better-characterized melanoma-cancer complexes is the BAP1 tumor syndrome. BAP1, a deubiquitylase involved in cell cycle regulation and DNA damage response pathways, was originally implicated in the pathogenesis of aggressive uveal melanomas. Germline mutations in *BAP1* have subsequently been associated with an increased risk of cutaneous melanoma, uveal melanoma, mesothelioma, and renal cell carcinoma. Affected individuals are also at slightly increased risk of basal cell carcinoma, meningioma, and cholangiocarcinoma[33].

A characteristic finding in this syndrome is the progressive appearance of small, red–orange to skin-colored papules, which histologically demonstrate distinctive epithelioid melanocytes with loss of BAP1 nuclear staining by immunohistochemistry. These benign skin lesions, termed melanocytic *BAP1*-mutated atypical intradermal tumors (MBAITs; also "BAPomas" or *BAP1*-inactivated melanocytomas), may occur sporadically or as part of the BAP1 tumor syndrome. Up to two-thirds of patients with the BAP1 tumor syndrome may present with multiple MBAITs during the first decades of life[30].

Genetic screening in familial melanoma

The decision to perform genetic testing in cases of familial melanoma is multifaceted and must take into account the pretest probability of an underlying genetic basis, patient wishes, and the perceived risks, benefits, and limitations of current testing strategies. Consultation with a qualified cancer genetic counselor or specialist is recommended to fully explore these issues and provide important patient education and counseling, regardless of whether testing is actually performed.

Currently, there is limited evidence as to whether genetic screening is harmful or helpful[34]. Identification of germline mutations, particularly those associated with other malignancies, may be helpful in guiding additional specialist evaluation and cancer surveillance. However, in addition to the high proportion of familial melanomas with an unknown genetic basis, testing may not identify pathogenic mutations in known susceptibility genes and variants of unknown significance may lead to greater uncertainty for both clinicians and patients. Although some have argued that knowledge of mutation status may not necessarily change dermatologic management, such as the frequency of skin examinations or sun protection education, studies of *CDKN2A* germline testing have found improved adherence to dermatologic screening and precautionary behaviors among both mutation-positive and mutation-negative patients[35].

While numerous assays for *CDKN2A* mutations are commercially available, they do not capture potentially relevant germline mutations in other melanoma susceptibility genes. Multi-gene panels are thus preferred for genetic risk assessment of familial melanoma and associated internal malignancies, with the caveat that formal guidelines for subsequent cancer surveillance may currently be lacking in some scenarios.

Regional variances in the background incidence of melanoma and penetrance of melanoma susceptibility genes make it difficult to create a single guideline for genetic testing that is applicable worldwide[28]. The 2019 American Academy of Dermatology (AAD) Melanoma Clinical Practice Guidelines included recommended selection criteria for genetic counseling (Table 113.4)[34]. For regions with moderate to high melanoma incidence rates, such as the US, the "rule of 3" identifies those with a high likelihood of a *CDKN2A* germline mutation who may benefit from testing. This includes individuals with three or more primary invasive melanomas as well as families with at least one invasive melanoma and two or more other diagnoses of invasive melanoma and/or pancreatic cancer among first- or second-degree relatives (on the same side of the family)[28]. A "3 by 40" modification of this rule has been suggested to focus testing on individuals under age 40 years, since multiple melanomas in older individuals are more likely to be related to cumulative UVR exposure[26,] and a "rule of 2" variation may be considered in regions with low melanoma incidence rates[28].

RECOMMENDATIONS FOR GENETIC SCREENING FOR FAMILIAL MELANOMA
Consider genetic testing for patients with cutaneous melanoma who have: • 2 or more relatives, particularly first-degree relatives, with a history of invasive cutaneous melanoma and/or pancreatic cancer (i.e. ≥3 affected family members on same side of the family) • Personal history of ≥3 primary invasive cutaneous melanomas, including 1 tumor before age 45 • ≥1 MBAIT/"BAPoma" and family history of mesothelioma, meningioma, and/or uveal melanoma • ≥2 MBAITs/"BAPomas"
Genetic counseling should be performed by a qualified genetic risk counselor
Use of multi-gene panels is preferred over single-gene testing (e.g. *CDKN2A*)

Table 113.4 Recommendations for genetic screening for familial melanoma. MBAIT, melanocytic BAP1-mutated atypical intradermal tumor. From reference 34.

Genetic counseling may also be considered for individuals in whom the BAP1 tumor syndrome is suspected – specifically, individuals with two or more histologically proven MBAITs or at least one MBAIT and a personal or family history of mesothelioma, meningioma, or uveal melanoma.

For patients with detected germline mutations, specialist referrals for risk-appropriate malignancy screening may be warranted, and a multidisciplinary approach with input from genetic counselors can be helpful in guiding specific management. Carriers of *CDKN2A* mutations, particularly those with a family history of pancreatic cancer, may benefit from evaluation by gastroenterology specialists and earlier screening for pancreatic cancer. For *BAP1* mutation carriers, referral to ophthalmology for ocular melanoma surveillance should be offered, in addition to other specialist evaluations for possible internal malignancy screening[34].

Phenotypic Risk Factors Reflecting Gene/Environment Interactions

The strongest independent risk factors for the development of cutaneous melanoma are those that reflect a combination of genetic and phenotypic susceptibility plus environmental exposure, i.e. melanocytic nevi, atypical/dysplastic melanocytic nevi, ephelides, and solar lentigines. Both an increased number of common/typical melanocytic nevi and the presence of clinically atypical/histologically dysplastic melanocytic nevi are independent risk factors for melanoma, as is the presence of solar lentigines. Acquired melanocytic nevi play a dual role as a risk factor: (1) they are indicators of UV exposure and DNA damage; and (2) they can be formal precursors of melanoma. However, remnants of benign melanocytic nevi are found in only a minority of melanomas. Based on epidemiologic data, the risk of malignant transformation in an individual melanocytic nevus has been estimated to be one melanoma in hundreds of atypical nevi and one in thousands of common nevi[36,37]. Consequently, prophylactic removal of clinically and dermoscopically banal melanocytic nevi is not justified given the low percentage of melanomas that arise in association with nevi.

Common melanocytic nevi

Although performed on populations from different regions and with varying skin phototypes, studies have consistently reported a continuous and almost linear increase in melanoma risk with greater numbers of common melanocytic nevi, particularly larger nevi (diameter >5 mm)[38,39] (Fig. 113.5). Light-skinned populations have higher melanocytic nevus counts than do darker-skinned populations. For those with >50 common melanocytic nevi, the relative melanoma risk has ranged from ~7 in southern Spain[40] to ~54 in Scotland[41]. Nonetheless, the dose-dependent relationship between number of common melanocytic nevi and risk of cutaneous melanoma holds true for all White populations.

The association of increased nevus counts and melanoma risk is strongest for superficial spreading and nodular subtypes, more recently classified as melanomas of low cumulative sun damage (CSD)[4]. This is in contrast to lentigo maligna melanoma (high-CSD melanoma) which is highly correlated with skin phototype and hair color[41]. These

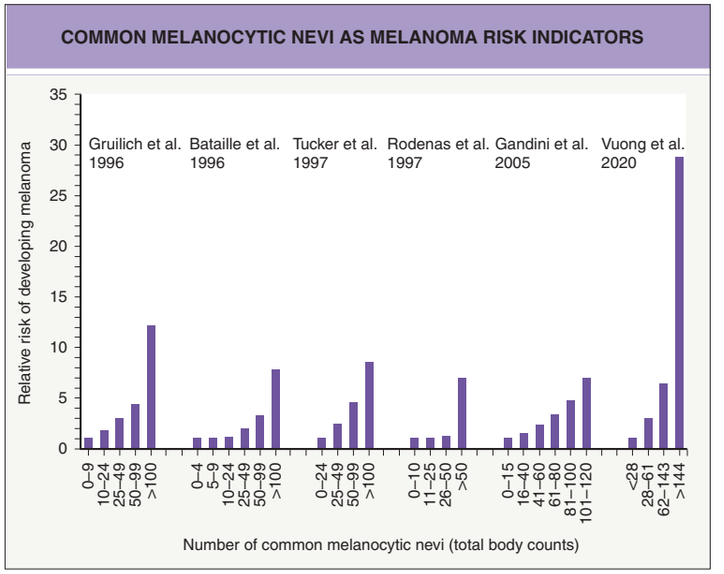

Fig. 113.5 Common melanocytic nevi as melanoma risk indicators. Relative risk of developing melanoma for a given number of common/typical melanocytic nevi (total body counts) as determined by five epidemiologic studies and one meta-analysis (Gandini et al.[47]). Nevus count studies have mostly been conducted in lighter skinned White populations; however, one study was conducted in southern Spain (Rodenas et al.[40]) Melanoma risk increases almost linearly with the number of common melanocytic nevi, rendering common nevi valuable as risk indicators.

findings suggest that there are additional genetic susceptibility factors and molecular mechanisms involved in the formation of melanoma in chronically versus intermittently sun-exposed skin. Melanoma at a particular anatomic site is more strongly related to the number of melanocytic nevi within that respective site than to the number of nevi in other body sites[40,41], highlighting the key role of local mutagenic effects of UVR in addition to genetic susceptibility (see below).

Atypical melanocytic nevi

Since the original description of BK-mole syndrome in 1978[42], several definitions of atypical melanocytic nevi as well as the atypical mole syndrome have been published. Although clinically atypical nevi often exhibit features of dysplasia histologically, the vast majority of histologically dysplastic nevi are benign and do not progress to melanoma. There is also significant variability in the histopathologic interpretation of dysplastic nevi, leading to much confusion regarding their role as melanoma precursor lesions. One study of 187 pathologists experienced in melanocytic lesion interpretation found *inter*observer concordance rates below 50% in the diagnosis of moderately dysplastic nevi, severely dysplastic nevi, melanoma *in situ*, and superficially invasive melanoma. *Intra*observer reproducibility rates for these diagnostic classes were also poor, ranging from 35% to 63%[43]. As a result of this diagnostic uncertainty, it becomes difficult to draw definitive conclusions regarding the relationship between histologically dysplastic nevi and melanoma risk[39].

In general, a diagnosis of clinically atypical melanocytic nevi is based upon the presence of at least three of the following criteria: (1) diameter ≥5 mm; (2) ill-defined borders; (3) an irregular margin; (4) varying shades within the lesion; and (5) the simultaneous presence of papular and macular components[44]. Distinguishing atypical nevi from melanoma can be aided by dermoscopy, with specific dermoscopic patterns having been identified within benign atypical nevi (e.g. reticular patchy, reticular with central hypo- or hyperpigmentation, homogeneous, peripheral reticular with central globules, peripheral globular, globular, two- or multi-component pattern; see Fig. 112.P9). A relative risk of up to 500-fold for developing cutaneous melanoma has been described for specific subgroups of the atypical mole syndrome[45]. However, sporadic atypical melanocytic nevi are commonly observed in individuals outside of the setting of the atypical mole syndrome. One possible explanation for the range of estimates of risk is the use of different definitions of clinically "atypical" melanocytic nevi by various investigators.

Several studies have found clinically atypical and/or histologically dysplastic nevi to be associated with increased melanoma risk outside of the context of familial melanoma (Fig. 113.6). The maximum reported relative risk for developing melanoma was as high as 32-fold when there were 10 or more atypical melanocytic nevi[46]. The consistency of these findings among multiple studies and across geographic locations supports the significance of clinically atypical/histologically dysplastic melanocytic nevi as an independent risk factor for sporadic melanoma.

In contrast to the continuous increase in melanoma risk with greater numbers of common melanocytic nevi, for atypical melanocytic nevi, a threshold level of five or more such lesions was associated with a clearly higher relative risk in several studies; however, there was no significant increase in risk beyond this number[44]. This finding suggests that at least five clinically atypical melanocytic nevi are needed to establish the diagnosis of atypical mole syndrome[47]; they are typically observed in conjunction with an increased mole count of at least 50, and often >100, common nevi. In patients with familial melanoma, atypical melanocytic nevi are an indicator of a markedly elevated melanoma risk.

Environmental Risk Factors

Ultraviolet radiation

The total risk for developing melanoma is determined by a complex interplay between genetic factors and exposure to UVR. It is well established that chronic suberythemal doses of UVR cause DNA mutations in skin cells. In mouse skin, repeated UVB irradiation at 10%–20% of the minimal erythema dose induced DNA damage. This damage persisted in the dermis and epidermis for several weeks following discontinuation of UVB exposure[48]. Therefore, low-dose UVB exposure in a repeated fashion could cause skin cancer. Initial indications of an etiologic role for UVR in melanoma development came from the observation that melanoma incidence was increased in White populations living closest to the equator. For example, melanoma incidence and mortality rates in Australia are 5–10 times higher than in Europe.

At the same time, numerous observations suggested factors other than chronic sun exposure played a role in melanomagenesis. Case–control studies demonstrated that melanoma risk was closely associated with the number of melanocytic nevi and with the occurrence of sunburns in childhood[49,50]. Interestingly, sunburns during childhood and adolescence significantly elevated the risk for melanoma development, but additional sunburns during adulthood did not contribute to any further risk elevation, suggesting that melanoma risk may incur primarily during childhood. Other studies found only a modest increase in melanoma risk in association with occupational or total sun exposure, but a significantly increased risk associated with intermittent sun exposure[51]. These findings were further supported by a large population-based study in New Zealand, which observed two divergent populations with high melanoma burden: young to middle-aged adults, who tended to develop melanoma in intermittently sun-exposed areas, and older adults with melanoma predominantly in areas of chronic sun exposure[52].

A bimodal age and site distribution of melanomas suggested two distinct mechanisms of UV-induced pathogenesis and this has been supported by genetic studies[53]. Early-onset melanomas, typically occurring in middle-aged adults at sites of low CSD, frequently demonstrate somatic *BRAF* or *NRAS* mutations and are often associated with an increased nevus count. In contrast, late-onset melanomas, typically lentigo maligna type, tend to occur on sites with high CSD such as the head and neck. The genomic changes seen in high-CSD melanomas are distinct from those seen in low-CSD melanomas and more clearly illustrate the role of cumulative UV damage in their pathogenesis, as evidenced by their higher mutational burden and more frequent UV signature mutations[2,54]. In comparison, the development of low-CSD melanomas appears largely related to intermittent UVR exposure during childhood.

Epidemiologic studies in young children have demonstrated a relationship between the frequency and duration of sun exposure and high numbers of melanocytic nevi early in life[55,56]. They also pointed to even moderate sun exposure as sufficient for the induction of nevi in children. The sites of subsequent melanomas often reflect the distribution pattern of melanocytic nevi[57], with both low-CSD melanomas and acquired nevi commonly harboring *BRAF* activating mutations[6]. Within acquired nevi, the high frequency of the specific *BRAF* V600E driver mutation, itself a low-probability event, suggests a high mutational burden is present in melanocytes at a young age[2]. Accumulation of additional UV-induced mutations affecting *TERT*, *CDKN2A*, and other key regulatory genes may contribute to eventual melanoma development during middle age[2,4]. It is interesting to note that the *BRAF* V600E mutation is not itself a UV signature mutation, suggesting a role for indirect UV-related mechanisms or other complex factors in the development of low-CSD melanoma.

The unique melanocyte response to UV damage, although not fully characterized, may provide additional explanations for melanoma development at both low- and high-CSD sites. In contrast to keratinocytes, which undergo apoptosis following severe UV damage, melanocytes do not undergo apoptosis as readily. Their function is to provide protective melanin to the surviving cells and so they are retained within the epidermis, even with damage that may have been sustained through either frequent, low-intensity UV exposures or infrequent, high-intensity exposures. Subsequently, melanoma can arise in anatomic sites with intermittent sun exposure.

Both UVB and UVA radiation are associated with the development of cutaneous melanoma, with UVB believed to be the stronger contributor. Data supporting *UVB* as a causative factor come from: (1) animal studies in which UVB was shown to induce melanoma in susceptible mice and in xenografted human skin engineered to express melanocytic growth factors[58,59]; and (2) the fact that there is a higher incidence of cutaneous melanoma in equatorial regions where UVB is most intense. Data implicating *UVA* in the development of cutaneous melanoma derive from: (1) studies in which UVA was shown to initiate melanoma (fish) and melanocytic hyperplasia (pigmented opossums)[60,61]; and (2) epidemiological studies showing an increased incidence of melanoma developing in users of indoor tanning beds and perhaps recipients of PUVA.

The risk of melanoma from artificial UVR exposure from tanning bed use is well documented. An estimated 10 000 melanoma cases each year in the US, Europe, and Australia are attributable to indoor tanning[62]. Indoor tanning is common among adolescents and young adults, with 55% of university students and 19% of adolescents in 2013 reporting any prior tanning bed use, and exposure to tanning beds before the age of 35 years has a statistically significant association with melanoma development. Large-scale meta-analyses have demonstrated an odds ratio of 1.16 for melanoma associated with any prior tanning bed use, with a significantly increased risk associated with >10 tanning sessions[63]. In 2009, the World Health Organization (WHO) International Agency for Research on Cancer (IARC) categorized tanning

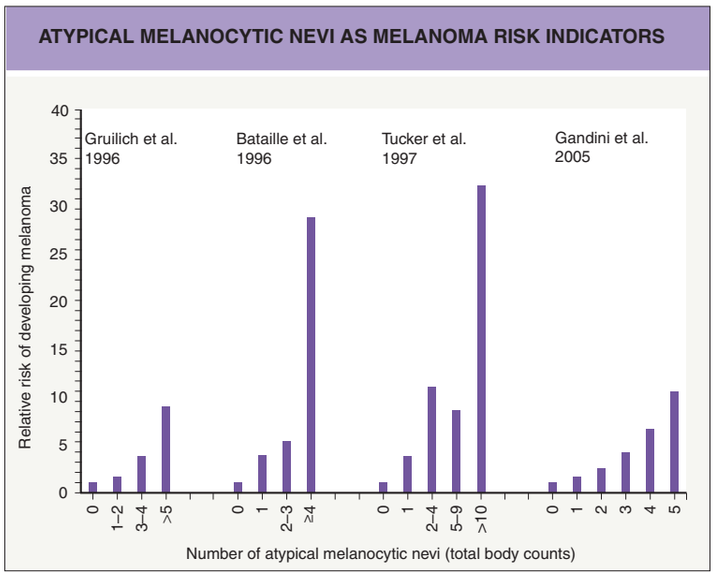

Fig. 113.6 Atypical melanocytic nevi as melanoma risk indicators. Relative risk of developing melanoma for a given number of atypical melanocytic nevi (total body counts) as determined by three epidemiologic studies and one meta-analysis (Gandini et al.[47]) An elevated risk is associated with relatively small numbers of atypical nevi. The relative risk as indicated by the number of atypical nevi is independent from the total number of melanocytic nevi, and it is related in a multiplicative fashion to the risk based on the total number of nevi. In other words, the individual risk for developing melanoma is calculated by multiplying the risk related to the total number of nevi times that due to the number of atypical nevi (see Table 113.3).

beds as a human carcinogen. Following this announcement and legislative changes limiting tanning bed access, tanning bed use worldwide has decreased by ~70% in adolescents and 35% in adults[64]. In the US, legislation banning indoor tanning among minors is state-dependent, with 24 states and the District of Columbia banning tanning bed use in individuals under 18 years (as of 2023)[65]. Additional efforts to improve legislative impact and public education will be important in addressing this ongoing public health concern.

Sun protection

Regular use of sunscreen and other sun protective measures has been shown to decrease the development of actinic keratoses and cutaneous SCCs, but evidence regarding sunscreen's ability to prevent cutaneous melanoma was not demonstrated until the results of the Nambour Skin Cancer Prevention trial were published in 2010 (see Ch. 132). This prospective randomized controlled trial (RCT) conducted in Queensland, Australia found that the daily application of SPF 16 sunscreen to the head and arms in half of 1621 adults (versus discretionary use in the other half) over a 4.5-year period reduced the incidence of new primary cutaneous melanoma by 50%–73%, 10 years after completion of the trial. This single RCT provides evidence for sunscreen efficacy in preventing melanoma development[66]. Given the low-SPF sunscreens and inferior UV filters available during the intervention period (1992–1996), as well as the age of the study population (25–75 years), it is likely that long-term use of improved broad-spectrum sunscreens in children and adolescents could have even greater benefits.

Sunscreen use is not without controversy. Some studies have raised potential safety concerns regarding chronic sunscreen use, including absorption through the skin[67] and possible endocrine-disrupting properties of some UV filters, although evidence for the latter is currently limited to studies of high-dose ingestion in rats[68]. Other studies have revealed the potential negative environmental impact of certain chemical UV filters, including potential damage to coral reefs through direct contact. Therefore, additional sun protective measures should be encouraged, including physical means of blocking the sun (e.g. non-transparent clothing, hats, eyewear) and reducing UV radiation exposure when possible (e.g. shade coverings, limiting outdoor activities between the hours of 10:00 a.m. and 4:00 p.m.).

TYPES OF PRIMARY MELANOMAS

Four major subtypes of primary cutaneous melanoma were originally described based upon their predominant growth patterns[69] (Table 113.5). The 2023 WHO Classification of Skin Tumours now recognizes nine major subtypes of melanoma based on their proposed etiopathogenesis: (1) low-CSD melanoma; (2) lentigo maligna melanoma (high-CSD melanoma); (3) desmoplastic melanoma; (4) Spitz melanoma; (5) acral melanoma; (6) mucosal melanoma; (7) melanoma arising in a giant congenital nevus; (8) melanoma arising in a blue nevus; and (9) ocular (uveal, conjunctival) melanoma[2,4–6]. Additional forms include primary CNS, nodular, nevoid, and dermal melanomas. Nonetheless, previous growth pattern-based classifications remain helpful, including for earlier clinical recognition.

FREQUENCY OF FOUR DIFFERENT SUBTYPES OF PRIMARY CUTANEOUS MELANOMA IN FOUR RACIAL GROUPS

Affected individuals	Superficial spreading	Nodular	Lentigo maligna	Acral lentiginous
Median age (years)	54	61	69	64
Average percentage	68%	16%	14%	2%
NHW (n, % by race/ethnicity)	84790 (69%)	19260 (16%)	17226 (14%)	1822 (1.5%)
HW (n, % by race/ethnicity)	1993 (62%)	689 (21%)	250 (8%)	300 (9%)
Black (n, % by race/ethnicity)	218 (37%)	106 (18%)	46 (8%)	215 (37%)
Asian/PI (n, % by race/ethnicity)	364 (48%)	160 (21%)	69 (9%)	168 (22%)

Table 113.5 Frequency of four different subtypes of primary cutaneous melanoma in four racial groups. See text for the seven major subtypes of cutaneous melanoma in the 2023 WHO Classification of Skin Tumours. Based upon Surveillance, Epidemiology, and End Results (SEER) data (n = 127 676)[263]. NHW, Non-Hispanic White; HW, Hispanic White; Asian/PI, Asian and Pacific Islanders.

Superficial Spreading Melanoma

Superficial spreading melanoma (SSM) – which in general corresponds to low-CSD melanoma – is the most common type of cutaneous melanoma in light-skinned individuals (Fig. 113.7) and is diagnosed most frequently between the ages of 40 and 60 years. It accounts for ~60%–70% of all melanomas and occurs at any site, but is most frequently observed on the trunk (mainly back) of men and the legs and trunk of women. It begins as an asymptomatic brown to black macule with color variations and irregular, notched borders (Fig. 113.8). SSM can arise *de novo* or in a pre-existing nevus (Fig. 113.9). When *in situ*, the melanoma is usually macular with an irregular outline and variable pigmentation (Fig. 113.10). SSMs may have a diameter ≤5 mm (Fig. 113.11). After a typically slow horizontal (radial) growth phase limited to the epidermis or focally within the papillary dermis, a more rapid vertical growth phase, which presents clinically with the development of a papule or nodule, can then occur. In up to two-thirds of tumors, regression (visible as gray, hypo- or depigmentation) of part of the lesion is observed, reflecting the interaction of the host immune system with the progressing tumor (see Fig. 113.2). SSM/low-CSD melanomas are the most likely subtype to arise in association with a pre-existing nevus, with one study demonstrating this relationship in about half of SSMs[70]. However, the likelihood of an individual nevus progressing to melanoma is exceedingly low (see above).

Nodular Melanoma

Nodular melanoma (NM) is the second most common subtype in individuals with lightly pigmented skin, although the lentigo maligna melanoma subtype accounts for a higher percentage in older individuals. NM is diagnosed most frequently during the sixth decade of life and more often in men than in women. It accounts for ~15%–25% of all melanomas (see Table 113.5) and occurs at any body site, but is most frequently seen on the trunk, head, and neck. While nodular melanoma does not appear to correlate with UV exposure specifically, histologically a nodular pattern may be evident in most of the subtypes in the 2023 WHO classification (see above)[4]. NM typically presents as a blue, brown, or black papule or nodule that may ulcerate and bleed (Fig. 113.12), but can also be clinically amelanotic, i.e. pink to red. Lesions typically develop rapidly over weeks to months. Although NM is rare in prepubertal children, it is often clinically amelanotic in this age group, particularly in non-White children[71].

Nodular melanoma is believed to arise as a *de novo* vertical growth phase tumor, without the pre-existing horizontal growth phase that characterizes the other histologic types. These melanomas tend to elude early detection and are often diagnosed at thicker, more advanced stages with an associated worse prognosis. Although overall NM only accounts

Fig. 113.7 Longstanding superficial spreading melanoma. Note asymmetry, irregular borders, variation in colors, scar-like regression zones, and an inferior pink papule, indicating vertical growth phase.

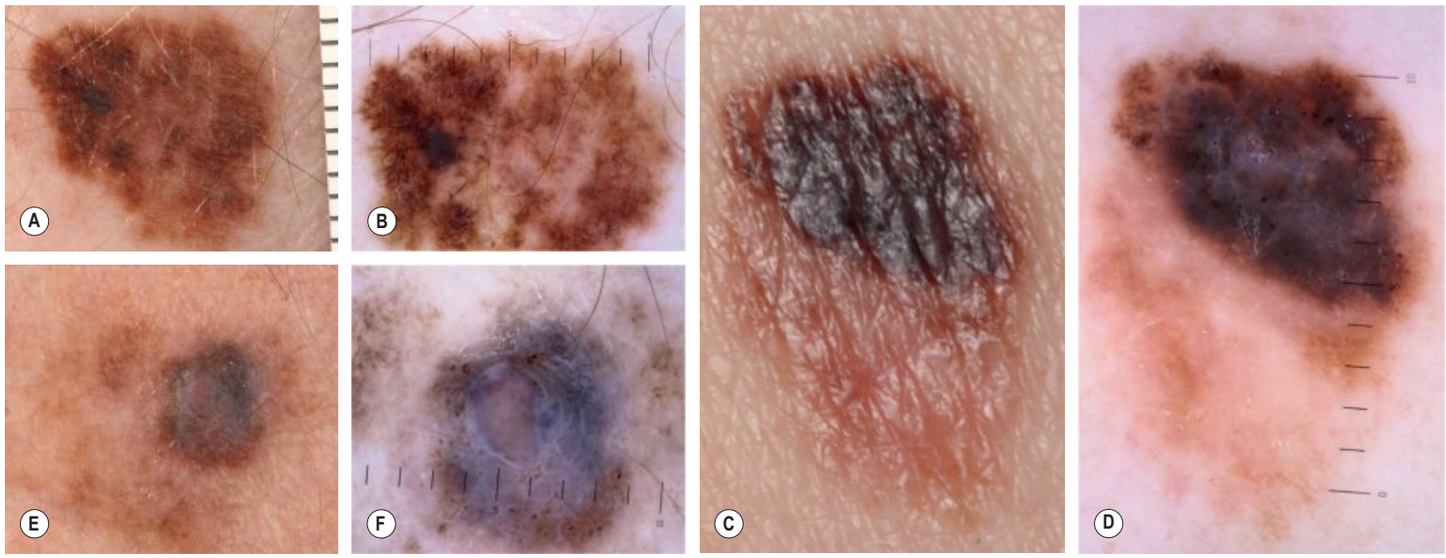

Fig. 113.8 Superficial spreading melanomas. Clinically, all of these lesions demonstrate asymmetry due to variation in color and irregularity in outline. Breslow depths for **A**, **C**, **E** were <0.5 mm, 0.58 mm, and 1.60 mm, respectively. **B**, **D**, **F** By dermoscopy, there is asymmetry, atypical pigment networks, irregular blotches, and multiple colors; in **D** and **F** a blue–white veil is present. *Courtesy Claus Garbe, MD and Jürgen Bauer, MD.*

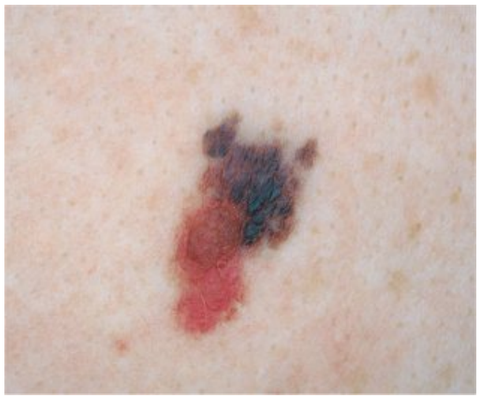

Fig. 113.9 Superficial spreading melanoma arising in a pre-existing melanocytic nevus. Note the irregular outline and variable pigmentation. The central brown papule represents the pre-existing melanocytic nevus; both the superior irregular brown-black plaque and the inferior erythematous plaque represent the melanoma.

for 10%–15% of histopathologically subtyped melanomas, it represents almost 50% of melanomas >2 mm in depth at diagnosis and nearly 40% of ultimately fatal cases[72,73]. Despite the seemingly "aggressive" behavior of NM, biological differences among melanoma subtypes have not been clearly linked to melanoma-specific survival (MSS), but rather to differences in clinical presentation that affect early detection.

Lentigo Maligna Melanoma

Although currently estimated to account for 10%–15% of cutaneous melanomas, with an aging population the incidence of lentigo maligna melanoma (LMM; corresponding to high-CSD melanoma) is on the rise (see Table 113.5). Although LMM is diagnosed most frequently during the seventh decade of life, it often occurs in younger patients who have had significant cumulative sun exposure. LMM develops within chronically sun-damaged skin, most commonly on the face, particularly the nose and cheek, as well as the scalp in older men with androgenetic alopecia. LMM usually appears as a slowly growing, asymmetric, tan to brown to black macule with color variation and an irregular, indented border. Invasive LMM typically presents as a papule or nodule in association with the macular precursor lesion (Fig. 113.13). The latter is termed lentigo maligna or melanoma *in situ*, lentigo maligna [MIS, LM] type (Fig. 113.14A,C,E). It has been estimated that 5% of LM lesions progress to invasive melanoma, but true rates of progression from the *in situ* precursor are unknown[74]. Because MIS, LM typically arises within a background of photodamaged skin, it can be difficult to distinguish from atypical/actinic melanocytic hyperplasia histologically. This phenomenon frequently confounds surgical margin assessment (see Fig. 150.4).

Lentigo maligna displays characteristic features on dermoscopic examination, although differentiation from pigmented actinic keratosis

Fig. 113.10 Melanoma *in situ* on the dorsal foot of an 84-year-old man. A, B The lesion is asymmetric and not well circumscribed. **C** The dermoscopic findings include asymmetry, variation in color, atypical pigment network, and irregular brown blotches. *Courtesy, Department of Dermatology, Medical University of Graz.*

is not always possible (Fig. 113.14B,D,F). In facial skin, hyperpigmented follicular openings (circle in a circle) are slowly overgrown by irregular pigmented dots around the follicles (annular granular pattern)[75]. Rhomboidal structures can also be seen (see Table 0.15).

Acral Lentiginous Melanoma

Acral lentiginous melanoma (ALM) is a relatively uncommon type of cutaneous melanoma and is diagnosed most frequently in the seventh decade of life. It typically occurs on the palms and soles or in and around the nail apparatus (e.g. subungual melanoma). ALM accounts for ~2%–5% of all melanomas, and the incidence of ALM is similar across all racial and ethnic groups. However, since individuals with darker skin phototypes develop fewer UV-related melanomas, ALM represents a disproportionate *percentage* of melanomas diagnosed in Black (up to 36%), Asian (up to 22%), and Hispanic (up to 9%) patients compared to only 2% of melanomas in non-Hispanic White patients (see Table 113.5)[76].

ALM typically presents as an asymmetric, brown to black macule with color variation and irregular borders (Fig. 113.15A). A higher percentage of ALMs are diagnosed at an advanced stage, likely related to: (1) lack of awareness of melanoma risk on acral sites, particularly in those with more darkly pigmented skin and an overall low risk of melanoma; (2) difficulty in clinically distinguishing this subtype from benign lesions and traumatic skin changes (Fig. 113.15B); and (3) an elevated threshold for biopsy due to the morbidity associated with surgery in acral sites. Primary misdiagnosis of ALM occurs in about one-third of all patients and leads to substantial delay in establishing the correct diagnosis. For example, when there are verrucous features, this can result in ALMs being treated as warts.

Melanoma of the nail matrix (subungual melanoma) can present as longitudinal melanonychia (Fig. 113.16) or as hyperpigmentation extending onto the hyponychium or beyond the lateral or proximal nail fold (Hutchinson sign) (see Ch. 71). The possibility of melanoma should be considered when pigmented nail bands have atypical features, in

Fig. 113.11 Melanoma *in situ*. This melanoma *in situ* measured <3 mm in diameter. Small melanomas can be easily overlooked, especially if they are less heavily pigmented. This lesion was the "ugly duckling" (outlier) among this patient's nevi. Dermoscopy assists in making an earlier diagnosis. *Courtesy Claus Garbe, MD and Jürgen Bauer, MD.*

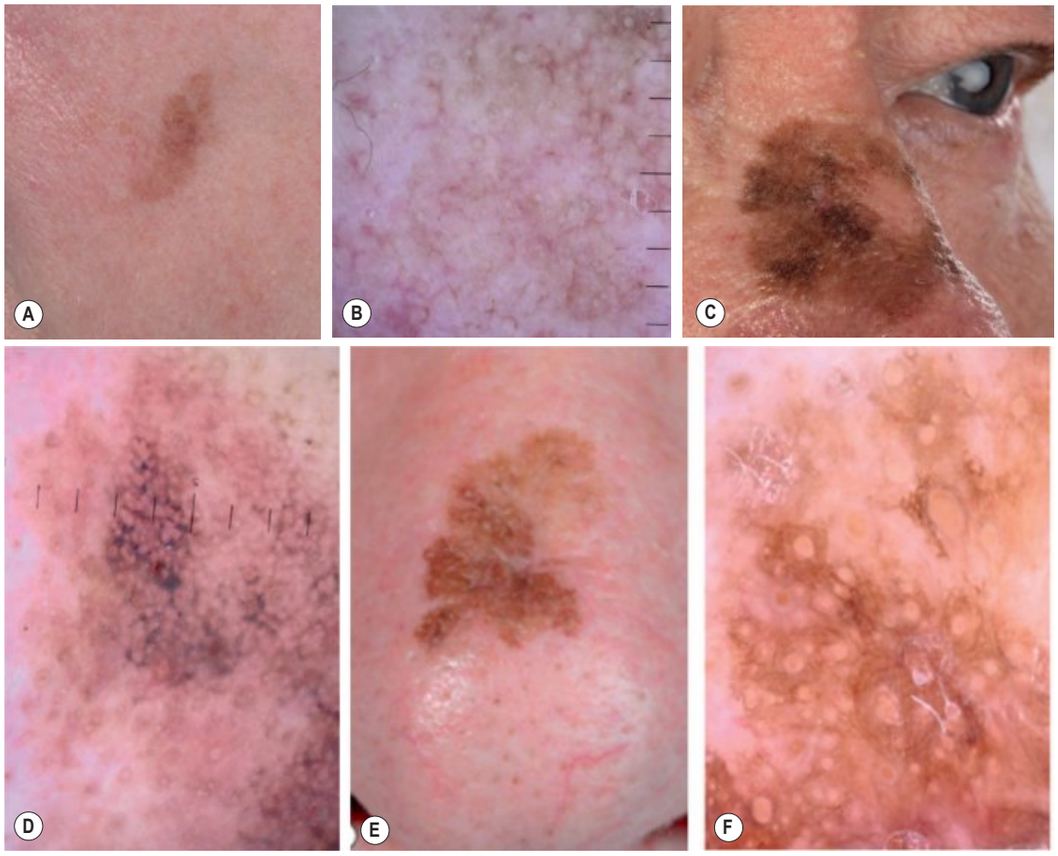

Fig. 113.14 Lentigo maligna (melanoma *in situ*, lentigo maligna type). A, **C** An early lentigo maligna presenting as a light brown patch with subtle, asymmetric pigmentation is compared to a more obvious lesion with readily apparent variation in pigmentation. **B**, **D** By dermoscopy, follicular openings surrounded by annular pigmentation are seen, referred to as a "circle in a circle". Findings are more subtle in **B** and a few rhomboidal structures are seen in **D**. **E** A pigmented lesion on the dorsal nose, with irregular borders, light to dark brown color, and marked asymmetry. **F** Dermoscopy demonstrating annular structures corresponding to follicular openings surrounded by melanoma cells ("circle in a circle"). *Courtesy Claus Garbe, MD and Jürgen Bauer, MD.*

particular if they are solitary, darkly pigmented, have irregular pigmentation, and/or have a width ≥3 mm.

ALM is a genetically distinct subtype of melanoma and clearly differs from the other types of cutaneous melanoma. It harbors more and different genetic changes than the other types and can display activating *KIT* mutations in exons 11, 13, and 17, which was hoped to lead to the successful use of KIT-inhibiting drugs (e.g. imatinib, sunitinib; see Fig. 113.1). Unfortunately, they have demonstrated limited efficacy in the treatment of metastatic disease[77].

OTHER MELANOMA VARIANTS

There are cutaneous melanomas that may present with unusual manifestations. Some of these are defined by clinical features, others by histologic findings.

Amelanotic Melanomas

Fortunately, the majority of melanomas are clinically pigmented, which aids in visual recognition and diagnosis. Melanomas lacking clinically evident pigment are termed "amelanotic" (Fig. 113.17). All four major histologic subtypes of melanoma discussed above can have amelanotic variants that may confound clinical diagnosis; recognition of dermoscopic features in amelanotic melanoma can be useful (see Figs. 0.38 and 0.39). Amelanotic SSMs, NMs, and LMMs are often biopsied due to clinical suspicion of basal or squamous cell carcinomas. Amelanotic ALMs, including subungual type, are especially challenging and may be mistaken for warts or SCC (see Fig. 113.15B). Amelanotic melanomas do not differ from pigmented melanomas in terms of prognosis or therapy.

Melanoma with Features of a Spitz Nevus (Spitzoid Melanoma and Spitz Melanoma)

Spitzoid melanomas comprise a heterogeneous category of melanomas demonstrating histomorphologic features suggestive of a Spitz nevus, e.g. well-circumscribed margins and epithelioid melanocytes that do not mature with progressively deeper dermal extension. However, unlike benign Spitz nevi, spitzoid melanomas may have features such as a large clinical diameter, deep infiltration into the dermis or subcutis, marked cytologic atypia of dermal melanocytes, or mitotic figures at the base of the lesion (see Table 112.7).

Within the category of "spitzoid melanoma" is Spitz melanoma, defined by the 2023 WHO classification as the malignant counterpart of the Spitz nevus based upon genetic characteristics[4]. Genomic analyses have revealed that many cases of *spitzoid melanomas* (e.g. with morphologic features of Spitz nevi) demonstrate genetic features of low-CSD melanoma, including *BRAF* and *NRAS* mutations not typically present in Spitz nevi. In contrast, *Spitz melanomas* demonstrate a distinct spectrum of MAPK-activating alterations more closely associated with Spitz lineage, such as mutations or fusions involving *HRAS*, *ALK*, *BAP1*, *ROS1* and *NTRK1/3*, among others[78].

A subset of spitzoid lesions demonstrate histopathologic features intermediate between benign Spitz nevi and melanoma and may present a significant diagnostic challenge, particularly since they present more often in pediatric, adolescent, and young adult populations. In the 2023 WHO classification, these lesions are termed *Spitz melanocytomas* whereas in the past, they were referred to by several terms including *a*typical *S*pitz *t*umors (ASTs), "*mel*anocytic *t*umors of *u*ncertain *m*alignant *p*otential" (MelTUMPs), or "*s*pitzoid *t*umors of *u*ncertain *m*alignant *p*otential" (STUMPs). These ambiguous lesions are considered to have biologically indeterminate behavior and are frequently treated with complete excision. Some ASTs may metastasize to regional lymph nodes, further confounding their distinction from melanoma. However, ASTs generally follow a more benign course than melanoma, even with nodal metastases, and the diagnostic and prognostic value of sentinel lymph node biopsy (SLNB) for this class of lesions has been questioned in recent years[79]. In the absence of widely accepted histomorphologic diagnostic criteria, several molecular approaches have been taken in attempts to distinguish these entities from melanoma, e.g. immunohistochemistry, fluorescence *in situ* hybridization (FISH), comparative genomic hybridization (CGH), gene expression profiling (GEP), next generation sequencing (NGS) analysis (see below).

Desmoplastic Melanoma

Desmoplastic melanoma (DM) is defined histologically by the presence of spindled melanocytes and prominent stromal fibrosis. The typical clinical lesion is a skin-colored, pink, or red plaque or nodule located on sun-exposed

skin. The lack of classic clinical findings for melanoma may result in a delay in diagnosis. DM may develop: (1) *de novo*; (2) in conjunction with an overlying LM, ALM, or other radial growth phase melanoma; or (3) rarely in mucosal sites. Deep tissue samples are necessary to establish the diagnosis (Fig. 113.18), as superficial portions of the tumor show subtle or non-diagnostic findings which may be mistaken for the fibrosis of a scar or other spindle cell neoplasms. Based upon the degree of desmoplasia and spindled melanocytes within the tumor, "pure" (>90% of tumor consists of a proliferation of spindle cells in a desmoplastic stroma) and "mixed" (<90% of the tumor has a desmoplastic stroma and focally there are nodules of melanoma cells) forms of DM have been described, with differing clinical behavior in the two forms (see below).

Compared to SSM and LMM subtypes, DM is more infiltrative and typically thicker at the time of diagnosis. Incomplete excision and local recurrences commonly occur. A subset of DMs may demonstrate neurotropism (i.e. perineural invasion), with associated higher rates of local recurrence following surgical resection; adjuvant radiation therapy may be considered to improve local control[80]. While deep DMs have significant potential for distant metastasis, conventional T-staging tends to overestimate the likelihood for metastasis. When matched for thickness, several studies have demonstrated improved melanoma-specific survival (MSS) for pure DMs as compared to other melanoma subtypes[81]. Prognosis appears to be worse for the mixed subtype compared to the pure subtype, although data are somewhat conflicting[82]. Regional lymph node metastases are generally uncommon in DM, but mixed DM is significantly more likely than pure DM to have nodal involvement, with positive SLNB rates comparable to conventional melanomas in some studies[82]. Lymphovascular invasion is also more commonly observed in the mixed form[83].

Dermoscopic findings include irregular diffuse pigmentation and a parallel ridge pattern (see Fig. 112.14). **B** Crusted pink nodule on the heel that had been treated for several months as a wart prior to diagnosis. *A, Courtesy Claus Garbe, MD and Jürgen Bauer, MD; B, Courtesy Department of Dermatology, Medical University of Graz.*

Clear Cell Sarcoma ("Melanoma of Soft Parts")

Clear cell sarcoma is an uncommon soft tissue malignancy that demonstrates substantial histopathologic overlap with melanoma, including

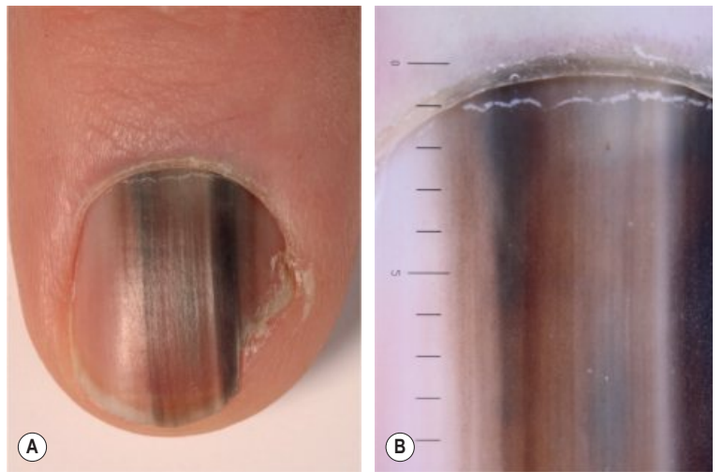

Fig. 113.16 Melanoma of the nail matrix. A, **B** The longitudinal pigmentation of the nail plate is non-homogeneous, both clinically and dermoscopically. Histologically, the Breslow depth was 0.7 mm. *Courtesy Claus Garbe, MD and Jürgen Bauer, MD.*

Fig. 113.17 Amelanotic melanoma. the presence of melanosomes by electron microscopy and immunohistochemical expression of S100, HMB-45, Melan-A, and other melanocytic markers[84,85]. Despite its close histopathologic resemblance to melanoma, leading to the designation "melanoma of soft parts", the exact cell of origin remains unknown, and its clinical presentation is distinctive from conventional melanoma.

Clear cell sarcoma most often presents on the distal extremities of adolescents and young adults, typically arising within the deep soft tissue in association with tendons and aponeuroses. Tumors are composed of nests and fascicles of oval to spindled cells with vesicular nuclei, basophilic nucleoli, and eosinophilic to clear cytoplasm. Multinucleated giant cells and melanin can frequently be seen. Rare cases of superficial clear cell sarcoma may be histologically challenging to distinguish from primary dermal melanomas or melanoma metastases. However, unlike melanoma, clear cell sarcoma demonstrates characteristic rearrangements of *EWSR1*; most frequently a reciprocal translocation t(12; 22)(q13; q12) results in a *EWS–ATF1* fusion gene[84]. These tumors tend to be aggressive, with a high likelihood of regional and distant metastases.

Fig. 113.19 Melanoma arising in a cellular blue nevus (blue nevus-like melanoma). Satellite (lymphatic) metastases are also present. *Courtesy Helmut Kerl, MD.*

Melanoma Arising in a Blue Nevus (Blue Nevus-Like Melanoma)

Blue nevus-like melanoma, also known as melanoma arising in blue nevus and formerly as malignant blue nevus, is a rare dermal tumor of melanocytes. It is most commonly located on the head and particularly the scalp (Fig. 113.19). The tumor presents as a blue–black, deeply situated nodule, generally >1 cm in diameter. Histologically, elements of a benign cellular blue nevus are associated with nodular areas of atypical spindle-shaped and bipolar dendritic melanocytes, mitotic figures, necrosis, and melanophages. The clinical course is characterized by a high rate of recurrence and metastasis. The associated cellular blue nevus may have mutations in *GNAQ* or less often *GNA11* (see Table 112.3), with mutations in *BAP1*, *SF3B1*, and *EIFA1X* detectable within the malignant portion.

Primary Dermal Melanoma

Although rare, dermal-based melanomas may mimic cutaneous or lymphatic metastases histologically and appear clinically similar to a cyst or other dermal tumor. These so-called "primary dermal melanomas" are characterized by a lack of overlying epidermal involvement and no regressive features, and they may be misclassified as stage III or IV melanoma at the outset. Although primary dermal melanomas present with an average Breslow depth of 3–9 mm, depending on the study[86,87], current evidence suggests a more favorable prognosis when compared to equivalently staged conventional primary melanomas – notably an estimated 5-year survival of 80%–100%. Histologic distinction between primary dermal melanoma and cutaneous metastasis may be challenging, if not impossible, and clinical exclusion of metastatic disease (often via imaging) is essential. Findings of an associated intradermal nevus and focal or weak immunohistochemical staining for proliferation-related markers (cyclin D1, Ki-67, and p53) have been described as potential distinguishing features of primary dermal melanoma[86,87].

Ocular Melanoma

Primary ocular melanomas, which are relatively rare (5% of all melanomas), can be divided into conjunctival melanomas and uveal melanomas (iris, choroidal, and ciliary body melanomas). Uveal melanomas frequently (up to 85%) harbor somatic activating mutations in *GNA11* or *GNAQ*. These genes encode members of the q class of G protein α-subunits. Heterotrimeric G proteins are involved in mediating signals between G-protein-coupled receptors (GPCRs) and downstream effectors (see Fig. 65.14)[88]. As noted previously, *GNAQ* (more frequently than *GNA11*) mutations have been detected in blue nevi but not in cutaneous melanomas.

Although biopsy of the primary tumor is not generally needed for diagnosis, it may be considered for prognostication purposes, with molecular testing via chromosomal analysis or GEP preferred over cytology alone[89]. Chromosomal changes of prognostic significance in ocular melanoma include monosomy 3 and alterations of 8q and 6p. Monosomy 3 reduces the 5-year survival from ~100% to <50%, and a particularly poor outcome has been associated with combined abnormalities in chromosomes 3 and 8[90]. However, chromosomal studies of fine needle biopsies can be limited due to sampling error resulting from tumor heterogeneity and technical failures.

Uveal melanomas can be divided into Class 1 (low metastatic risk) and Class 2 (high metastatic risk) based upon a GEP of 15 genes[91]. The GEP of Class 1 uveal melanomas resembles normal uveal melanocytes with >95% of patients free of metastasis at 4 years. In contrast, the GEP of Class 2 uveal melanomas resembles primitive neural/ectodermal stem cells with <20% of these patients free of metastasis at 4 years[92]. *BAP1* mutations are associated with Class 2 uveal melanomas[93].

The management of uveal melanoma has shifted to eye-sparing approaches, without significantly impacting patient survival. Radiotherapy with proton beams has replaced eye enucleation as the standard treatment. Unfortunately, immune checkpoint inhibitors have not led to responses similar to those seen in cutaneous melanoma. Tebentafusp, a bispecific engager that brings together $CD3^+$ T cells and melanoma cells with the gp100/HLA-A*02:01 complex, is approved for unresectable or metastatic uveal melanoma in HLA-A*02:01-positive adults. Surveillance imaging with contrast-enhanced magnetic resonance imaging or ultrasound is primarily directed at the liver, the most frequent site of uveal melanoma metastasis.

Mucosal Melanoma

Mucosal melanomas are rare lesions that may occur in the mouth, nasopharynx, larynx, and anogenital mucosae. They tend to occur near the mucocutaneous junctions of squamous and columnar epithelia and account for ~1% of melanomas. As many as 35% of mucosal melanomas are reportedly amelanotic, further complicating clinical diagnosis[94]. Not surprisingly, these tumors tend to be diagnosed at a locally advanced stage with associated poor prognosis. Similar to ALM, mucosal melanomas are a genetically distinct subtype of melanoma. They harbor more and different DNA copy number changes than do cutaneous melanomas and they can harbor activating *KIT* mutations, which could make the tumor sensitive to KIT-inhibiting drugs (e.g. imatinib; see Fig. 113.1)[77]. However, as with ALM, response rates to KIT inhibitors have so far been limited.

MELANOMA AND PREGNANCY

Melanoma accounts for 25%–30% of all cancers diagnosed during pregnancy, and the incidence has been increasing[95,96]. Although 10% of women experience darkening of their melanocytic nevi during the first 3 months of pregnancy[97], proportionate enlargement of nevi occurs within skin that has expanded due to the pregnancy (e.g. abdomen, breasts)[98]. Both biopsy and wide local excision (WLE) with small amounts of lidocaine and epinephrine (adrenaline) are considered safe to perform during pregnancy and should not be delayed. If SLNB is indicated, US National Comprehensive Cancer Network (NCCN) and AAD (2019) guidelines suggest waiting until at least the second trimester to avoid potential fetal complications of general anesthesia[34]. Both isosulfan blue and methylene blue are contraindicated in pregnancy due to risk of fetal harm, but use of radiotracer is supported by limited data, although fetal radiation dose is not known. Alternatively, in lieu of immediate SLNB, regional surveillance ultrasound can be safely utilized to monitor the draining nodal basin(s) until SLNB can be safely performed. For surveillance and imaging, non-ionizing radiation modalities such as MRI and ultrasound are preferred, as exposure to radiation from CT, X-ray, and PET scans may lead to an increased risk of fetal carcinogenesis.

An association between hormonal changes during pregnancy and development of melanoma or worsening of the prognosis of an existing melanoma has not been demonstrated in stage 0–III disease[99]. Moreover, there are no studies demonstrating that exogenous hormones (e.g. oral contraceptives, hormone-containing contraceptive devices/implants, postmenopausal hormone replacement therapy, hormones associated with assisted reproductive technology) increase the risk of developing cutaneous melanoma. There is also no evidence to suggest that subsequent pregnancies after a cutaneous melanoma diagnosis result in an increased risk of recurrence or development of additional primary melanomas. In fact, higher parity is associated with decreased risk of developing melanoma[100]. That said, in women diagnosed with stage II/III melanomas, consideration of a 2- to 3-year waiting period may be practical given that most recurrences occur during that time period. Lastly, with systemic treatments such as immune checkpoint inhibitors and targeted agents there may be increased risk of fetal toxicity[101,102].

MELANOMA IN THE PEDIATRIC AND ADOLESCENT POPULATION

Childhood melanoma is very rare. Approximately 2% of melanomas occur in patients younger than 20 years of age, and 0.3% in those younger than 14 years[103]. Risk factors for melanoma in children parallel those in adults. The exceedingly rare conditions of xeroderma pigmentosum and giant congenital melanocytic nevi contribute minimally to the prepubertal incidence of melanoma.

Pediatric melanomas, especially in prepubertal children, were found in a series of 70 patients to frequently lack conventional criteria. As a result, alternative ABCD criteria were proposed: **A** – amelanotic; **B** – bleeding, bump; **C** – color uniformity; and **D** – *de novo* appearance, any diameter[104]. In one prospective series, non-White children and adolescents were more likely to present with melanomas that were clinically amelanotic, on the extremities, and nodular subtype, compared to White children and adolescents, who presented more frequently with superficial spreading melanomas[71].

Histologically, melanomas in children may resemble those of adults, but melanomas with features resembling Spitz nevus or deep penetrating nevus are reported to be more common in this age group. As noted above, the differentiation of melanoma from atypical Spitz tumor (Spitz melanocytoma), pigmented epithelial melanocytoma, or other indeterminate melanocytic neoplasms remains a diagnostic challenge. Additional molecular tests (e.g. CGH, FISH, GEP, NGS [see below]) are often required to avoid overdiagnosis of childhood melanoma[105]. Prognosis and survival of pediatric melanoma is stage-dependent, similar to that in adults[106]. As such, treatment should follow the same rationale, regardless of age.

DIAGNOSIS

Early detection is a key factor for improving survival in patients with melanoma. The clinical diagnosis of cutaneous melanoma continues to be based on visual inspection and dermoscopy. A history of change in the color, shape, or size of a pigmented skin lesion over the course of months or years is the most sensitive clinical sign for melanoma, and it may be detected by the patient or by serial screening examinations plus dermoscopy. In high-risk patients, the latter may be supplemented with comparison of stored digital and dermoscopic images and/or total body photography.

Public awareness campaigns have highlighted the ABCDEs of melanoma: **A**symmetry, **B**order irregularity, **C**olor variegation, **D**iameter >5 mm, and **E**volution. It has been shown that patients more commonly recognize a melanoma by the development of a new pigmented lesion or by an increase in size or change in color of a pre-existing lesion, highlighting the importance of "E"[107]. Additionally, the ABCD features broadly overlap with clinically atypical melanocytic nevi, including those that are banal and have low-grade histologic dysplasia, making ABCD less specific as warning signs for melanoma in certain patients.

Dermatologists often unconsciously rely on cognitive (overall pattern) and comparative (ugly duckling sign) processes rather than an algorithm of morphologic criteria (ABCD). A diagnostic clue is the so-called *"ugly duckling" sign*, which focuses on the morphologic differences between a single striking lesion and the surrounding benign "signature" nevi[108]. There is a good interobserver reproducibility of this sign, supporting the significance of recognizing the "outlier" nevus[109].

Two other helpful clinical clues are the *"Little Red Riding Hood" sign* and the *"EFG" rule*. The former represents the finding of erythema or inflammation that at times will surround a cutaneous melanoma[110]. "EFG" stands for an **E**levated, **F**irm, or **G**rowing lesion and is helpful to keep in mind for accurately diagnosing a clinically amelanotic nodular melanoma.

MELANOCYTIC LESIONS THAT SIMULATE MELANOMAS		
Melanocytic lesion	**Clinical simulators**	**Histopathologic simulators**

• Ancient nevi		√
• Atypical (dysplastic, Clark's) nevi	√	√
• Atypical Spitz tumors	√	√
• Black (hypermelanotic) nevi	√	
• Blue nevi and variants	√	*
• Combined nevi	√	√
• Congenital nevi	√	√ (when biopsied shortly after birth)
• Deep penetrating nevi	√	√
• Halo nevi	√	√
• Hyperplasia of melanocytes in sun-damaged skin		√
• Longitudinal melanonychia	√	
• Melanocytic proliferation overlying a benign neoplasm		√
• Melanosis of mucosal regions	√	
• Nevi exposed to UV radiation		√
• Nevi and lentigines in anogenital regions	√	√
• Nevi in other "special sites", e.g. milk line, flexures, on or around the ear		√
• Nevi in patients with epidermolysis bullosa or lichen sclerosus	√	√
• Pigmented streaks in melanoma scars	√	
• Proliferating nodules within congenital nevi	√	√
• Recurrent nevi	√	√
• Reticulated (ink-spot) lentigo	√	
• Spitz nevi	√	√

*Some melanoma metastases are histologically indistinguishable from common blue nevi.

Table 113.6 Melanocytic lesions that simulate melanomas.

NON-MELANOCYTIC CLINICAL SIMULATORS OF MELANOMA
Simulating superficial spreading melanoma
• Solar lentigo • Seborrheic keratosis • Thrombosed hemangioma, angiokeratoma • Pigmented superficial basal cell carcinoma • Pigmented actinic keratosis • Extramammary Paget disease • Bowen disease including pigmented variant
Simulating nodular melanoma
• Seborrheic keratosis • Pyogenic granuloma • Dermatofibroma • Thrombosed hemangioma, angiokeratoma • Pigmented basal cell carcinoma • Pigmented poroma and pigmented porocarcinoma • Pigmented pilomatricoma and melanocytic matricoma • Pigmented dermatofibrosarcoma protuberans (Bednar tumor)
Simulating lentigo maligna/lentigo maligna melanoma
• Solar lentigo/macular seborrheic keratosis • Actinic keratosis, including the pigmented variant • Lichenoid keratosis • Pigmented superficial basal cell carcinoma
Simulating acral lentiginous melanoma of the palms and soles
• Black heel (hemorrhage in stratum corneum caused by trauma) • Plantar warts • Trophic ulcers • Plantar callosity • Tinea nigra
Simulating subungual acral lentiginous melanoma
• Subungual hematoma • Bowen disease • Verruca • Paronychia • Drug-induced nail pigmentation
Simulating desmoplastic melanoma
• Basal cell carcinoma • Squamous cell carcinoma • Dermatofibrosarcoma protuberans • Pseudolymphoma • Ruptured hair follicle/cyst • Adnexal tumor • Arthropod bite reaction (persistent)

Table 113.7 Non-melanocytic clinical simulators of melanoma. In addition to the keratinocytic carcinomas and other tumors listed above, the differential diagnosis of amelanotic melanomas includes warts, ruptured cysts, and persistent arthropod reactions.

It is important to keep in mind that not all cutaneous melanomas present with typical clinical clues. Based on visual inspection alone, accuracy for the clinical diagnosis of melanoma does not exceed 75% and may be increased to up to 90% with the use of dermoscopy by experts. However, 10%–25% of melanomas may still be missed despite these diagnostic efforts. The term "featureless melanoma" has been coined for early and difficult-to-diagnose melanomas and may partially explain this statistic[111]. Sometimes, patients are the first to recognize these featureless cutaneous melanomas, and there should be a low threshold for biopsying any persistent lesion that arouses patient concern for "being different" from the rest.

Differential Diagnosis

A variety of conditions may simulate melanoma, either clinically or histopathologically, or both. Awareness of these simulators is of great practical importance in order to avoid misdiagnosis or overdiagnosis of melanoma. Tables 113.6 and 113.7 list several melanocytic and non-melanocytic lesions that can mimic melanomas.

Dermoscopy

Dermoscopy, also known as skin surface microscopy or epiluminescence microscopy (ELM), is an essential, non-invasive tool for diagnosing pigmented skin lesions and for recognizing cutaneous melanoma (see Figs. 113.8, 113.10, 113.12, 113.14). Clinical diagnostic sensitivity is significantly enhanced by the use of dermoscopy, and the correct diagnosis of melanoma is improved by nearly 50% in the hands of experienced/trained practitioners who utilize this diagnostic technique. It therefore can prevent unnecessary biopsies[112].

In one form of dermoscopy, a magnifying lens system is combined with a fluid interface in order to eliminate skin surface reflection. Hand-held lenses or cameras equipped with lenses and coupled with digital imaging systems are used. A glass plate makes direct contact with the skin, and ultrasound contact gel or a disinfectant spray can be used for the fluid interface. Morphologic structures within the epidermis, the dermal–epidermal junction, and the superficial dermis can be visualized with this technique. An alternative and more commonly employed form of dermoscopy uses polarized light to eliminate the surface reflection so that neither a liquid interface nor direct skin contact is required. The magnifications of these instruments range from 6- to 100-fold, but the most widely used dermoscope provides a 10-fold magnification, which is sufficient for routine assessment of most pigmented skin lesions.

The dermoscopic evaluation of cutaneous pigmented lesions involves a two-step algorithm. First, the observer determines whether the lesion under investigation is of melanocytic origin or not. For a lesion to be

considered melanocytic, it needs to have at least one of the following dermoscopic structures/features: pigment network, streaks, aggregated globules, homogeneous blue pigment, or parallel pattern (acral lesions). If the lesion does not possess one of the aforementioned melanocytic features, then it needs to be evaluated further to determine if it has any dermoscopic characteristics consistent with other entities such as a seborrheic keratosis, dermatofibroma, or pigmented basal cell carcinoma (see Tables 0.14 & 0.15). However, if the lesion does not have any features of a melanocytic lesion *and* it does not have any features of a non-melanocytic tumor, then, by default, the lesion is considered to be of melanocytic origin.

Once a lesion is deemed to be melanocytic in origin, the second step of the algorithm is to differentiate between a benign melanocytic nevus and melanoma. To this end, multiple algorithms have been created, including pattern analysis, the ABCD rule, Menzies method, and the 7-point checklist, among others, which assist the clinician in deciding which lesions require a biopsy (see Tables 0.17–0.20)[75]. Several typical dermoscopic patterns have been described for benign nevi, including those with low-grade clinical atypia/histologic dysplasia, recognition of which can prevent unnecessary biopsy (see above).

The major dermoscopic criteria for melanoma can be broken down into global features, patterns, and local features. Global features of melanoma include dermoscopic asymmetry and the presence of multiple colors. Patterns seen by dermoscopy include reticular, globular, reticular–globular, homogeneous, reticular–homogeneous, and starburst. In melanoma, the most common patterns are the multicomponent pattern (three or more dermoscopic structures distributed asymmetrically), asymmetric starburst pattern, and nonspecific pattern (does not fit one of the known benign patterns). Lastly, the presence of any of the following local features should raise concern for melanoma: atypical network, negative pigment network, streaks, atypical dots or globules, irregular blood vessels, regression structures, crystalline structures, and blue–white veil (Table 113.8).

Over the past several years, dermoscopic criteria have been further refined in order to recognize difficult-to-diagnose melanomas such as ALMs and subungual melanomas[113]. Additionally, diagnostic clues for early nodular melanomas and for amelanotic melanomas have been described, as these melanomas do not display the classic features (see above)[114]. As with clinical examination, not all melanomas can be clearly recognized by dermoscopy and "featureless" melanomas exist[111].

Photography

In high-risk patients, especially those with complex mole patterns, total body digital photography can be a helpful adjunct in the identification of new and changing lesions[115]. The availability of baseline images for comparison, including dermoscopic images, permits the detection of melanomas that are growing or changing without manifesting obvious clinical characteristics, while simultaneously avoiding the removal of stable clinically atypical nevi[115]. Future adoption of new and developing technologies, including automated two- and three-dimensional total body photography, sequential digital dermoscopic imaging, and computer-assisted diagnostic algorithms that incorporate artificial intelligence, may further enhance longitudinal evaluation of melanocytic lesions[116].

DERMOSCOPIC CRITERIA AND THEIR CORRESPONDING HISTOPATHOLOGIC FEATURES			
Criterion	**Morphologic definition**	**Associated histopathologic changes**	**Diagnosis**
Pigment network	Network of brownish lines over a diffuse tan background	Pigmented rete ridges	Melanocytic lesion
Typical network	Brown-colored, regularly meshed and narrowly spaced network	Regular and elongated rete ridges	Benign melanocytic lesion
Atypical network	Black, brown, or gray network with irregular meshes and thick lines	Irregular and broadened rete ridges	Melanoma
Dots/globules	Black, brown, and/or gray, round to oval, variably sized structures regularly or irregularly distributed within the lesion	Pigment aggregates within the stratum corneum, epidermis, dermal–epidermal junction or papillary dermis	If regular: benign melanocytic lesion; if irregular: melanoma
Streaks	Irregular, linear structures not clearly combined with pigment network lines at the margins	Confluent junctional nests of melanocytes	Melanoma
Blue–white veil	Irregular, confluent, gray–blue to whitish-blue diffuse pigmentation	Acanthotic epidermis with focal hypergranulosis above sheets of heavily pigmented melanocytes in the dermis	Melanoma
Blotches	Black-, brown-, and/or gray-colored areas with regular or irregular shape/distribution	Hyperpigmentation throughout the epidermis and/or upper dermis	If regular: benign melanocytic lesion; if irregular: melanoma
Regression structures	White (scar-like) areas, blue (pepper-like) areas or combinations of both	Thickened papillary dermis with fibrosis and/or variable amounts of melanophages	Melanoma
Milia-like cysts	White–yellowish, roundish dots	Intraepidermal horn globules, also called horn pseudocysts	Seborrheic keratosis (occasionally observed in papillomatous melanocytic nevi)
Comedo-like openings	Brown–yellowish, round to oval or even irregularly shaped, sharply circumscribed structures	Keratin plugs situated within dilated follicular openings	Seborrheic keratosis
Leaf-like areas	Brown–gray to gray–black patches revealing a leaf-like configuration	Pigmented, solid aggregations of basaloid cells in the papillary dermis	Basal cell carcinoma
Red–blue lacunas	Sharply demarcated, roundish to oval areas with a reddish, red–bluish, or red–black color	Dilated vascular spaces situated in the upper dermis	Vascular lesion
Vascular structures	Comma-like vessels		Benign melanocytic lesion
	Arborizing vessels		Basal cell carcinoma
	Hairpin vessels		Seborrheic keratosis
	Dotted or irregular vessels		Melanoma

Non-Invasive Diagnostic Imaging

Non-invasive diagnostic imaging modalities are increasingly being utilized for melanoma detection. These technologies have the potential to augment clinical diagnosis and triage, decreasing unnecessary biopsies and excisions. However, their performance in "real-world" clinical settings remains to be seen, and they do not replace the gold standard of histopathologic diagnosis; widespread availability of novel imaging techniques is another limitation. While many are still in development, two modalities have been FDA-approved for clinical use: reflectance confocal microscopy and electrical impedance spectroscopy.

Reflectance confocal microscopy (RCM) uses a near-infrared, low-intensity diode laser designed for non-invasive *in vivo* imaging of the skin. Structures within the epidermis and papillary dermis are visualized with high resolution, producing images akin to traditional histology (see Ch. 0). This technique has been used to analyze various cutaneous tumors, including melanoma (Fig. 113.20), with a pooled sensitivity of 92% and pooled specificity of 70% for melanoma detection in a recent meta-analysis[117]. RCM improves diagnostic accuracy for cutaneous melanoma compared to clinical and dermoscopic examination, preventing over half of benign lesions from unnecessary removal[116]. RCM may also enable more accurate intraoperative assessment of subclinical extension of LMM, with excellent agreement (>80%) between RCM mapping and histopathologic margin assessment during staged excision[118]. Additional applications of RCM include evaluation of dermoscopically equivocal lesions in difficult-to-biopsy situations (e.g. cosmetically sensitive areas, acral sites, young children) as well as short-term clinical monitoring of suspected lentigo maligna or amelanotic lesions whose initial RCM imaging appears negative for melanoma[119].

Electrical impedance spectroscopy (EIS) relies on the different electrical properties of normal and abnormal tissue to distinguish between benign nevi and melanoma. A hand-held probe with "microinvasive" electrode pins that penetrate the stratum corneum delivers an imperceptible low-level electrical current through the skin to measure the bioimpedance of the area of interest. EIS demonstrates high sensitivity: >96% melanoma detection for lesions deemed suspicious for melanoma on clinical and dermoscopic examination. However, specificity is much lower (~35% in one prospective trial[120]). Notably, seborrheic keratoses may display a high false-positive rate with EIS, underscoring the importance of clinical judgment when adopting these imaging technologies.

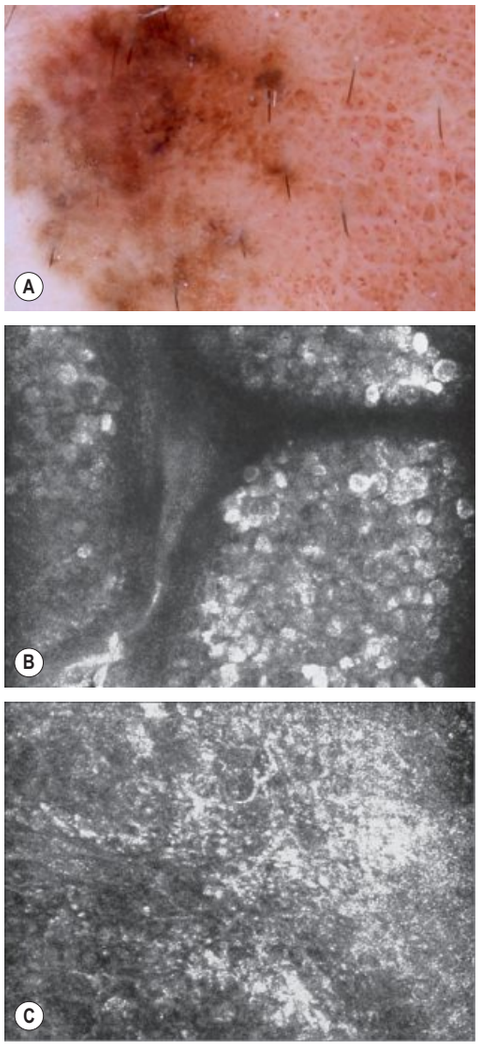

Fig. 113.20 Cutaneous melanoma arising within a compound melanocytic nevus – dermoscopy and reflectance confocal microscopy (RCM). A By dermoscopy, the nevus has a regular cobblestone pattern (right) whereas the melanoma component has a disorganized pattern with an atypical pigment network as well as atypical dots and globules (left). **B** RCM of the nevus portion demonstrates regularly organized collections of reflective melanocyte cells within nests. **C** In the melanoma portion, there is architectural disorder of the epidermis with large round solitary atypical refractive (pagetoid) cells as well as bright atypical dendritic cells. *Courtesy Anthony Rossi, MD and Ashfaq Marghoob, MD.*

PATHOLOGY

Histopathology remains the gold standard for melanoma diagnosis, although studies have demonstrated significant interobserver variability in the application of diagnostic criteria for melanocytic neoplasms ranging from moderately dysplastic nevi to *in situ* and thin (T1) melanomas[43]. While most melanomas are readily distinguished from melanocytic nevi based on standard criteria (Table 113.9), some melanocytic lesions remain diagnostically challenging despite incorporation of immunohistochemistry and various molecular techniques.

It has been proposed that melanomas progress through two phases. The first is the radial (horizontal) growth phase (RGP), characterized by centrifugal spread of neoplastic melanocytes within the epidermis and infiltration of the papillary dermis by single cells or small nests. The second, vertical growth phase (VGP) is characterized by the presence of dermal nests/nodules of atypical melanocytes that are larger than and/or cytologically distinct from their intraepidermal counterparts. It has been further postulated that the RGP lacks metastatic potential even in the presence of dermal invasion, whereas the VGP correlates with the capacity for metastasis. The major histologic types of melanoma described above differ with regard to the presence and morphology of the RGP. However, because the value of RGP versus VGP in assessing prognosis has not been confirmed by larger studies, the "growth phase" is not part of current classification schemes.

CRITERIA FOR THE HISTOPATHOLOGIC DIAGNOSIS OF MELANOMA
Architectural pattern
• Asymmetry • Poor circumscription of intraepidermal melanocytic component • Silhouette of tumor base is uneven (except in nevoid melanoma) • No maturation of melanocytes with progressive descent into the dermis (maturation may be present in some nevoid melanomas) • Nests of melanocytes within the epidermis are not equidistant from one another • Nests of melanocytes vary in size and shape • Some nests of melanocytes become confluent • Scatter of melanocytes above the dermal–epidermal junction • Melanocytes arranged as solitary units predominate over nests within the epidermis • Melanocytes in some nests are not cohesive • Melanocytes extend down adnexal epithelium • Sheets of melanocytes within the dermis • Nests at the base of lesion are occasionally large
Cytomorphology
• Atypical melanocytes (with pleomorphic nuclei) • Mitotic figures • Necrotic melanocytes
Other features
• Signs of regression (especially if extensive [>75%] or extending beneath measured Breslow thickness) • Actinic (solar) elastosis (i.e. CSD vs non-CSD melanoma), particularly if pushed down by newly formed collagen containing complexes of melanocytes (sign of a recent growth) • "Dusty" melanin within tumor cells • Melanin is not distributed in a uniform fashion • Plasma cells at the base of the lesion

Table 113.9 Criteria for the histopathologic diagnosis of melanoma. CSD, cumulative sun damage. *Adapted from Ackerman A, Cerroni L, Kerl H. Pitfalls in Histopathologic Diagnosis of Malignant Melanoma. Philadelphia: Lea & Febiger, 1994.*

Typically, cutaneous melanoma is asymmetric, poorly circumscribed, and characterized by nests of melanocytes within the epidermis that are not equidistant from one another, vary in size and shape, and focally become confluent (Fig. 113.21)[69]. Within the epidermis, solitary melanocytes often predominate over nests. Some solitary melanocytes and nests of melanocytes are found well above the dermal–epidermal junction, at times extending into the upper epidermis, even the cornified layer; this is referred to as "pagetoid" scatter. These findings define melanoma *in situ* (Fig. 113.22). The presence of such features along with atypical melanocytes within the dermis constitute invasive melanoma. One element of histologic asymmetry in melanoma is the extension of the intraepidermal tumor cells far from the invasive intradermal component. Similar findings are present in the adnexal epithelium of folliculosebaceous units and eccrine ducts. Within the dermis, the melanocyte nuclei do not become smaller within the deeper portions of the tumor (absence of maturation). In parallel, the nests of melanocytes also do not become smaller with progressive descent.

In SSM, the radial growth phase predominates histologically with broad, horizontal extension of atypical melanocytic nests and single cells within the epidermis and superficial dermis. As these tumors frequently represent low-CSD melanomas, solar elastosis within the dermis is usually minimal. In nodular melanoma, the tumor extends vertically in the dermis with a comparatively limited involvement of the overlying epidermis (Fig. 113.23). Overall, the tumor may exhibit a nodular, polypoid, or pedunculated architecture.

LMM (high-CSD melanoma) differs from the prototypic melanoma by the presence of marked solar elastosis (a sign of chronic sun damage) as well as the tendency to have little pagetoid spread within the epidermis. Tumor cells show lentiginous spread, i.e. solitary tumor cells in the epidermal basal layer predominate over tumor cell nests within the epidermis. The atypical melanocytes are commonly present within the epithelium of adnexal structures, especially along the outer root sheath of hair follicles (Fig. 113.24). The invasive component is more often composed of spindle cells, although any morphology is possible. Reflecting the role of high CSD in the pathogenesis of this subtype, epidermal atrophy, in addition to solar elastosis in the upper dermis, is commonly observed.

ALM often has a proliferation of atypical melanocytes within the basal layer of a hyperplastic epidermis, i.e. a lentiginous spread of single melanoma cells (Fig. 113.25). These findings may be subtle in early lesions or at the tumor's periphery. In volar and subungual sites, this lentiginous component may contain strikingly dendritic melanocytes with hyperchromatic, vertically elongated nuclei and irregular dendritic processes that may reach the mid spinous layers. Throughout the lesion, atypical melanocytes are arranged singly and in irregularly shaped nests at all levels of the epidermis ("pagetoid scatter"), with a predominance of single cells. In the cornified layer, numerous melanocytes and melanin granules are diffusely scattered. These findings are in contrast to the mild cytomorphologic atypia that may characterize benign acral nevi and nevi in other "special sites" (e.g. genitalia, milk line), a finding commonly referred to as "special site atypia". For example, while some pagetoid scatter may be present in acral nevi, this is typically confined to the skin furrows ("columnar scatter"), whereas in melanoma it is present throughout the lesion, involving both ridges and furrows ("diffuse scatter").

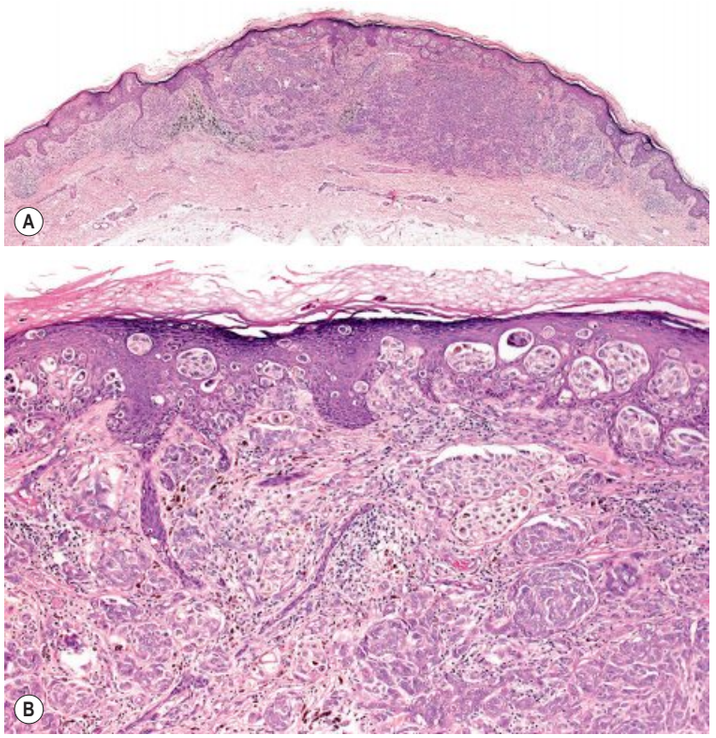

Fig. 113.21 Histopathologic features of a typical superficial spreading (low-CSD) cutaneous melanoma. A Asymmetric melanocytic tumor with asymmetry in both distribution of melanocytic complexes and pigment. **B** Pagetoid melanocytes organized as solitary units and nests varying in size and shape are present throughout the entire epidermis. Neoplastic melanocytes extend into the dermis. There is absence of maturation at deeper levels of the dermis. *Courtesy Lorenzo Cerroni, MD.*

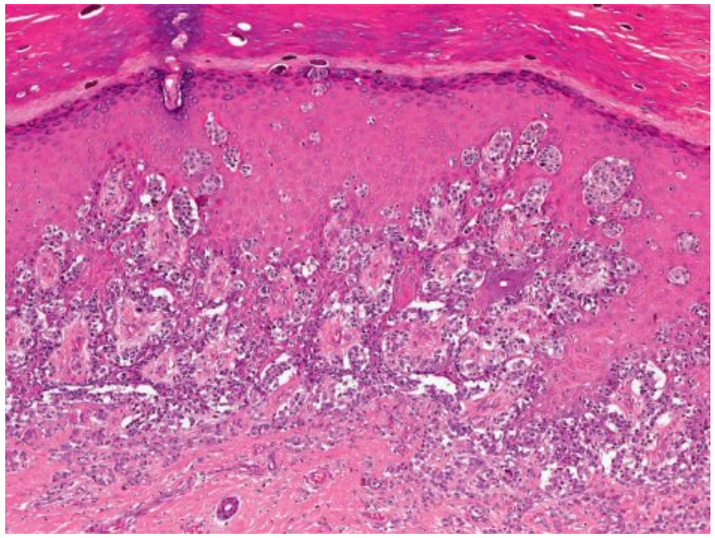

Fig. 113.25 Histopathologic features of an acral lentiginous melanoma. Irregular, sometimes confluent, nests of atypical melanocytes within a hyperplastic epidermis. Some of the melanocytes are hyperchromatic and are also present within the cornified layer. Note the thick stratum corneum typical of acral skin. *Courtesy Lorenzo Cerroni, MD.*

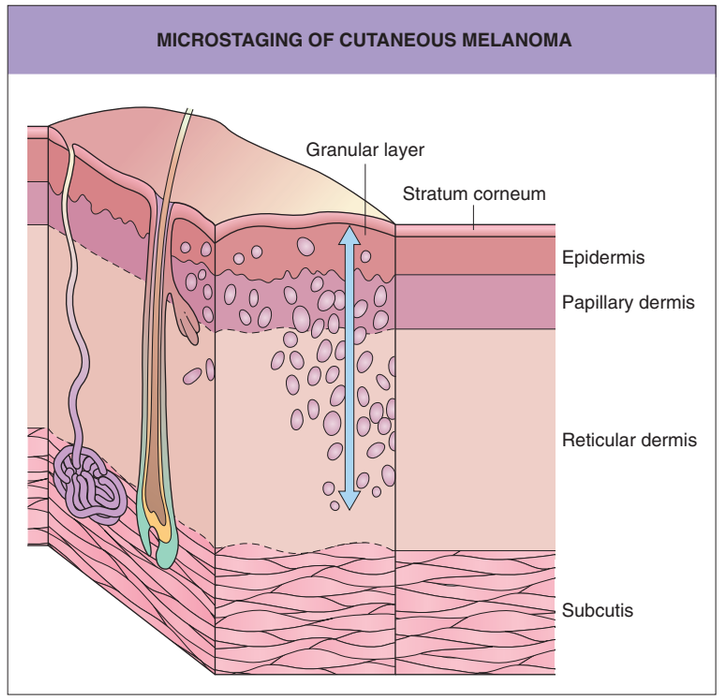

Fig. 113.26 Microstaging of cutaneous melanoma: Breslow tumor thickness. Breslow method: measure from the granular layer of the epidermis to the deepest part of the tumor.

Microstaging

Of the histologic features in a primary cutaneous melanoma, Breslow depth (i.e. tumor thickness) is the strongest predictor of survival. Melanoma thickness is measured in millimeters from the top of the granular cell layer of the epidermis (or the base of an ulcer) to the deepest point of tumor penetration, using an ocular micrometer (Fig. 113.26). In addition to tumor thickness, a number of other histologic features should be noted such as ulceration and involvement of margins[121–123]. Tumor thickness and ulceration are major determinants of T-stage in the current AJCC-8/UICC staging system, with ulceration defined histologically as the absence of an intact epidermis overlying a major portion of the primary tumor plus an associated host response (e.g. fibrinous exudate, acute inflammatory infiltrate).

Although dermal mitotic count (measured according to the "hot spot" method and reported as number/mm^2) does not currently upstage primary melanoma, it was viewed as a prognostic factor in the previous AJCC staging system. Guidelines for the histopathologic examination and reporting of melanoma features have been published by the International Collaboration on Cancer Reporting and the College of American Pathologists[121–123]. However, a number of experienced dermatopathologists only report criteria essential for the current staging classification – tumor thickness, ulceration (if present), satellites (if present), and assessment of margins.

Immunohistopathology

Immunohistochemical studies can be helpful in the assessment of diagnostically difficult cases of primary melanoma as well as in the assessment of metastatic tumors of unknown origin (see Tables 0.13 & 122.4). However, the diagnosis of cutaneous melanoma is based upon routine H&E staining, as immunostaining patterns alone cannot clearly differentiate between benign and malignant lesions. A wide range of melanoma-associated antigens have been identified for which immunohistochemical stains are available. Melanocyte differentiation antigens, e.g. PMEL17/gp100 (HMB45), tyrosinase, MART-1/Melan-A, MITF, are useful for: (1) distinguishing cells of melanocytic lineage from other tumor types; (2) visualizing the full extent of tumor cells of a primary melanoma; and (3) identifying minute foci of melanoma in sentinel lymph node biopsies. HMB45, which recognizes the melanosome-specific glycoprotein PMEL17/gp100, has high specificity for melanocytes and nevus cells, but its utility is limited by its heterogeneous staining pattern and limited sensitivity. Transfer of melanosomes to keratinocytes can also lead to positive staining for tyrosinase and PMEL17/gp100 (HMB45) in keratinocytes. Because MITF is a transcription factor in melanocytes, it does not stain melanosome-containing keratinocytes. Of note, HMB45, tyrosinase, MART-1/Melan-A, and MITF may all be negative in desmoplastic melanoma, representing an important potential pitfall.

Staining for S100, a calcium-binding protein, has high sensitivity for melanocytes and melanoma, including desmoplastic or spindled cell melanoma. However, this protein is also expressed by Langerhans cells, other dendritic cells, eccrine glands, Schwann cells, chondrocytes, and adipose tissue. SOX10, a transcription factor, has emerged as a popular alternative to S100 and other melanocytic markers due to easier interpretation of its nuclear staining pattern. Although SOX10 is not entirely melanocyte-specific (expressed in myoepithelial cells and other cells of Schwannian lineage), it will identify the spindled component of most desmoplastic melanomas. There is also less background staining of dermal fibrohistiocytic cells by SOX10 compared to S100, making SOX10 useful in distinguishing residual desmoplastic melanoma from

scar. In sum, the use of panels of these antibodies improves sensitivity and specificity, but remains diagnostically imperfect.

More recently, immunohistochemical staining for PRAME (PReferentially expressed Antigen in MElanoma) was introduced. Initially identified in tumor-reactive T cells from patients with cutaneous melanoma, *PRAME* was one of the few GEP genes that discriminated between melanoma and benign melanocytic neoplasms. Immunohistochemical staining for PRAME is generally negative in benign nevi, solar lentigines, melanocytic hyperplasia in sun-damaged skin, and other melanocytic lesions with intermediate histopathologic features[124]. In contrast, the majority of primary cutaneous melanomas and their metastases demonstrate diffuse nuclear PRAME immunostaining, which appears to be strongly concordant with abnormal cytogenetic test results[125]. PRAME may be a useful marker in the assessment of melanoma surgical margins (including LM), in distinguishing melanoma micrometastases from nodal nevi in sentinel lymph nodes, and in the evaluation of ambiguous melanocytic lesions[126]. Potential exceptions include desmoplastic melanomas, of which only a third may be PRAME-positive, and spitzoid neoplasms, in which PRAME positivity may correlate less strongly with histopathologic features[124]. Although it currently appears to be a promising immunohistochemical marker for melanoma, because a minority of melanocytic nevi are PRAME-positive, correlation with conventional histopathologic features is paramount for proper classification of both PRAME-positive and PRAME-negative lesions.

Molecular Analysis

Some cutaneous melanomas prove challenging to diagnose, and differentiation between atypical Spitz tumor (AST)/Spitz melanocytoma and spitzoid melanoma or between deep penetrating nevus or atypical blue nevus and melanoma can be difficult based upon histopathology. In such cases, CGH or FISH in addition to newer molecular techniques (NGS, GEP) may be helpful (Table 113.10).

CGH is a method for the genome-wide assessment of DNA copy number changes in tumor cells. Fluorescence-labeled tumor DNA and reference DNA from a healthy donor are hybridized onto metaphase chromosomes or on arrays of oligonucleotides (array CGH). From the relative fluorescence copy number, gains or losses within the tumor can be calculated. The oligonucleotide spots on the array can be mapped to the respective position within the human genome. CGH analysis of benign melanocytic nevi typically shows *no* clonally expanded chromosomal aberrations, while in the vast majority of melanomas, *gains and losses* of particular segments of chromosomes or entire chromosomes are found, including copy number gains of 1q, 6p, 7p, 7q, 8q, 17q, and 20q and losses of chromosomes 6q, 8p, 9p, and 10q[127]. As an exception, ~20% of Spitz nevi show an increase in copy number of chromosome 11p (corresponding to *HRAS* activation) or an isolated loss of chromosome 3 (corresponding to loss of *BAP1*), aberrations not typically found in cutaneous melanoma[127–129].

FISH can also assist in differentiating between benign and malignant melanocytic tumors (see Fig. 3.8). These assays often focus on chromosomal loci that are frequently affected by copy number changes in melanoma. Studies have shown that FISH assays that target various combinations of 6p25 (*RREB1*), 6q23 (*MYB*), 8q24 (*cMYC*), 11q13 (*CCND1*), CEP6 (centromere of chromosome 6), and 9p21/CEP9 (*CDKN2A*) discriminate between benign nevi and melanoma with high sensitivity and specificity[130–132]. The disadvantage of FISH is that only gains and losses involving a limited number of chromosomes are detected. However, compared to CGH, FISH is typically faster, less expensive, and requires less tumor tissue to perform.

NGS has also been used to further characterize the genomic landscape of multiple tumors, including melanoma and various spitzoid tumors[133,134]. This method allows for the analysis of hundreds of genes in a single study (see Fig. 3.5), and it can potentially point to new prognostic markers or therapeutic targets. NGS has facilitated the discovery of various fusion kinases that underly the pathogenesis of some melanocytic neoplasms, including spitzoid neoplasms. Due to the immense data infrastructure and bioinformatics expertise required for NGS, its availability is currently limited to a few commercial laboratories and academic research centers.

A frequent application of the above molecular techniques is in the evaluation of AST versus spitzoid melanoma. One or multiple methods can be utilized given that complementary information is provided by each assay[135]. For FISH, inclusion of the 9p21/CEP9 probe significantly increases sensitivity for spitzoid melanoma, as homozygous loss of this locus has been associated with advanced locoregional disease or death. Gains of 8q24 and 11q13 also correlate with an aggressive clinical course, but the risk is lower than with homozygous 9p21 deletions[136]. In cases with ambiguous or negative FISH results, CGH may provide additional information regarding other copy number alterations supportive of melanoma. Identification of *TERT* promoter mutations via NGS is also suggestive of more aggressive clinical behavior, with one study demonstrating a significant association with extranodal metastasis and death[137]. In the assessment of ASTs, identification of an underlying *BRAF* or *NRAS* mutation by NGS may favor a conventional melanoma with spitzoid features over AST[138]. Regardless of which techniques are used, definitive classification of ASTs remains a significant challenge.

DIFFERENTIAL DIAGNOSIS OF MELANOMA – MOLECULAR DIAGNOSTICS THAT CAN BE UTILIZED

Test	Detects	Advantages	Disadvantages
Comparative genomic hybridization (CGH) – FFPE tissue	Chromosomal gains and losses (DNA copy number changes)	Genome-wide screening for chromosomal gains and losses without prior knowledge of the genomic aberrations	• No detection of mutations (single nucleotide changes), small gains or deletions, balanced translocations, and polyploidy • A low percentage of neoplastic cells in the specimen leads to false negative results
Fluorescent *in situ* hybridization (FISH; see Fig. 3.8) – FFPE tissue	Deletions, amplifications, translocations	Each cell nucleus is evaluated individually so that even tumors with a low percentage of neoplastic cells can be analyzed without the risk of false-negative results	• Prior knowledge of the genomic aberrations necessary to build the probe • Poor interobserver reproducibility • No detection of mutations or small copy number aberrations • Analyzes only a limited number of chromosomal loci (usually 4–6)
Next generation sequencing (NGS; see Fig. 3.5) – FFPE	Sequence of nucleotides in RNA or DNA, eiither n specific regions or entire genome	Most comprehensive method for genomic analysis and gene expression prolifiling	• Currently quite expensive and labor intensive • Performed primarily in academic centers (e.g. for identification of therapeutic targets)
Gene expression profiling (GEP) *Post biopsy* – FFPE tissue *Pre biopsy* – tape stripping	Gene expression levels of selected genes	• May provide information regarding risk of metastasis for uveal and cutaneous melanomas* • May distinguish benign melanocytic nevi from cutaneous melanomas	• Evaluates gene expression levels, but gives no information regarding the underlying genomic aberrations • In selected, unequivocal benign or malignant lesions, the sensitivity and specificity appears to be ~80%–90%, but the diagnostic value for ambiguous lesions remains undetermined

*Currently used to predict metastatic risk in uveal melanomas.

Table 113.10 Differential diagnosis of melanoma – molecular diagnostics that can be utilized. These tests have been used to assist in the diagnosis of ambiguous and/or controversial melanocytic tumors as well as for prognostication; the latter is primarily GEP for melanomas. Next generation sequencing is covered in the text. FFPE, formalin-fixed, paraffin-embedded.

Gene Expression Profiling (GEP)

GEP has gained attention as a potentially useful molecular technique in the field of melanoma, and GEP assays for diagnosis as well as prognostication have been developed. Whereas diagnostic GEP aims to classify an undiagnosed melanocytic lesion as benign, intermediate, or malignant, prognostic GEP aims to provide further clinical risk stratification for melanomas beyond AJCC stage and other clinicopathologic factors. GEP assays typically use quantitative reverse transcriptase PCR (qRT-PCR) to measure the mRNA expression levels of a limited panel of genes; the latter have been correlated with pre-specified outcomes, such as benignity, tendency to metastasize, or SLNB risk prediction, and the goal is to accurately predict this outcome in the queried lesion. Ideally, during development of prognostic GEP assays, fully annotated cohorts of archival melanoma tissue samples would be analyzed, with subsequent prospective validation among separate melanoma cohorts as well as comparison against all known clinicopathologic factors and AJCC stage to determine prognostic accuracy and clinical utility.

Gene expression profiling for diagnosis

Development of diagnostic GEP assays was based on several DNA microarray studies that demonstrated disparate gene expression patterns when benign melanocytic lesions were compared to melanoma[139–142]. There are currently two commercially available diagnostic GEP tests, a 3-gene assay (DermTech Smart Stickers™) that was initially a 2-gene assay, and a 23-gene expression signature (23-GES) assay (myPath® Melanoma). Both the initial 2-gene assay and the current 3-gene assay use adhesive tape stripping pre-biopsy to determine the likelihood of malignancy (and need for biopsy) of a melanocytic neoplasm based on melanoma-associated genes – *LINC*, *PRAME*, and more recently, *TERT*. The original 2-gene assay demonstrated a sensitivity of 91% and specificity of 69% in the classification of suspicious melanocytic lesions[143], with subsequent real-world studies demonstrating even higher specificity (91%) and high negative predictive value (99%) without decreased sensitivity for melanoma[144]. The addition of *TERT* to the 3-gene assay was reported to increase diagnostic sensitivity to 97% in a study of 103 pigmented skin lesions clinically suspicious for melanoma[145].

The 23-GES assay uses formalin-fixed paraffin-embedded tissue samples from diagnostic biopsies, when histopathologic analysis is indeterminate for melanoma[146]. Some studies of the 23-GES assay have demonstrated high sensitivity (93%) and specificity (96%) in distinguishing melanoma from benign nevi, with clinically proven outcomes[147]. However, other studies have noted its limitations in more ambiguous melanocytic lesions, including spitzoid tumors[148]. Given the novelty of diagnostic GEP assays and limited experience in clinical settings, current appropriate use criteria published by US dermatology and dermatopathology societies maintain an uncertain role for qRT-PCR-based assays in melanoma diagnosis[149,150].

Gene expression profiling for prognosis

Current AJCC-8 melanoma staging and international guidelines use primary tumor histologic factors, e.g. Breslow thickness, ulceration, and pathologic status of the regional lymph nodes (via SLNB) to estimate patient prognosis. Prognostic GEP aims to improve on AJCC melanoma staging by classifying metastatic risk and predicting disease recurrence, potentially identifying patients who would benefit from surveillance imaging and/or adjuvant therapy.

Currently, there are three commercially available prognostic GEP tests including the 31-gene DecisionDx®-Melanoma (US) and 11-gene MelaGenix (Europe). These two assays use a dichotomous class assignment of risk for metastasis (class 1 vs class 2 or low risk vs high risk) rather than calculating an estimated MSS as is done with AJCC staging and other risk-based predictive nomograms. The third Merlin Test combines an 8-gene GEP test with Breslow thickness and patient age to predict SLNB positivity or negativity, with the potential goal of reducing unnecessary SLNBs in patients at low risk of a positive result; prospective validation studies are ongoing[151]. The 11-GEP MelaGenix assay was studied in Europe and reported as an independent prognostic factor for MSS, along with tumor thickness and age, in 291 stage I–III melanoma tumors, suggesting a potential role for this assay in clinical decisions regarding adjuvant therapy[152].

Currently, in the US, the majority of prognostic GEP testing is performed with the 31-gene panel. Most clinicians who order this test report an increased frequency of clinical or imaging surveillance in patients designated as having class 2 disease, regardless of AJCC stage[153]. However, the clinical utility of prognostic GEP testing and its impact on patient outcomes remains uncertain, and routine prognostic GEP testing is not recommended in current US national guidelines (NCCN and AAD)[25,34].

A major criticism of current GEP tests is their relatively low positive predictive value in stage I melanoma, particularly thin (T1) tumors[154]. A meta-analysis of melanomas tested with 31-GEP demonstrated a true positive rate of 1% (6/623) and false positive rate of 10% (61/623) for stage I melanomas[155]; this means that 100 stage I melanomas would need to be tested to identify one that will metastasize while 10 individuals would be falsely identified as having high-risk melanoma. Stage II melanomas had a better prognostic performance with a true positive rate of 28% (59/212) and false positive rate of 37% (78/212), suggesting that GEP testing may ultimately prove more useful in guiding adjuvant therapy use and/or surveillance imaging in this subset of patients. However, stage II melanoma patients are typically followed more intensely than those with stage I due to their increased chance of disease recurrence.

In thin melanomas, the lower positive predictive values of available GEP tests may be related to low numbers of metastases in the cohorts of stage I melanomas used to train and validate the models (e.g. 9% and 3%, respectively)[156]. Alternatively, predicting metastatic potential based upon mRNA expression may represent a biological obstacle for earlier stage melanomas, i.e. a small percentage of cells conferring metastatic potential is not detectable with existing technology platforms[157]. An additional criticism is that designation of a dichotomous value (e.g. class 1 vs class 2) to a continuous variable (e.g. disease-free survival) leads to assignment of equal risk to heterogeneous populations[158]. The major argument for testing thin melanomas with 31-GEP is the high negative predictive value (87%), which could provide additional reassurance to patients. However, the contribution of GEP testing beyond AJCC-8 staging and other known clinicopathologic factors (e.g. primary tumor mitotic rate, lymphovascular invasion, patient age, biologic sex) is unclear. In addition, the implications of a false-positive result should be discussed with the patient, preferably in a multidisciplinary care setting.

There is great interest in risk prediction for SLN-positivity in order to reduce the number of unnecessary SLNBs performed. Two commercially available GEP tests have been studied in this regard: (1) the 8-gene Merlin Test (combined with Breslow thickness and patient age)[159]; and (2) a modified i-31-GEP DecisionDx® that uses artificial intelligence to integrate a continuous GEP score with clinicopathologic factors (age, biologic sex, anatomic location, Breslow thickness, mitotic rate, ulceration, subtype, tumor infiltrating lymphocytes, deep margin transection). Three US and European validation cohort studies with 208, 210, and 421 patients[159–161] have been performed, with the largest study reporting a 35% SLNB reduction rate (via a low risk score) in patients with T1–T2 melanomas (95% CI, 29.4–41.8), with a negative predictive value of 96.5% (95% CI: 90.0–99.3). In a validation cohort of 1674 T1–T4 melanomas from 25 surgical and 5 dermatology centers, the i-31-GEP model identified an additional 19% of tumors (compared with T-stage alone) with <5% SLNB risk, for which the procedure would not be recommended[162]. A recent decision-analytic study suggested that the i-31-GEP model could help to risk stratify patients with T1b melanoma, identifying 23% who could safely forego SLNB (using a 5% risk threshold), though its role in patients with T1a and T2 melanoma requires further study[155]. Various SLNB risk calculators have been developed worldwide that incorporate relevant clinicopathologic factors (e.g. Breslow thickness, ulceration, age, melanoma subtype, lymphovascular invasion) and may provide additional means to more easily predict SLN-positivity[163,164].

While current data are insufficient to support the use of available prognostic/predictive GEP tests to determine the need for SLNB, surveillance imaging, and/or adjuvant treatment, the field is rapidly evolving. There is consensus that further investigation of existing and novel GEP tests should meet certain criteria before being routinely incorporated into clinical practice[165,166]. The latest NCCN guidelines note the need for ongoing study of large data sets of unselected patients to determine whether a combination of GEP testing and clinicopathologic variables provides clinically actionable information, given the previously cited limitations in stage I melanoma[25,165,167]. As GEP testing is further

refined and newer technologies (e.g. circulating tumor DNA) evolve, there is great promise that clinical decision-making will be guided by molecular tumor classifications.

STAGING

Accurate staging of melanoma is essential for clinical prognostication and management. The current tumor–node–metastases (TNM) staging system was introduced by the American Joint Committee on Cancer (AJCC) in 2001 and most recently revised in 2017 (AJCC-8; Table 113.11)[168,169].

The two main factors that determine the **T** classification are: (1) Breslow depth; and (2) histopathologic evidence of ulceration. The **N** classification reflects the extent of tumor within the regional lymph node basin. The most important prognostic factors in the **N** classification are: (1) the number of metastatic lymph nodes; (2) whether the lymph node involvement is clinically occult (microscopic) versus clinically detectable (macroscopic); and (3) the presence or absence of satellite, in-transit, and microsatellite metastases. The **M** classification refers to metastatic disease and is based on three important features: (1) the anatomic site of the distant metastases; (2) the serum lactate dehydrogenase (LDH) level; and (3) the presence or absence of central nervous system (CNS) metastasis. The **T**, **N**, **M** classifications are combined to determine the AJCC stage (Table 113.12), and this allows one to predict survival and assists in selecting the most appropriate treatment. Fig. 113.27 includes 10-year MSS curves for stage I–III melanomas based on the international melanoma database and AJCC-8[169]. Stage IV survival estimates were not included in this model given the recent introduction of novel immune and targeted therapies that lead to markedly improved survival.

AJCC MELANOMA TNM CLASSIFICATION (2017)

Definition of primary tumor (T)

T category	*Thickness*	*Ulceration status*
TX (primary tumor thickness cannot be assessed*)	NA	NA
T0 (no evidence of primary tumor†)	NA	NA
Tis (melanoma *in situ*)	NA	NA
T1	≤1.0 mm	Unknown or unspecified
T1a	<0.8 mm	Without ulceration
T1b	<0.8 mm 0.8–1.0 mm	With ulceration With or without ulceration
T2	>1.0–2.0 mm	Unknown or unspecified
T2a	>1.0–2.0 mm	Without ulceration
T2b	>1.0–2.0 mm	With ulceration
T3	>2.0–4.0 mm	Unknown or unspecified
T3a	>2.0–4.0 mm	Without ulceration
T3b	>2.0–4.0 mm	With ulceration
T4	>4.0 mm	Unknown or unspecified
T4a	>4.0 mm	Without ulceration
T4b	>4.0 mm	With ulceration

Definition of regional lymph node (N)

N category	*Extent of regional lymph node and/or lymphatic metastasis*	
	Number of tumor-involved regional lymph nodes	*Presence of in-transit, satellite, and/or microsatellite metastases*¶
NX	Regional nodes not assessed‡	No
N0	No regional metastases detected	No
N1	One tumor-involved node – *or* – in-transit, satellite, and/or microsatellite metastases with no tumor-involved nodes	
N1a	One clinically occult (i.e. detected by SLN biopsy)	No
N1b	One clinically detected	No
N1c	No regional lymph node disease	Yes
N2	Two or three tumor-involved nodes – *or* – in-transit, satellite, and/or microsatellite metastases with one tumor-involved node	
N2a	Two or three clinically occult (i.e. detected by SLN biopsy)	No
N2b	Two or three, at least one of which was clinically detected	No
N2c	One clinically occult or clinically detected	Yes
N3	Four or more tumor-involved nodes – *or* – in-transit, satellite, and/or microsatellite metastases with two or more tumor-involved nodes – *or* – any number of matted nodes without or with in-transit, satellite, and/or microsatellite metastases	
N3a	Four or more clinically occult (i.e. detected by SLN biopsy)	No
N3b	Four or more, at least one of which was clinically detected, or presence of any number of matted nodes	No
N3c	Two or more clinically occult or clinically detected and/or presence of any number of matted nodes	Yes

Table 113.11 AJCC melanoma TNM classification (2017).

AJCC MELANOMA TNM CLASSIFICATION (2017)		
Definition of distant metastasis (M)		
M category	***M criteria***	
	Anatomic site	***LDH level[§]***
M0	No evidence of distant metastasis	NA
M1	Evidence of distant metastases	
M1a	Distant metastasis to skin, soft tissue including muscle, and/or non-regional lymph node	Not recorded or unspecified
M1a(0)		Not elevated
M1a(1)		Elevated
M1b	Distant metastasis to lung with or without M1a sites of disease	Not recorded or unspecified
M1b(0)		Not elevated
M1b(1)		Elevated
M1c	Distant metastasis to non-CNS visceral sites with or without M1a or M1b sites of disease	Not recorded or unspecified
M1c(0)		Not elevated
M1c(1)		Elevated
M1d	Distant metastasis to CNS with or without M1a, M1b or M1c sites of disease	Not recorded or unspecified
M1d(0)		Not elevated
M1d(1)		Elevated

*For example, diagnosis by curettage.
†For example, unknown primary or completely regressed melanoma.
‡For example, SLN biopsy not performed or regional nodes previously removed for another reason; exception: pathological N category is not required for most T1 melanomas, use cN when SLNB is not performed.
¶In-transit metastases are >2 cm from the primary tumor but not beyond the regional lymph nodes, while satellite lesions are within 2 cm of the primary, although both represent lymphatic metastasis with similar prognosis. Satellite lesions can be detected clinically or microscopically; the latter are referred to as microsatellite metastases.
§Suffixes for M category: (0) LDH not elevated, (1) LDH elevated. No suffix is used if LDH is not recorded or is unspecified.

Table 113.11 AJCC melanoma TNM classification (2017). Histologic evaluation of lymph nodes must include at least one immunohistochemical marker (e.g. HMB45, MART-1/Melan-A). CNS, central nervous system; LDH, lactic dehydrogenase; NA, not applicable; SLN, sentinel lymph node. *Adapted from AJCC Cancer Staging Manual. American Joint Committee on Cancer, 8th edn. Springer, 2017:563–85.*

Stage 0 represents melanoma *in situ* and stages I and II represent localized cutaneous disease. Distinction is made between stage IA patients (T1a: Breslow depth <0.8 mm without ulceration), who are *not* generally considered for sentinel node biopsy, and stage IB (T1b: <0.8 mm with ulceration, 0.8–1 mm with or without ulceration; T2a: >1.0–2.0 mm without ulceration) or stage II patients for whom SLNB is typically discussed and offered (Table 113.13). Stage III represents regional nodal and/or lymphatic (microsatellite/satellite/in-transit) metastases. Stage IV represents distant metastases, including distant skin, nodal, visceral, and/or brain metastasis.

PROGNOSIS

The prognosis of a patient with melanoma depends upon the stage at diagnosis. Prognosis for patients with surgically resected localized primary cutaneous melanoma and no nodal or distant metastases (stage I or II) is generally excellent (see Table 113.12). Patients with stage IA melanoma have a 5-year survival expectancy of 99% per the AJCC-8 international database, compared to patients with thick (>4 mm), ulcerated melanoma (T4b N0) who have a 5-year survival rate of 82%[170]. Although dermal mitotic rate is not incorporated into AJCC-8 staging, it is an independent prognostic factor for survival; for example, a mitotic rate of ≥1/mm^2 decreases 5-year survival in node-negative T1–T4 melanoma to 84%[170]. In addition to the microstaging variables discussed above, clinical variables with prognostic significance in stage I/II disease include sex, age, and anatomic site (Table 113.14). For example, women with stage I/II disease tend to have a better MSS than men. Location of the primary melanoma on the trunk, head (particularly scalp), or neck portends a poorer prognosis than melanoma on the extremities.

Stage III melanoma patients are a heterogeneous group with respect to risk for distant metastases and MSS. Per AJCC-8 data, the 5-year survival rates range from 93% for patients with pathologic stage IIIA melanoma (non-ulcerated primary tumor ≤2 mm in depth and up to 3 nodal micrometastases [T1a/b–T2a N1a–N2a M0]) to a low of ~32% for patients with pathologic stage IIID melanoma (ulcerated T4 primary tumor plus four or more clinically occult or detected lymph nodes ± lymphatic metastasis [T4b N3a/b/c M0])[170]. However, with the advent of newer targeted agents and immune checkpoint inhibitors, survival rates for both stage III and IV melanoma have increased over the past decade. Major prognostic factors in stage III melanoma are primary tumor characteristics (thickness and ulceration), the number of lymph nodes with metastases, and tumor burden. The latter is based on whether nodal metastases are clinically occult (micrometastases, as detected by SLNB) or clinically palpable (macrometastases), in addition to the presence or absence of lymphatic (microsatellite/satellite/in-transit) metastasis.

In stage IV patients, the major prognostic factor is the site of distant metastases, with a poorer prognosis for visceral than for non-visceral (e.g. skin, subcutaneous, distant lymph node) metastases. Prior to the use of more effective systemic agents over the past decade, the median survival for stage IV patients was 9 months, and the estimated 5-year survival rate was <10% when the serum LDH level was abnormally elevated. Variables that influence survival are initial site of metastasis, disease-free interval before distant metastases, stage of disease preceding distant metastases, and tumor burden at the time of diagnosis. Lower tumor burden in patients with unresectable stage III/IV melanoma (defined as normal serum LDH level and <3 organ sites with metastasis) is associated with improved response to targeted therapy, suggesting that earlier detection and treatment of metastatic disease may improve long-term survival[171].

EVALUATION OF A PATIENT WITH SUSPECTED MELANOMA

Medical History

A thorough medical history should be taken, focusing especially on risk factors for the development of melanoma such as a personal or family history of melanoma, skin phototype I/II, tanning bed use, childhood history of sunburns, and iatrogenic or acquired immunosuppression (see Table 113.3). A thorough review of symptoms should

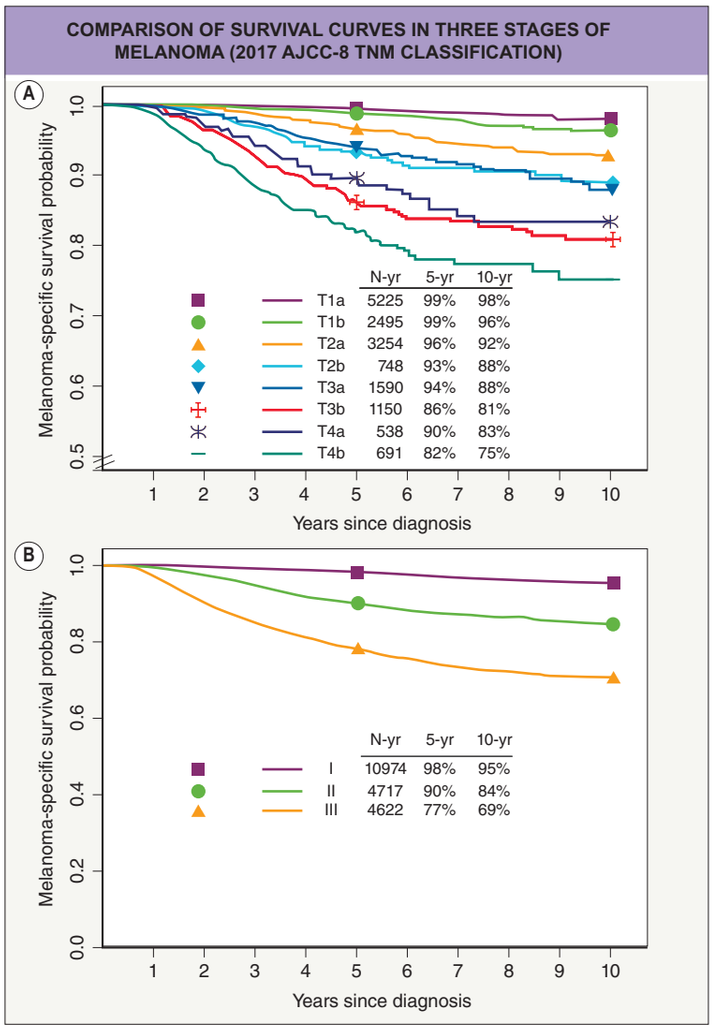

Fig. 113.27 Comparison of survival curves in three stages of melanoma based upon 2017 AJCC-8 melanoma TNM classification and prior to FDA approval of targeted therapy or immunotherapy for stage III disease. These curves represent melanoma-specific survival probabilities prior to FDA approval of targeted therapy or immunotherapy for stage III disease. **A** Melanoma-specific survival curves according to T subcategory for patients with stage I and II cutaneous melanoma from AJCC-8 international melanoma database. Data for T2–T4 patients filtered to include only those with negative SLNB; T1 patients included regardless of whether SLNB performed. **B** Melanoma-specific survival curves according to stage in patients with stage I to III melanoma from AJCC-8 international melanoma database. *With permission from Gershenwald JE, Scolyer RA, Hess KR, et al. *Estimated 5-year melanoma-specific survival is based on the AJCC-8 international melanoma database and TMN classification; of note, they predate the use of newer systemic therapies for stage III disease.
†Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases. Stage 0 and T1a melanomas (with exceptions) are clinically staged; T1b melanoma may be considered for pathologic staging with sentinel lymph node biopsy.
‡Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes following sentinel lymph node biopsy (for T2a–T4b melanoma in the AJCC-8 database) or following complete or therapeutic lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception.
¶There are no stage III subgroups for clinical staging.
§Survival estimates for stage IV disease were not included in AJCC-8 data given incorporation of targeted and immune therapies associated with markedly improved melanoma-specific survival.

Table 113.12 AJCC-8 staging groups for cutaneous melanoma (2017). *Adapted from Gershenwald JE, Scolyer RA, Hess KR, et al. Melanoma staging: Evidence-based changes in the American Joint Committee on Cancer Eighth Edition Cancer Staging Manual. CA Cancer J Clin 2017;67:472–92*

SENTINEL LYMPH NODE BIOPSY (SLNB) CONSIDERATIONS

Clinical stage*		Breslow depth (mm)	Ulceration (present/absent)	Probability of positive SLNB	SLNB recommendation
0	Tis	NA	NA	0	No
IA	T1a	<0.8	–	<5%	Not typically†
IB	T1b	<0.8	+	5%–10%	Discuss and consider
		0.8–1.0	–		
	T2a	1.1–2.0	–	>10%	Discuss and offer
IIA	T2b	1.1–2.0	+		
	T3a	2.1–4.0	–		
IIB	T3b	2.1–4.0	+		
	T4a	>4.0	–		
IIC	T4b	>4.0	+		

*Based upon AJCC-8.
†Consider offering if one or more high-risk features: mitotic index ≥2/mm^2 (particularly in a young patient), lymphovascular invasion, and incomplete microstaging (deep margin diffusely involved and/or large clinical residual lesion following partial biopsy).

Table 113.13 Sentinel lymph node biopsy (SLNB) considerations. NA, not applicable.

diffusely

MELANOMA – MAJOR INDEPENDENT PROGNOSTIC FACTORS FOR SURVIVAL IN MULTIVARIATE ANALYSES	
Prognostic factor	**Commentary**
Tumor thickness	≤1 mm, low risk; >1 mm, higher risk
Ulceration	Worse prognosis with ulceration
Mitotic rate	Worse prognosis with high mitotic rate (e.g. 5-year survival of 84% with ≥11 mitoses/mm^2)
Age	Worse prognosis with older age
Sex	Men have poorer prognosis (only for localized disease)
Anatomic site	Trunk, head (particularly scalp), and neck associated with poorer prognosis than extremities
Number of involved lymph nodes	Cut-off points: 1, 2–3, 4 or more lymph nodes (see Table 113.11)
Regional lymph node tumor burden	Clinically detectable (palpable) nodal metastases with poorer prognosis than clinically occult (microscopic) nodal metastases
Site of distant metastases	Visceral metastases associated with poorer prognosis than non-visceral metastases (skin, subcutaneous, distant lymph nodes)

Table 113.14 Cutaneous melanoma – major independent prognostic factors for survival in multivariate analyses.

address unintentional weight loss, fatigue, headache, and other constitutional symptoms, although cutaneous melanoma rarely presents with synchronous distant metastasis. Other family members should be screened if either melanoma or atypical melanocytic nevi are present, with a detailed history of malignancies, especially pancreatic cancer, that may warrant *CDKN2A* and/or multi-gene testing for hereditary cancer syndromes. All individuals at risk should be educated about the clinical features of melanoma, skin self-examination practices, and routine sun protection measures.

Skin Investigation and Clinical Diagnosis

A total body skin examination (TBSE) should be performed to estimate the total number of melanocytic nevi and the number of clinically atypical nevi, as well as the presence of congenital nevi. Atypical pigmented lesions should be examined by dermoscopy. Any lesion suspected of being melanoma or severely dysplastic should undergo excisional/complete biopsy, when possible.

Excisional biopsy is intended to completely remove the tumor with narrow (1–3 mm) peripheral margins and adequate depth to avoid histologic transection. Complete biopsy is recommended for suspected melanomas to prevent sampling error (e.g. missing a focus of melanoma arising in a precursor benign lesion) and to enable the pathologist to assess the overall architecture of the lesion and accurately microstage the tumor. Excisional/complete biopsy may be performed via full-thickness elliptical, disc, or punch technique or with deep shave/saucerization to the level of the deep reticular dermis; the latter is the biopsy technique most commonly used by US dermatologists.

Superficial shave biopsies should generally be avoided for palpable lesions in order to avoid histologic transection and underestimation of tumor thickness. However, a broad shave biopsy may optimize histopathologic assessment of suspected MIS, LM type, to exclude potential microinvasion. One must keep in mind that malignant melanocytes grow along adnexal structures in MIS, LM type, and therefore they commonly reach the basal resection margin of a shave biopsy.

The specimen should be sent to a pathologist experienced in the diagnosis of melanocytic tumors, preferably a board-certified dermatopathologist. A second opinion is sometimes necessary for difficult cases. Since cutaneous melanoma most commonly metastasizes to regional lymph nodes, palpation of lymph node basins should also be routinely performed, both initially and longitudinally.

Laboratory Investigations and Imaging

Worldwide evidence-based clinical practice guidelines[25,172] are uniform in recommending against *baseline* imaging or laboratory tests in asymptomatic patients with cutaneous melanoma of any thickness. Evaluation should be pursued for any signs or symptoms concerning for regional nodal and/or distant metastasis, but this is seldom encountered in most newly diagnosed patients. There is some variation among international guidelines regarding *surveillance* imaging and laboratory tests, although the consensus opinion is that appropriate studies should be done as clinically warranted for signs/symptoms concerning for disease recurrence.

The NCCN and AAD (2019) guidelines consider surveillance imaging (generally CT with contrast of the chest/abdomen/pelvis or whole-body FDG PET-CT) in asymptomatic patients with stage IIB melanoma and higher, recognizing its potential merits of surveillance in patients at higher risk for disease recurrence[25,34]. However, it remains to be proven that pre-symptomatic detection of metastatic recurrences is associated with improved patient outcomes, although as noted previously, there is some evidence that systemic targeted therapy is more efficacious in the setting of lower tumor burden[171]. Of note, in a single-center study of 353 stage IIB–IIIC patients treated with immune checkpoint inhibitors, improved MSS was observed in those who underwent intensive imaging surveillance for detection of asymptomatic recurrences, as compared to those with symptomatic recurrences[173].

An effective and noninvasive examination technique which was first introduced in Europe is lymph node ultrasound[174]. The scar of the primary cutaneous melanoma, the lymphatic drainage areas, and the regional lymph node basin are examined by ultrasound with a 7.5–10 MHz probe. In one-third of patients, metastases can be detected before they become palpable with this technique. In some European countries, lymph node ultrasound is recommended for staging and follow-up of patients with melanomas >1 mm in thickness[175]. NCCN guidelines recognize the merits of nodal ultrasound when clinical lymph node examination is equivocal for concerning adenopathy (at baseline or in follow-up) or completion lymph node dissection (CLND) is not pursued following a positive SLNB (see below). There may be additional value in obtaining regional nodal ultrasound in stage II (T2b/T3/T4) patients who do not undergo SLNB or when the procedure is not successful. However, regional nodal ultrasound assessment should only be performed if radiologic expertise is available[25].

Several serum markers for metastatic melanoma have been investigated. The most frequently employed biomarkers are LDH (US and Australia/New Zealand) and protein S100B and melanoma inhibitory activity (MIA; Europe). Since 2002, testing for LDH has been a standard component of the AJCC subclassification of stage IV melanoma, as LDH is an important predictor of survival and response to therapy in this subgroup[169,171]. However, LDH determination is not recommended in lower stage patients due to low sensitivity and specificity for detection of metastasis[34]. Primarily in Europe, protein S100B is employed as a serum biomarker for the detection of metastasis in patients at higher risk for recurrence[175].

In the future, circulating tumor DNA (ctDNA) may be utilized to monitor tumor burden/disease progression and thereby predict residual melanoma following surgical resection and risk for disease recurrence[176]. After sequencing the patient's primary tumor for tumor-specific mutations, RT-PCR is performed on peripheral blood to look for the presence of these mutations. Because ctDNA has a very short half-life (hours to days), it assesses active disease.

Investigation of stage III/IV melanoma patients may include radiologic investigations such as whole-body FDG PET-CT, ultrasound of the nodal basin, CT scan with contrast of the chest, abdomen and pelvis, and CT or MRI of the brain (Table 113.15). Chest radiography lacks sensitivity for metastatic detection but may be considered for pulmonary screening in certain patients. While the current average costs of PET-CT and CT scans in the US are ~$5750 and $3200, respectively (newchoicehealth.com), median specificity for identification of metastatic disease for CT scans was ~20% less than for PET-CT, and sensitivity was ~5% less for both primary staging and surveillance. For routine staging, a meta-analysis of 74 studies (n = 10 528 patients) determined that PET-CT had the highest sensitivity for detection of distant metastasis (80%, 95% CI 53%–93%) and specificity (87%, 95% CI 54%–97%), and nodal basin ultrasound had the highest sensitivity for detecting nodal involvement (60%, CI 33%–83%, specificity 97%, CI 98%–99%)[177]. Therefore, when possible, PET-CT is the preferred imaging modality for staging and surveillance of higher stage melanomas, although CT scans are less costly and frequently performed. MRI with contrast is preferred

SYMPTOMS AND DIAGNOSTIC TESTS FOR METASTATIC MELANOMA		
Metastatic site (TNM)	**Symptoms**	**Diagnostic tests***
Skin, soft tissue metastasis (TxNxM1a), in-transit metastasis (TxN1–3cM0)	Papules or nodules that vary in color from skin-toned to pink–red to blue, brown, or black; secondary ulceration or bleeding	Biopsy or fine needle aspiration for histopathologic confirmation; radiologic imaging as indicated for metastatic evaluation (CT C/A/P with contrast or PET-CT)
Brain metastasis (TxNxM1d)	Headache, nausea, seizures, focal weakness, visual disturbance, paresthesias	MRI with contrast (preferred), CT with contrast; neurosurgical consultation for tissue confirmation
